While forecasting overheating risks until 2080, 1,157 zones did not fail within our analysis period, leaving the delay effect of passive strategies unclear. Future work could extend the analysis to cover all zones. Although passive strategies mitigate overheating risks, findings highlight the future need for active cooling systems. Further research should explore active systems (e.g., air conditioning, heat pumps) and provide a detailed analysis of various other environmental and financial parameters such as energy use, cost, and carbon emissions on an urban scale. The urban building layout and the corresponding resolution is too high to accommodate the functional differences in a residential unit due to the high number of buildings comprised in this UBEM. Future work can increase zonal resolution of buildings and apply CIBSE criteria separately to assess different functional zones, i.e., bedroom and living room. However, the additional modeling and computational burden should be considered accordingly.

The forecast of the year in which each zone will fail CIBSE overheating risk criteria can lead to the impact assessment in terms of the reduction of carbon footprint that passive cooling strategies can promise, and therefore, inform the urban-scale policymaking.

Evaluating the impact of bio/geobased building materials on summer thermal comfort

Thibaut COLINART[1], Chi-Kien NGUYEN[2]

[1]*Univ. Bretagne Sud, UMR CNRS 6027, IRDL, F-56100 Lorient, France, thibaut.colinart@univ-ubs.fr*
[2]*Saint-Gobain Recherche Paris, F-93300 Aubervilliers, France, Chi-Kien.Nguyen@saint-gobain.com*

SUMMARY
This study aims to quantify the impact of bio/geobased materials, through their hygrothermal properties, on comfort at building scale, compared with other materials. To this end, dynamic hygrothermal simulations are carried out at the scale of a model building (Bestest type), considering coupled heat and moisture transfers in the envelopes, using WUFI Plus software. Several wall typologies are tested for residential or tertiary building subjected to different climates in France (Brest, Nancy, Marseille). Various thermal comfort metrics are analysed over the summer period. The impact of wall designs on summer thermal comfort is compared with conventional summer thermal comfort measures, such as night-time over-ventilation or solar gain management. Results shows that actions to limit and manage solar gain have more influence on thermal comfort than wall design including or not bio/geobased materials.

Keywords: hygrothermal behaviour, thermal comfort, biobased materials

1. INTRODUCTION

Maintaining the hygrothermal comfort of a building's occupants at a minimum energy cost is a key concern for thermal engineers. However, several challenges lie behind this simple objective. Firstly, although a generic definition is proposed in ASHRAE Standard 55, assessing thermal comfort remains complex. It depends on numerous variables such as temperature, humidity, and air speed, which are influenced by factors related to the building, external conditions, human activities, and physiological and psychosociological factors (Rupp et al., 2015). Secondly, numerous thermal comfort indicators have been developed over the last few decades, each with its own well-defined construction logic. For instance, Attia et al. (2023) list various overheating indicators used in Europe and note that the *DH* indicator proposed in the latest French thermal regulation, *RE 2020*, is one of the most advanced and relevant indicators for assessing summer thermal comfort. These indicators are frequently evaluated through building thermal simulations carried out with dedicated software, which have their own limitations. These tools offer great flexibility for assessing the impact of envelope design (level of insulation and thermal inertia, glazing and solar protection, etc.) and/or building operation (ventilation scenarios, shading, etc.) on thermal comfort (Alrasheed and Mourshed, 2023; Verbeke and Audenaert, 2018; Guo et al., 2019; Evola et al., 2013). In the case of summer thermal comfort, these studies confirm the importance of limiting heat gains and managing these gains over time. Recently, bio/geosourced materials have been increasingly used in the building sector, both for new construction and renovation, due to their low environmental impact and their potential benefits for summer thermal comfort, which are related to notions of inertia and hygrothermal transfers. However, studies on summer thermal comfort in buildings containing bio/geosourced materials in the envelope are scarce and sometimes imprecise or unrealistic (Barclay et al., 2019; Hema et al., 2020; Ben-Alon

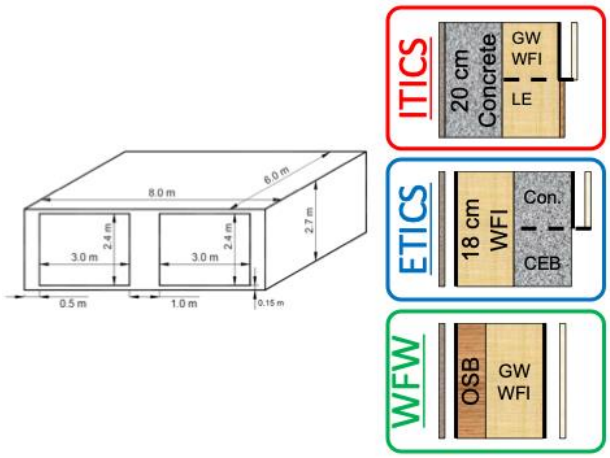
and Rempel, 2023). This study therefore aims to clarify the impact of bio/geosourced materials on summer thermal comfort compared with more conventional solutions, using a geometrically simple building as a case study.

2. CASE STUDY

The case study concerns a BESTEST building with a simple geometry (6 m long, 8 m wide and 2.7 m high). The floor and ceiling (composed of very closed vapour barriers, 10 cm concrete and external insulation) have thermal resistances of 3.8 and 6.3 $m^2.K.W^{-1}$ respectively. Three representative types of opaque side walls (R = 5 $m^2.K.W^{-1}$) are studied:

- ITICS (Internal Thermal Insulation Composite System): rendered concrete walls are insulated from the inside either with insulation (glass wool GW or wood fibre WFI) under vapour barrier (Sd = 1 m), cavity and gypsum board, or with light-earth (LE) covered with a straw-earth render.
- ETICS (Internal Thermal Insulation Composite System): exterior insulation under cladding is applied to two walls: concrete combined with cavity and gypsum board or uncovered compressed earth bricks (CEB) to potentially maximize moisture exchange with indoor room.
- WFW (wood-framed walls): it comprises cladding, ventilated cavity, rainscreen, OSB board, insulation (GW or WFI) under a vapour barrier (Sd = 1 m), cavity and gypsum board.

Fig. 1 illustrates the wall designs, insulation thicknesses, and main hygrothermal characteristics, including the damping factor and phase shift calculated according to ISO 13786. Due to the higher thermal conductivity of LE, the ITICS LE wall is the thickest. Although the thermal mass per unit area of the heavy walls (ITICS/ETICS) is approximately two times greater than that of the ceiling and floor, the vertical and horizontal walls contribute equally to the building's inertia when considering their respective surface areas. Phase shift and damping are closely correlated with thermal mass: the greater the mass, the lower the damping factor and the greater the phase shift. Additionally, all walls containing concrete are more resistant to vapor transfer compared to other walls. In accordance with the design of Bestest buildings, two 6 m² double-glazed windows (g = 0.6, Uw = 2.7 W/m²K) are integrated into the south façade. By default, these windows have no solar shading or overhangs to limit solar gain in the summer.



Wall	Insul. th. [cm]	C [kJ.m^{-2}.K^{-1}]	*f* [-]	φ [h]	Sd [m]
Ceiling	25	208	0.36	8.4	28.5
Floor	15	203	0.42	6.2	28.4
ITICS GW	14.9	432	0.16	8.8	36.5
ITICS WFI	19.5	470	0.07	15.5	37.0
ITICS LE	38.3	552	0.03	21.4	37.6
ETICS Con	18.6	460	0.06	15.9	37.2
ETICS CEB	18.9	388	0.13	15.8	3.2
WFW GW	14.3	35	0.93	2.7	2.4
WFW WFI	18.8	72	0.4	9.5	2.8

Figure 1. Overview of the building and opaque walls considered in the case study.

Residential (single-family home) and tertiary occupancy scenarios are defined for two people, in accordance with current French thermal regulations (with no other internal thermal loads). Air renewal is provided by infiltration (calculated for a permeability of 0.6 $m^3.h^{-1}.m^{-2}$) and by a mechanical ventilation system (with a default flow rate of 50 $m^3.h^{-1}$, i.e., 0.38 volumes per hour). An ideal, high-powered heating system maintains a minimum temperature of 20 °C in the building. However, there are no restrictions on maximum temperature or relative humidity.

Building simulations are carried out using WUFI Plus (v3.3). This building thermal simulation software has the particular capability of solving hygrothermal transfer equations in walls. The hygrothermal properties of materials are either measured in the laboratory (Colinart et al., 2020) or taken from the WUFI database. To eliminate the effect of initial conditions, simulations are carried out over five consecutive years. The building's hygrothermal behavior is evaluated for three climates in France: Brest (oceanic climate, Köppen climate zone Cfb), Nancy (semi-continental climate, Köppen climate zones Cfb to Dfb), and Marseille (Mediterranean climate, Köppen climate zone Csa). The TMY weather files available by default in the software and used for the simulations do not include any heatwave periods, notably due to their age (Nancy: 1996; Marseille: 1999). The simulated operative temperature, defined as mean of indoor temperature and mean indoor surface temperature, is used to evaluate four thermal comfort indicators in occupancy (Lauzet et al., 2021):

- The cumulative number of hours when the operating temperature is above 28 °C. This criterion is used in design programs or in CIBSE's "Guide A: Environmental design".
- Cumulative hours spent outside a Givoni comfort zone defined on the psychrometric diagram for still air (corresponding to a maximum temperature of 27 °C).
- Cumulative hours spent outside an adaptive comfort zone defined in accordance with EN 16798-1 (category II building). This indicator allows to consider the adaptability of users when assessing comfort.
- Cumulative hours spent outside an adaptive comfort zone defined in the French thermal regulation *RE 2020* and the number of *DH* degree-hours.

These thermal comfort indicators are evaluated over an entire year or over the summer period (June 1 to September 30), as well as over the hours of occupancy of an entire day or night (10 pm to 6 am). Note that these indicators do not require information on human clothing or metabolic rate.

3. RESULTS AND DISCUSSIONS

3.1. Analysis of a non-optimized reference case in terms of summer comfort

The case of a building with walls insulated on the inside with light earth (ITICS LE) in the climate of Nancy is presented in detail. Indoor temperature and relative humidity vary between 20 °C and 32 °C and 20 %rh and 58 %rh respectively, while exterior values vary between -13 °C and 32 °C and 15 %rh and 100 %rh respectively. These indoor data are analyzed using the summer thermal comfort indicators shown in Figure 2. Several observations can be made:

- Comfort indicators vary by a few hours from one year to the next, given the shift in days over the years (Year 1 starts on a Monday, Year 5 on a Saturday). For the remainder of the study, the results for Year 5 are analyzed. Moreover, discomfort occurs almost exclusively during the summer period (June 1 to September 30).
- The different indicators inevitably lead to varying levels of discomfort, due to their construction. They range from 557h to 806h over the entire summer period and from 159h

to 426h over the night periods. For the latter, the following order is observed: *RE 2020* (426h) > *Givoni* (302h) > *Adaptive* (159h), due to nighttime temperature thresholds of 26 °C, 27 °C and 28 °C, respectively.

- In relation to annual occupancy hours, discomfort ranges from 5% to 15%. On the other hand, since discomfort occurs only during the summer period, it should be considered in relation to the number of hours the dwelling is occupied during this period. In this case, discomfort range from 24% (*Adaptive*) to 35% (*Givoni*) over the entire day and from 16% (*Adaptive*) to 44% (*RE 2020*) during nighttime only. Ultimately, discomfort occurs between 23% and 54% of the time at night. The *RE 2020* indicator shows a high level of discomfort at night, due to a lower threshold temperature than during the day (26 °C vs. adaptive temperature). This leads to a high *DH* of 1240 °C.h.

These periods of discomfort do not necessarily occur simultaneously. However, discomfort is predicted by all indicators for 490h (i.e. 21% of summer occupancy), including 155h during the night (i.e. 16% of summer night occupancy). These periods of discomfort occur over a few days in June and especially in July and August, mainly at the end of the day and into the early hours of the night. With rare exceptions, discomfort is not continuous throughout the day.

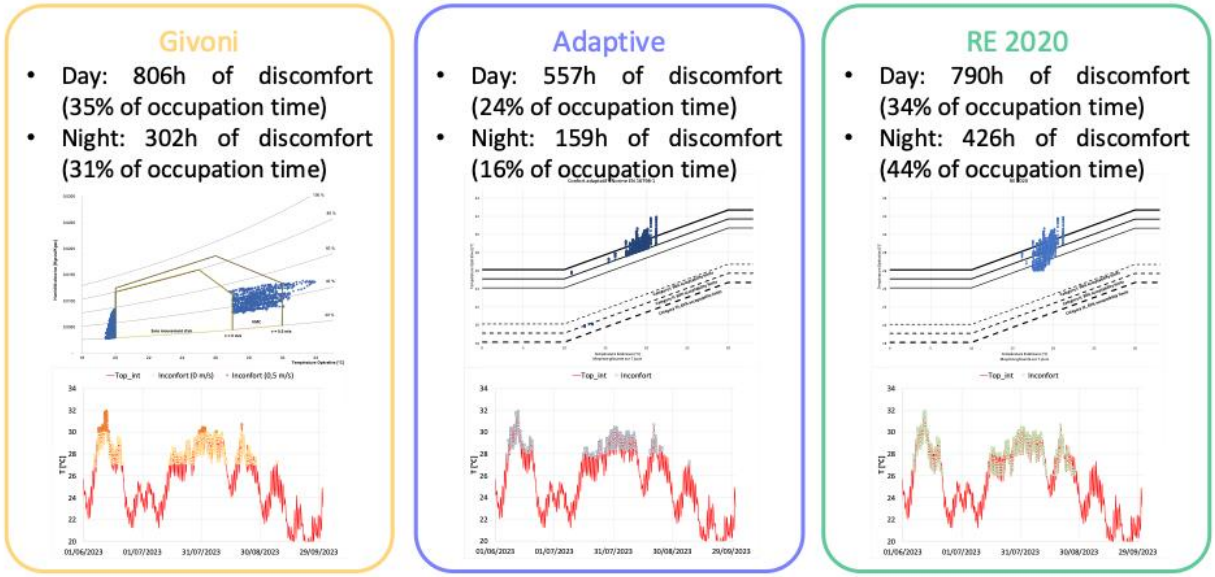


Figure 2. Analysis of summer thermal discomfort periods in a building internally insulated with light earth in a Nancy climate.

These discomfort levels are well in excess of frequently defined or tolerated thresholds. Therefore, additional simulations (noted as *V1*) are therefore carried out using conventional summer comfort control measures, specially 40% shading of windows from 2 to 7 p.m. and night ventilation of 150 $m^3.h^{-1}$ from 10 p.m. to 7 a.m. during the summer period. As shown in Fig. 3, these two measures lead to a drastic reduction in summer thermal discomfort, both during the day and at night, compared to the original simulation (noted as *V0*). Consequently, the *DH* indicator reaches a value of 216 °C.h, which is in line with the thresholds recommended by the French thermal regulation. These measures are retained for the remainder of the study.

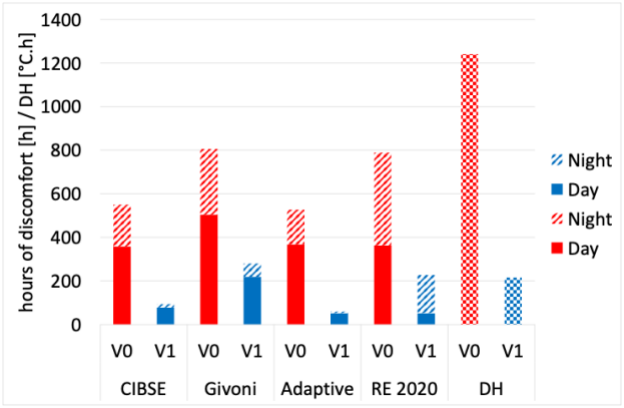

Figure 3. Number of hours of summer thermal discomfort and *DH* before (red-V0) and after (blue-V1) improvement in a building internally insulated with light earth in Nancy climate.

3.2. Influence of wall's type

Summer thermal discomfort indicators have been evaluated for various buildings made with the walls shown in Fig. 1. The *Adaptive* and *DH* indicators are presented in Fig. 4. Several observations can be made:

- For ITICS walls, replacing light thermal insulation (GW, WFI) with more inertial insulation (LE) results in a decrease of approximately 1 °C in interior temperature variations. This is due to latent effects associated with moisture exchanges: moisture flows from the wall to the zone, and this desorption at the surface is accompanied by a drop in surface temperature, and consequently, in operative temperature. As a result, discomfort is reduced by a maximum of 26h (i.e. a difference in occupancy of around 1%) and *DH* by 38 °C.h. Alternatively, reducing the light earth thickness to 20 cm (note as LE20), in line with current craftsman practices (i.e. a reduction of approximately 50% in the wall's thermal resistance) improves comfort. Since the indoor temperature is predominantly higher than the outdoor temperature in summer, losses through this wall are higher, allowing the building to cool down during both day and night. The reduction in discomfort ranges between 27 and 40%.
- Insulating walls from the outside reduces discomfort by approximately 50h during the day and 10h at night (i.e. a difference in occupancy of around 2.5%) and significantly reduces *DH* compared to ITICS WFI. Bringing inertia indoors dampens the temperature load, but heat accumulated in the envelope also requires longer periods to be removed during summer. Comparatively, a concrete wall provides more comfort than CEB masonry, due to its higher thermal effusivity, which allows the envelope to be unloaded at night. On the other hand, although humidity responses are slightly different, their impact on comfort indicators is minimal.
- Lightweight WFW results in discomfort levels equivalent to those observed for internally insulated walls. The GW wall exhibits higher discomfort level than the WFI wall due to its lower thermal inertia, which leads to greater interior temperature variations (of 0.5 °C on average) and more frequent threshold overshoots. Integrated over time, these overshoots balance out, resulting in equivalent *DH* levels between the two walls. A variant (walls marked *) involves incorporating a 15 cm internal partition made of CEB to provide additional internal thermal inertia (thermal mass = 246 $kJ.m^{-2}.K^{-1}$). The modification is beneficial for comfort, although it slightly reduces the room's air volume (by 2.43 m^3) and

thus its thermal inertia and infiltration rates, making the analysis of this variant more complex from a computational point of view. Finally, an additional simulation with light earth (with the same insulation thickness as WFI) also results in lower discomfort levels due to reduced thermal resistance (similar to the variant with the ITICS LE wall).

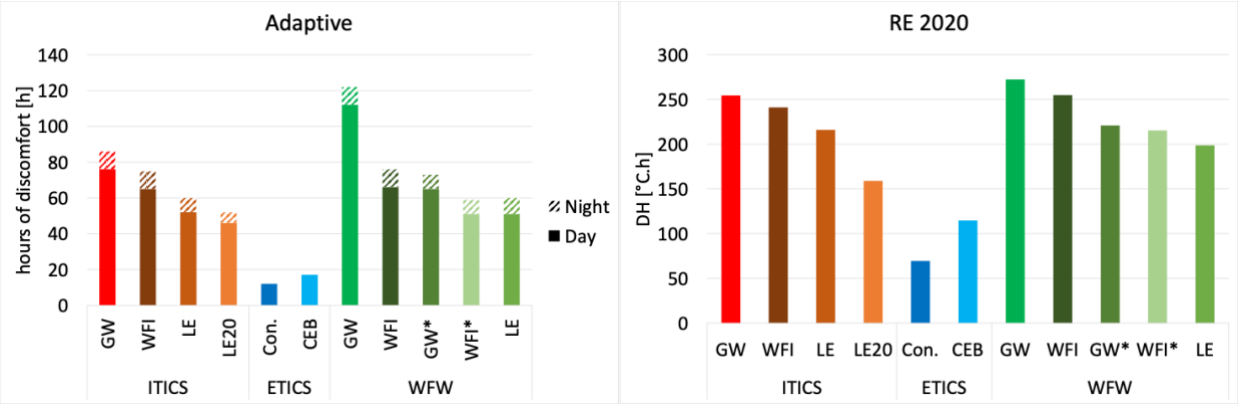

Figure 4. Influence of wall type on the number of hours of summer thermal discomfort (left) and on *DH* indicator (right) in a residential building in Nancy climate.

3.3. Influence of climate and occupancy

These analyses are reproduced for the oceanic climate of Brest and the mediterranean climate of Marseille. For Brest, there is no thermal discomfort in summer due to moderate outdoor temperatures. In contrast, for Marseille, discomfort frequently exceeds 1000h and *DH* exceeds 5000 °C.h due to high outdoor temperatures. This indicates that the summer thermal comfort improvement measures proposed for a semi-continental climate are insufficient for a mediterranean climate. Despite this observation, a relative discomfort analysis is carried out for four wall typologies, including wood fiber as thermal insulation. For each indicator, the relative discomfort presented in Fig. 5 is calculated in relation to the most unfavorable wall in terms of comfort. For example, for the climate of Nancy and the adaptive indicator, the WFW wall is the most unfavorable (relative discomfort = 100%), followed by the ITICS, WFW + CEB and ETICS walls. This beneficial effect of thermal inertia is observed for all indicators for a building optimized for summer thermal comfort in Nancy's climate. In contrast, inertia plays a lesser role for a building in Marseille's climate. Therefore, it is advisable to first optimize measures to improve summer comfort, such as shading of transparent walls and managing ventilation before addressing the level and location of thermal inertia.

These initial observations were made for residential buildings. The analysis is extended for tertiary buildings, with results shown in Fig. 6. Firstly, the number of hours of discomfort is greater for tertiary buildings due to higher occupancy (and therefore higher internal loads) during the day and zero at night. In relation to the number of hours of occupancy (792h), discomfort can exceed 20%. Secondly, the benefits of interior thermal inertia are confirmed.

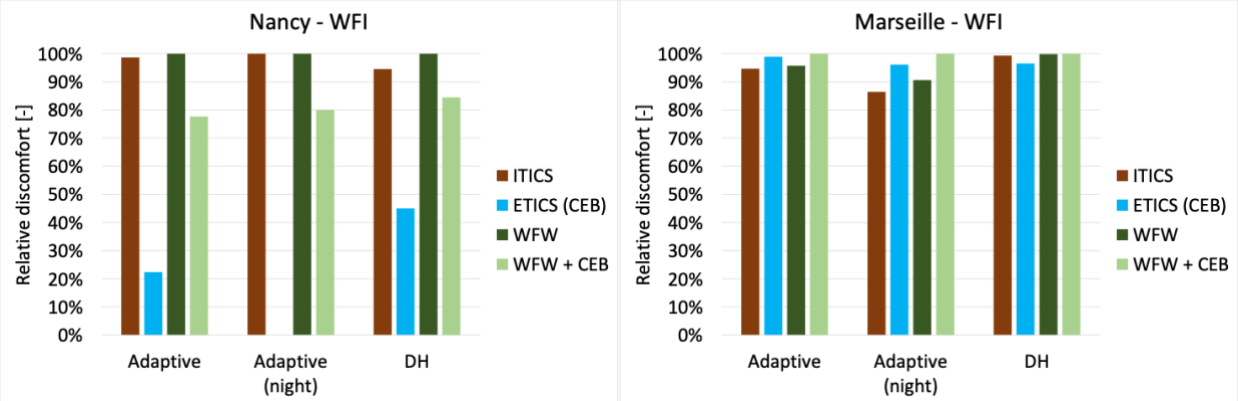

Figure 5. Influence of thermal inertia on the number of hours of summer thermal discomfort in a residential building in the climates of Nancy and Marseille.

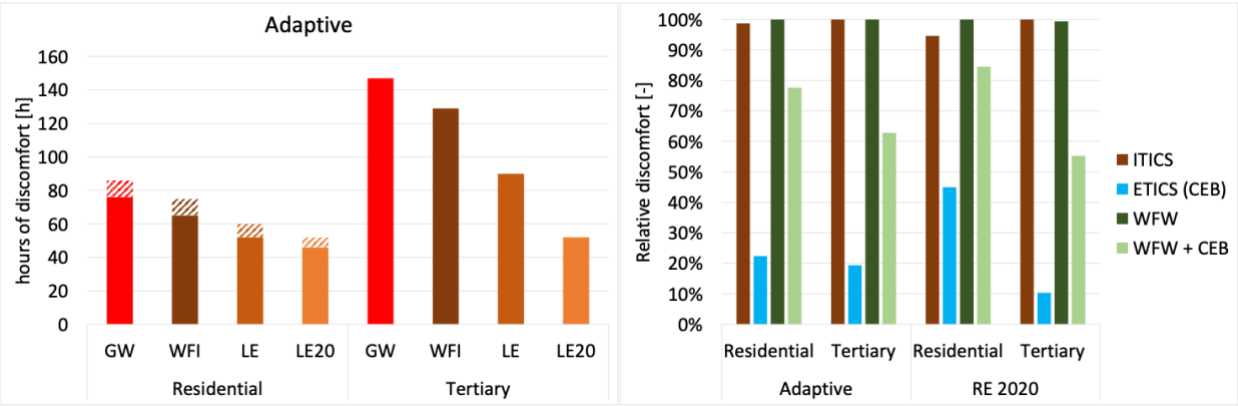

Figure 6. Influence of occupancy type on the number of hours of summer thermal discomfort in a tertiary building in a Nancy climate.

4. CONCLUSIONS AND OUTLOOK

Using Wufi Plus software, this study assessed summer thermal comfort in a model building that could incorporate bio/geosourced materials in its envelope. The results indicate that the most significant factors in predicting summer thermal comfort are actions to limit and manage solar gain, such as shading of glazed surfaces and implementing night-time over-ventilation. Additionally, wall design also plays an important role: adding thermal inertia inside the building (ETICS, WFW + CEB) is more beneficial for summer thermal comfort, provided that the building is already "optimized" (otherwise discomfort may be accentuated). Finally, walls incorporating bio/geosourced insulating materials, which generally offer greater thermal inertia, are less beneficial in terms of summer comfort than conventional walls.

This initial study should be continued to expand the scope of these preliminary conclusions. While retaining the simplicity of the Bestest building, other variants can first be tested to assess the influence of building design (orientation/size of glazing, floor/ceiling inertia, etc.), climate (current/future) or materials (formulation of lightened earth and coatings, wall design, etc.). The goal is to identify and classify the various parameters affecting summer thermal comfort, particularly the effects of water transfers and associated latent transfers on daily or seasonal heat

balances, as well as on comfort indicators. However, to meet the industry expectations, these results need to be confirmed for more realistic building types (e.g., detached houses, apartment blocks, etc.) and should be ideally experimentally validated.

SUMMARY
This study investigates the thermal responses and adaptive behaviors of the human body during seasonal transitions in Taiwan. The research employs objective physical measurements and subjective thermal questionnaire surveys to analyze the effects of short-term thermal history on thermal perception and comfort. The study period encompasses two transitional seasons: the warming period (January to August) and the cooling period (July to the following February). The results reveal a significant asymmetry in thermal sensitivity between the warming and cooling transition processes, influenced by prior thermal experiences. During the warming period, clothing adjustments exhibit a certain lag, whereas during the cooling period, adjustments are relatively prompt, reflecting a heightened sensitivity of residents to cooling environments. This study highlights the importance of thermal history on thermal perception and adaptive behavior, emphasizing the need to fully consider its effects during seasonal transitions between warm and cold periods.

Keywords: Climate Transitions, Thermal Comfort, Psychological Adaptation, Universal Thermal Climate Index.

1. INTRODUCITON

The outdoor thermal environment is directly related to thermal comfort. During the transition between warm and cold conditions, the previous thermal conditions experienced by residents, i.e. the thermal history, plays a crucial role in influencing their thermal responses and preferences (Brager & de Dear, 1998). Brychkov et al. suggested that thermal history can be divided into long-term and short-term thermal history (Brychkov et al., 2018). Jowkar et al. defined long-term thermal history as the climatic influence of people's place of residence over many years or an entire season, while short-term thermal history refers to the effects of daily thermal exposure over shorter time scales, ranging from weeks, days, and hours to even seconds (Jowkar et al., 2020). In recent years, the impact of thermal history on thermal comfort has attracted significant attention. Additionally, personal factors such as clothing insulation, psychological factors, and cultural aspects also significantly affect subjective perceptions of thermal comfort (Zhang et al., 2010).

Xie et al. explored outdoor thermal comfort among Hong Kong residents using a questionnaire survey, proposing the interactive effects between seasonal thermal history changes and thermal comfort criteria (Xie et al., 2019). Hwang et al. combining field questionnaire surveys with

environmental physical measurements, discussing on how short-term thermal history affects the thermal perception of pedestrians walking on sidewalks (Hwang et al., 2022). Hwang et al. also assessed the transitional spaces between outdoor and indoor environments, investigating the thermal sensation of individuals experiencing abrupt temperature changes and confirming that thermal comfort in these spaces is closely related to prior thermal exposure (Hwang et al., 2008). Lam et al. conducted outdoor thermal comfort surveys in Guangzhou, Zhuhai, and Melbourne, analyzing the interaction of long-term and short-term thermal histories on outdoor thermal comfort as well as examining the influence of prior exposure environments across different climate zones (Lam et al., 2021).

Previous studies have extensively explored the relationships and effects among thermal history, thermal adaptation, and thermal perception. However, relatively little analysis has focused on changes in thermal history during transitions between warm and cold outdoor climates. This study aims to examine the impact of short-term thermal history on dynamic changes in thermal perception during these transitions. Furthermore, this study investigates the driving mechanisms of thermal adaptive behaviors, explores how thermal history affects the inertia of clothing adjustment behaviors, and reveals residents' responses to thermal stress during outdoor cold-to-warm climate transitions.

2. METHOD

2.1. Physical measurement and subjective survey

The physical microclimate measurement and the subjective thermal perception questionnaire investigation was simultaneously conducted in university campuses, parks, and other locations in Taichung City, central Taiwan. Each survey session lasted 8 hours, from 9:00 AM to 5:00 PM. All surveys were conducted on days with favorable weather, avoiding strong winds or rain. Meteorological parameters measured includes air temperature, relative humidity, wind speed, and globe temperature. The questionnaire consisted of two parts to collect the following information: (1) Basic participant information, including clothing insulation, gender, age, height, weight, and long-term place of residence; (2) Questions related to thermal perception, designed to understand participants' thermal sensations in outdoor environments. Thermal perception was assessed based on the ASHRAE classification, using a 7-point scale, including thermal perception levels of cold, cool, slightly cool, neutral, slightly warm, warm, and hot (Standard, 1992).

2.2. Data Analysis

To explore the relationship between climate transitions (especially seasonal changes from warm to cold or cold to warm) and human thermal responses, as well as to evaluate the influence of thermal history and behavioral adaptation on thermal comfort. This study utilizes the weather variation recorded in the TMY3 weather data of Taichung City (TAIWAN) as the basis for seasonal transition classification. As shown in Figure 1, the weather data are divided into two weather transition periods: the warming period, which refers to the period from the coldest month gradually warming to the hottest month (January to August); and the cooling period, which refers to the period from the hottest month gradually cooling to the coldest month (July to February of the following year). Based on this transitional weather classification, the study analyzes the experimental data to investigate the characteristics of residents' thermal perceptions and adaptive behaviors during the outdoor environment's warm-to-cold and cold-to-warm transition processes.

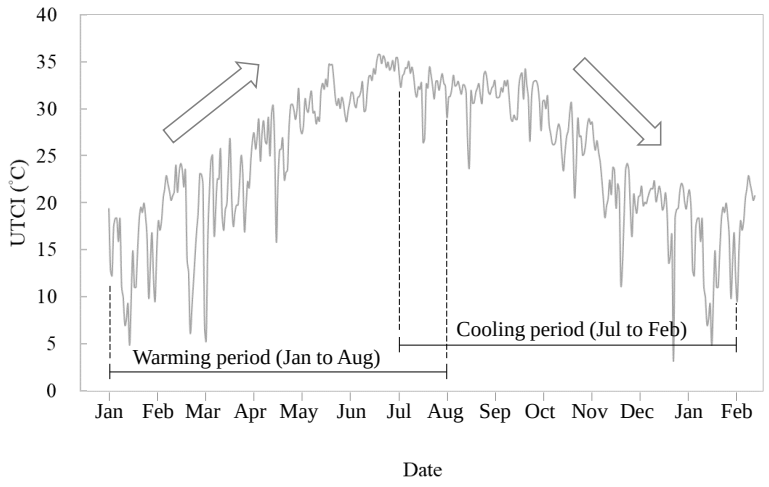

Figure 1. Seasonal transition group for cold-to-warm and warm-to-cold environments

The Universal Thermal Climate Index (UTCI) was used as an indicator to evaluate outdoor thermal comfort. The UTCI is a biometeorological index developed by a team of multidisciplinary experts to describe the thermal stress experienced by the human body in real environments, considering factors such as air temperature, mean radiant temperature, wind speed, and humidity. The metabolic rate in the UTCI multi-node model (Fiala et al., 2012) is assumed to be a constant value of 2.3 Met, which is similar to the metabolic rate of a person walking outdoors at a speed of 1.1 m/s (Bröde et al., 2012). Due to its comprehensiveness and applicability, the localized UTCI scale model has been developed in Taiwan (Chen et al., 2025) and many other countries, becoming one of the most widely used indicators in the field of outdoor thermal comfort assessment.

To understand the participants' responses to varying environmental thermal stimuli during questionnaire completion, this study analyzes the transition temperatures associated with each thermal sensation vote (TSV) based on a substantial dataset of participant's TSVs collected during climatic transitions. The transition temperature is defined as "the temperature at which the maximum number of people change their vote from one thermal sensation to the next." As shown in Table 1, six types of responses can be listed using the seven-point TSV thermal sensation voting scale (Nicol et al., 2012; Xie et al., 2019), by dividing the TSV data into two groups. In the third row of Table 1 as an example, Group 1 refers to participants who consider "colder than neutral," while Group 2 refers to those who consider "neutral to warm."Ballantynre et al. proposed the use of probability analysis for thermal perception analysis (Ballantyne et al., 1977). By treating thermal stimuli as the independent variable and thermal sensation as the dependent variable in binary logistic regression analysis, as shown in formula (1). Logistic regression can effectively describe how the probability of response changes with thermal stimuli, and the likelihood of transition is established as a linear relationship between the two variables, as shown in formulas (2) and (3). The S-shaped curve obtained from the binary response logistic probability fitting model using P and (1-P) represents the transition temperature at the point where the probability equals 50%, which is the threshold temperature corresponding to the TSV transition from 0 to 1. The temperature change between the two transition temperatures defines the thermal sensation range (Ballantyne et al., 1977).

Table 1. Example of thermal sensation vote combination.

Group1 (P)	Group2 (1-P)	Criteria for Group
P(-3)	P(-2)+P(-1)+P(0)+P(+1)+P(+2)+P(+3)	P(TSV≧-2)
P (-3)+P(-2)	P(-1)+P(0)+P(+1)+P(+2)+P(+3)	P(TSV≧-1)
P (-3)+P(-2)+P(-1)	P(0)+P(+1)+P(+2)+P(+3)	P(TSV≧0)
P (-3)+P(-2)+P(-1)+P(0)	P(+1)+P(+2)+P(+3)	P(TSV≧+1)
P (-3)+P(-2)+P(-1)+P(0)+P(+1)	P(+2)+P(+3)	P(TSV≧+2)
P (-3)+P(-2)+P(-1)+P(0)+P(+1)+P(+2)	P(+3)	P(TSV≧+3)

$$P = f(\beta_0 + \beta_1 x) \tag{1}$$

$$Logit\ P = ln\left[\frac{P}{1-P}\right] = \beta_0 + \beta_1 x \tag{2}$$

$$P = \frac{\exp(\beta_0 + \beta_1 x)}{1 + \exp(\beta_0 + \beta_1 x)} \tag{3}$$

Where P represents the probability of response to a stimulus, as the cumulative distribution function; β_0, β_1, are constants; x is UTCI.

3. RESULTS AND DISCUSSION

3.1. Questionnaire investigation results

Figure 2 shows significant changes in outdoor thermal conditions during the transition periods, encompassing a wide range of climate conditions. In both transition seasons, the UTCI ranged from 1°C to 49°C. During the warming period, the mean UTCI was 28.44°C, while during the cooling period, it was 28.37°C. A total of 12,872 valid responses were collected during the entire experimental period, with 7,326 responses during the warming period and 10,353 responses during the cooling period. As the UTCI increased, the TSV gradually rose from -3 to 3, showing high consistency across both seasons. Notably, when the UTCI exceeded 31°C, the mean UTCI during the cooling period was lower than that during the warming period, with most TSV values concentrated between 1 and 2. The TSV distribution for both periods when UTCI was below 17°C showed smaller differences, but it was observed that the mean UTCI during the warming period was higher than that during the cooling period. Between the UTCI range of 19°C to 31°C, the TSV distribution was wide.

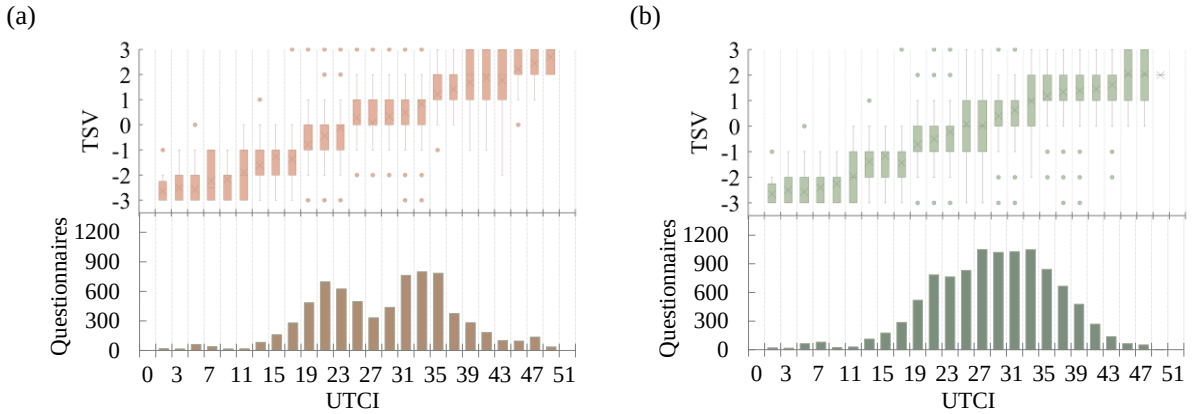

Figure 2. Distribution of thermal sensation votes (a) during the warming period, (b) during the cooling period.

3.2 Clothing Adaptation Behavior

Clothing adjustment is a key adaptive behavior people use to maintain thermal comfort in outdoor environments. As shown in Figure 3, the distribution of clothing insulation values during the experimental period is primarily concentrated between 0.35 and 1.8, with mean values ranging from approximately 0.35 to 1.0. When the UTCI exceeds 30°C, the mean clothing insulation value is below 0.6 and remains stable, indicating that even in hot environments, individuals maintain a minimum level of clothing, demonstrating limited capacity for further clothing reduction. In cold environments, a stable upper limit of clothing insulation was not observed; individuals adjusted their clothing freely according to the decreasing temperatures to adapt to the progressively cooler conditions. In Figure 3, data from the coldest months (January-February) and the hottest months (July-August) are distinguished by light gray and light yellow dots, respectively. The transition periods from cold to warm (March-June) and from warm to cold (September-December) are represented by orange and blue dots, as shown in Figure 3. Regression analysis revealed that the linear slope of clothing insulation during the warming period is -0.0129, while during the cooling period, the slope is -0.0165. This indicates a faster rate of clothing insulation change during the cooling period than during the warming period. This result suggests that under Taiwan's hot and humid climate, individuals exhibit greater sensitivity to cold weather after prolonged adaptation to hot conditions. During the cooling period, as the weather transitions from warm to cold, individuals tend to increase their clothing more rapidly. Additionally, when the UTCI is the same, individuals are influenced by their thermal history and tend to delay taking off their clothing. Thus, for a given UTCI, thermal history influences individuals to delay clothing removal, resulting in higher clothing insulation values during the warming period compared to the cooling period.

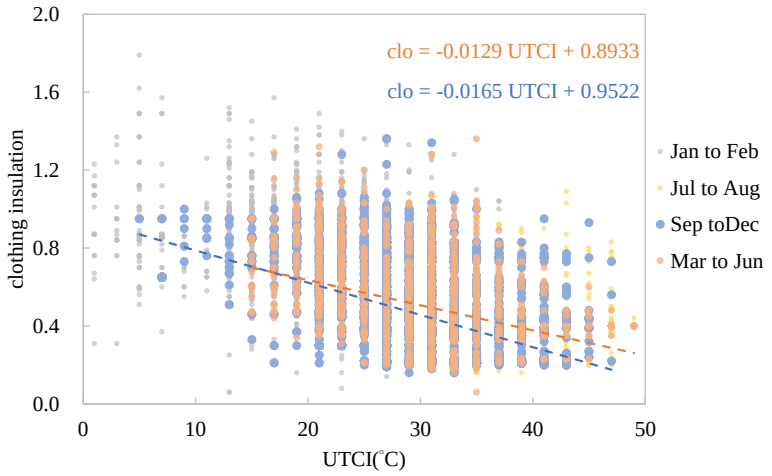

Figure 3. Trend of clothing amount variation with outdoor UTCI changes

3.3 Transition temperatures during the two periods

Figures 4 (a) and (b) show that the range of transition temperatures spans from 6.4°C to 45.4°C during the warming period and from 5.3°C to 48.0°C during the cooling period, with transition temperatures in the latter period generally exceeding those in the former. Among all thermal sensation values (TSVs), the neutral sensation (TSV=0) exhibits the broadest temperature range. As UTCI increases or decreases, it reflects that the more extreme the thermal environment, the narrower the temperature range. Focusing on the transition between warm and cold environments,

it is observed that in a progressively warming environment, the thermal sensation range for TSV = -2 is only 6.3°C (from 6.4°C to 12.7°C) when the TSV changes from -3 to -1. This represents the narrowest range observed during the warming process, suggesting that individuals, having experiencing a prolonged cold season, develop an anticipatory expectation of warming. Consequently, they exhibit heightened sensitivity to thermal conditions exceeding their prior thermal experience.

In contrast, during the cooling period, when TSV changes from 3 to 1, the transition temperature ranges from 48.0°C to 40.2°C. Although individuals may also anticipate a gradually cooling environment, for those with prolonged exposure to hot and humid climates, the influence of their established thermal history necessitates a more substantial cooling effect for the environment to be perceived as cool. This phenomenon confirms that sensitivity to hot and cold environments is influenced by factors such as thermal history, psychological expectations, and clothing adjustments, and further demonstrates an asymmetry in thermal sensations.

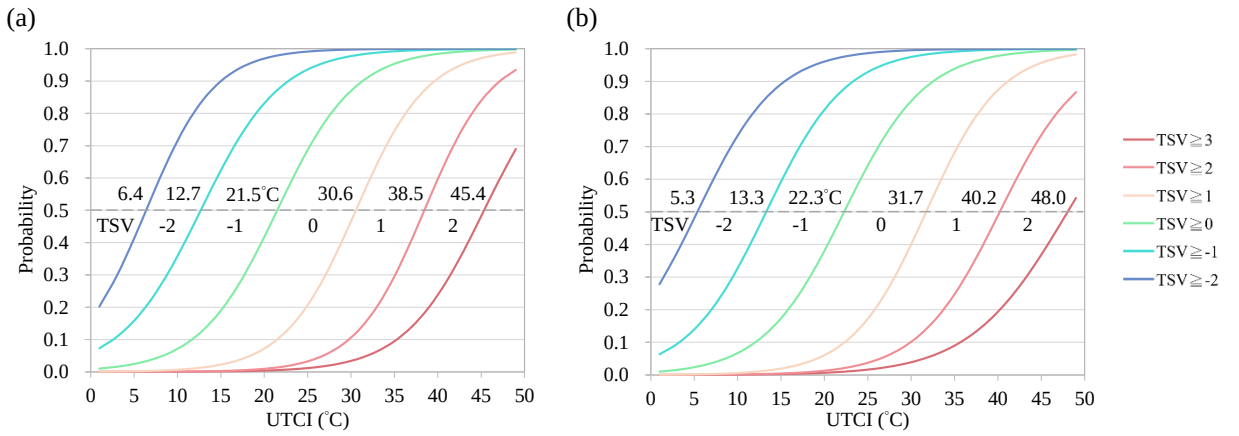

Figure 4. (a) Warming phase, (b) Cooling phase ordinal logistic regression fitting curves for the changes in thermal sensation

3. 4 Relationship between clothing insulation and transition temperature

Environmental changes not only directly affect individuals' thermal perception but also interact with adaptive behaviors, thereby influencing thermal comfort. As shown in Figure 5, during the warming period, the mean clothing insulation across all thermal sensation ranges is higher than that during the cooling period. Comparing the transition temperatures between the two periods reveals that the transition temperature during the warming period is lower than that during the cooling period. This finding suggests that the higher clothing insulation during the warming period may lead individuals to experience greater thermal discomfort as the weather becomes increasingly hot. Conversely, during the cooling period, the reduced clothing insulation may exacerbate cold discomfort as ambient temperatures decrease. Furthermore, it is noteworthy that in hot environments (TSV > 1), the clothing-based adaptation is limited, with little difference in the thermal sensation range at TSV = 2 between the two periods. Despite the reduction of clothing insulation to a mean clothing insulation of 0.4 during the warming period, the impact of prior thermal discomfort resulting from neutral-to-warming conditions leads to a 1.7°C higher transition temperature during the warming period (40.2°C - 38.5°C). Conversely, in cold environments, clothing insulation does not reach a limit, and the adaptive capacity is comparatively greater. Clothing adaptation has a greater effect on the thermal sensation range at TSV = -2, with a higher

clothing insulation during the warming period exacerbating thermal discomfort from warming conditions and resulting in lower transition temperatures. During the cooling period, despite the influence of prior discomfort from neutral-to-cooling thermal history, the increase in clothing insulation to a mean of 0.85 is sufficient to mitigate cold discomfort, resulting in a transition temperature during the cooling period that is only 0.6°C higher than that during the warming period (13.3°C - 12.7°C). This analysis not only highlights the differences and contributions of clothing behavior in thermal adaptation during cold-to-warm and warm-to-cold transitions but also emphasizes the significant impact of thermal history on individuals' thermal perception and adaptive behaviors.

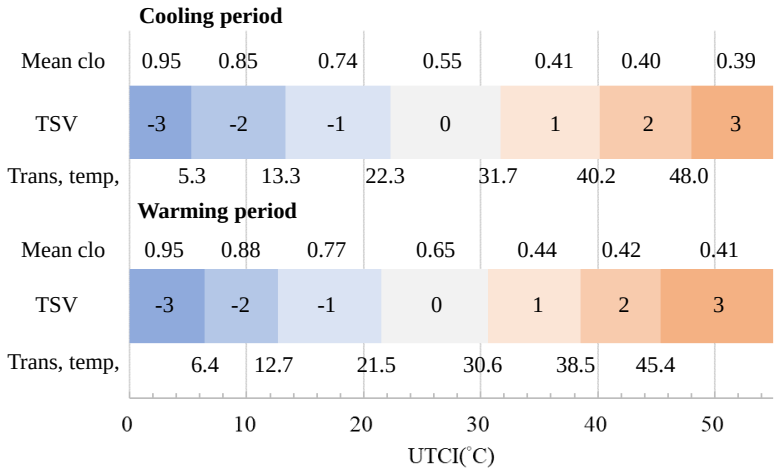

Figure 5. Thermal sensation range and mean clothing volume

4. CONCLUSION

This study, through analysis of outdoor microclimate measurements and subjective questionnaire surveys, elucidates the dynamic role of thermal history during the warming and cooling periods of temperature transitions. The influence of short-term thermal history on individuals' thermal perception and adaptive behavior during seasonal transitions is also investigated. The principal findings are as follows:

- This study confirms that short-term thermal history significantly affects individuals' thermal perception and adaptive behavior, particularly during seasonal transitions, where its influence on thermal comfort exhibit dynamic changes.
- Thermal perception during the warming and cooling periods is asymmetric, with transition temperatures influenced by thermal history. Specifically, thermal perception during the warming period is generally lower than that during the cooling period.
- During the warming period, individuals exhibit inertia influenced by thermal history, tending to delay reducing clothing insulation; conversely, during the cooling period, a delay in increasing clothing insulation is observed. In hot environments, the capacity for clothing adjustment is limited, whereas in cold environments, clothing adjustments are more flexible, indicating differences in adaptation to environmental changes.

SUMMARY
This study explores "lightscape" perception in Longmenhao Old Street, Chongqing. Six key sites were analyzed through lightwalk and questionnaires based on 18 perception indicators. Results show that tourists prefer traditional architecture, interactive natural light, and landmark features, while commercial clutter and mismatched facilities negatively impact perception. Strong correlations were found between preference and visual indicators like scenic quality and spatial diversity. The findings highlight the need to enhance visual appeal and spatial layering in historical street renewal.

Keywords: Longmenhao Old Street, Lightscape, Lightwalk, Perception.

1. INSTRUCTIONS

In the process of urban evolution, Historical and Cultural Districts face many challenges. On the one hand, some districts are at risk of destruction and disappearance, and urgently need protection; On the other hand, from a development perspective, the material and intangible cultural heritage of the district should be maintained; And at the policy level, it actively guides Historical and Cultural Districts to move towards a direction conducive to urban cultural development, which coincides with the current "city walk" trend of people's enthusiasm for characteristic cultural spaces. Chongqing Historical and Cultural Districts, with their profound historical accumulation, rich cultural resources, and unique street and alley spaces shaped by mountainous terrain, have extremely high research value. As an important aspect of public perception, Lightscape can deepen people's understanding of the history, culture, and spatial charm of the districts, effectively enhance the aesthetic value of districts, and inject vitality into the protection, inheritance, and future development of Historical and Cultural Districts.

2. RESEARCH STATUS

2.1. Current Status of Research on Historical and Cultural Districts

The research object and scope of Historical and Cultural Districts have mainly developed from the protection of individual historical buildings to traditional architectural complexes with historical significance (Jing, 2022). Then, economic factors have been included in the consideration of protection policies (Liu, 2021). Based on this, scholars have coincidentally studied the overall situation of Historical and Cultural Districts from the perspective of urban planning. Hossain explored the ways of planning activities for historic districts and emphasized

the rational preservation of their structure, cultural heritage, and overall environment (Hossain, 2013). Tutkboni analysed and proposed various impacts of newly built urban districts on historic districts (Shehata,2022). Ren Huan studied the mountainous street and alley spaces of Liziba Old Street, Chongqing, exploring the traditional views and cultural characteristics that reflect regional customs (Ren, 2017). In order to further study the elements and values of Historical and Cultural Districts, scholars have conducted evaluation analysis. Yu Hongxia conducted a decentralized assessment of several indicators of the architectural environment when studying the value assessment system of Qingdao Historical and Cultural Districts (Yu et al., 2014). Wang Haobin constructed an evaluation index system for the quality of tourism experience in Historical and Cultural Districts (Wang, 2023). After completing the analysis of the district environment, the focus of research gradually shifted to people's perception. For example, Taketo Naoi analysed tourists' evaluation of the authenticity of historical urban areas (Naoi, 2004). In terms of soundscape, Zhou Min (Zhou, 2015), Liu Jiang (Liu et al., 2019) conducted sound walks and fixed-point surveys in various historical districts. In terms of lightscape, Chen Ranpeng conducted a lightscape study on the Xiguan historical area in Guangzhou, emphasizing the importance of light-visual elements in improving satisfaction and artistic conception (Chen, 2021). In terms of visual perception, Meysam studied the impact of the visual preference dimension of historic urban areas on urban heritage protection (Najd et al., 2015). From the perspective of comprehensive perception, Yu Hui took the Zhongshan Road Historical and Cultural District in Shenyang as the research object, studied the current status of the district in terms of the five senses of vision, hearing, smell, taste, and touch, and proposed to create a "multi-sensory" experience environment (Yu et al., 2023).

2.2. Current Status of Research on Lightscape

In 2017, Wu Shuoxian, an academician of the Chinese Academy of Sciences, first proposed the concept of "lightscape", which refers to landscapes that cause strong visual impressions mainly due to light sources, light and shadows, and their changes (Wu, 2017). Except China, scholars in other countries have conducted little studies on lightscape, and more focus on studying light environment and lighting. At present, the research on lightscape is mainly concentrated in three aspects. First, scholars Bian Yu (Bian et al., 2020), Wu Jihong (Wu, 2022), and Li Yating (Li et al., 2023) separately have sorted out lightscape from three perspectives: ancient Chinese literature and classics, Chinese classical folk scenes, and natural images, and summarized the techniques of lightscape creation. Second, many Chinese scholars have conducted lightscape analysis and application in spaces such as buildings (Qiu et al., 2017), gardens (Qiu et al., 2018), squares (Qiu et al., 2020), historical districts (Chen, 2021), and campuses (Qiu et al., 2022). Among them, Chen Ranpeng (Chen, 2021) explored the lightscape creation strategy for Xiguan historical area in Guangzhou, and proposed balancing the old and new designs and optimizing the light colour and brightness to match the environment. Finally, scholars emphasize the importance of using light to integrate health elements into design.

In general, there is little research on lightscape in Historical and Cultural Districts, especially for Chongqing, a city with a unique historical and cultural background and mountainous features. The research on lightscape perception in its historical and cultural districts is of great significance for understanding the public's perception and evaluation of urban space. Incorporating light as a new perspective into its planning and protection design will also have a positive effect on the heritage protection work within the districts.

3. MATERIALS AND METHODS

3.1. Overview of the Lightscape in Longmenhao Old Street

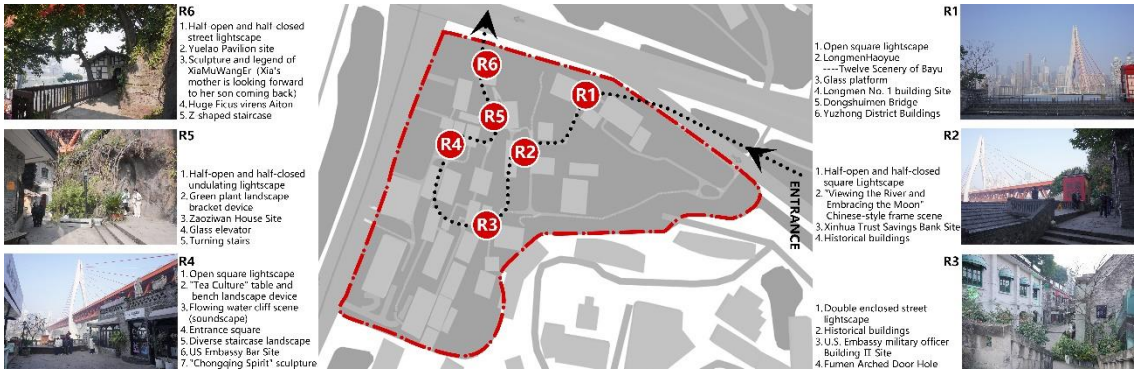

Figure 1. Overview of Lightscape Site

Longmenhao Old Street is located in the Nan'an District of Chongqing and is one of the most well-preserved historical and cultural Districts in the city's main urban area. Based on preliminary research, six representative sites within the street were selected as evaluation sites for lightscape perception, which include famous attractions and key pedestrian nodes. The sites are numbered from R1 to R6 according to the typical order. On-site photos and the main features of each lightscape site are shown in Figure 1.

3.2. Lightwalk Questionnaire Design

In order to fully understand tourists' perception and evaluation of lightscape, a structured questionnaire was designed, consisting of three parts. The first part collects basic information, including gender, educational background, etc. The second part focuses on lightscape evaluation: (1) participants indicate the lightscape elements liked and disliked at each site; (2)Score the 18 lightscape perception indicators using a 5-point Likert scale; (3)The third part addresses overall preference, in which each participant selects their favorite lightscape site from among R1 to R6.

3.3. Participant Selection and Implementation of the Lightwalk Survey

The "Lightwalk" survey recruited 27 health participants, aged between 18 and 27 years old. The survey was arranged on sunny days on weekdays, guided by 3 researchers from Chongqing University. Participants followed the lightscape map of the six lightscape sites (R1-R6) as shown in Figure 1. At each site, participants stayed for 5 to 20 minutes to fully experience the lightscape characteristics, and fill out the questionnaire based on their individual perceptions (Figure 2 - Figure 3). A total of 27 questionnaires were collected at each site, resulting in 216 valid responses overall.

Figure 2. On-site photo 1

Figure 3. On-site photo 2

4. RESULTS

This chapter explores the relationship between the characteristics of different lightscape sites in Longmenhao Old Street and tourists' preferences. It further investigates the weight and impact pathways of 18 lightscape perception indicators in perceptual evaluation.

4.1. Analysis of Preferred and Non-Preferred Lightscape Types

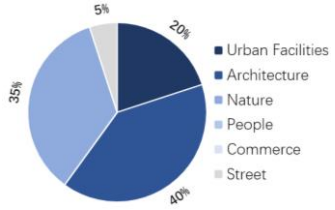

Figure 4. Preferred lightscape type

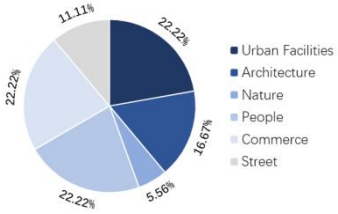

Figure 5. Non-preferred lightscape types

Figure 6. Disliked lightscape word cloud

Survey results indicate that the most preferred types of lightscape respondents are architecture, natural landscape and urban facilities(Figure 4). On the contrary, the least favored types include commercial elements, human activities, and certain urban facilities (Figure 5).

Further analyze the favorite lightscape of R1-R6 sites (Figure 7):

(1) Areas with a historical architecture generally received higher evaluations. For example, historical buildings with traditional elements (sloped roofs, gray bricks, and framed views, etc.) are more popular among tourists, which indicates that the tangible expression of traditional culture significantly enhances lightscape perception.

(2) In terms of natural lightscapes, dynamic scenes involving strong light interaction—such as water reflections and shaking tree shadows—elicited strong emotional resonance from visitors. Accompanying soundscapes (e.g., flowing water, wind) further contributed to an immersive experience.

(3) Landmark urban facilities with strong regional characteristics, such as the Dongshuimen Bridge, also received high ratings. Its distinctive form and vivid color made it a visual focus. And lightscape elements involving the bridge were consistently among the most favored.

Figure 7. Top 3 Favorite Lightscape Elements at R1–R6 Sites

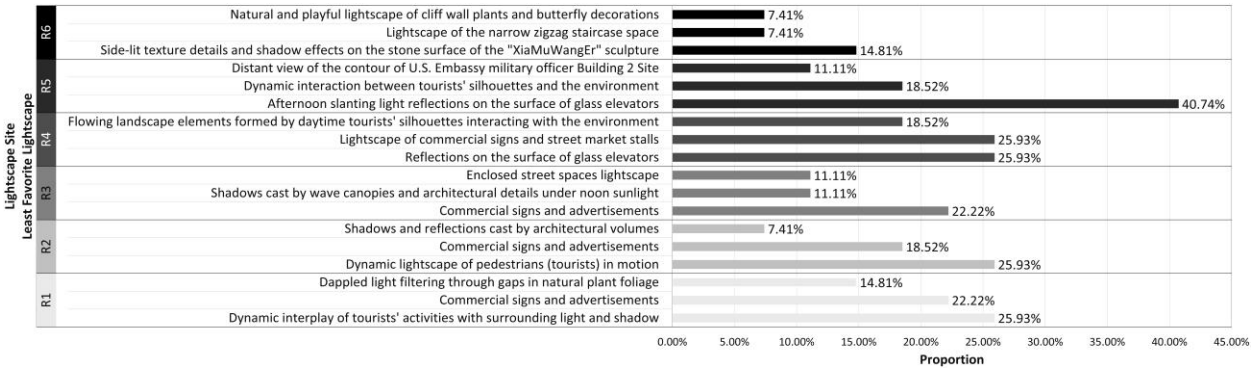

Figure 8. Least Favorite Lightscape Elements at R1–R6 Sites

According to the word cloud of "disliked lightscape" (Figure 6), commercial advertisements and related activities were identified as the primary sources of disturbance, which include signage, advertising boards, and street stall markets, etc.; Secondly, the gathering and activities of high-density people also significantly affect quality of the lightscape experience. Together, these factors reflect that excessive commercialization and dynamic visual disturbances tend to undermine tourists' perception of the lightscape. Moreover, inconsistent urban facilities and improper light treatments are frequently mentioned, such as glass elevators that produce strong reflections under sunlight, strong shadows formed by strong midday light, and landscape devices that do not match the historical atmosphere (Figure 8). These elements weaken the overall quality of the lightscape experience of visitors to varying degrees.

4.2. Analysis of Lightscape Indicator Scores at Each Point

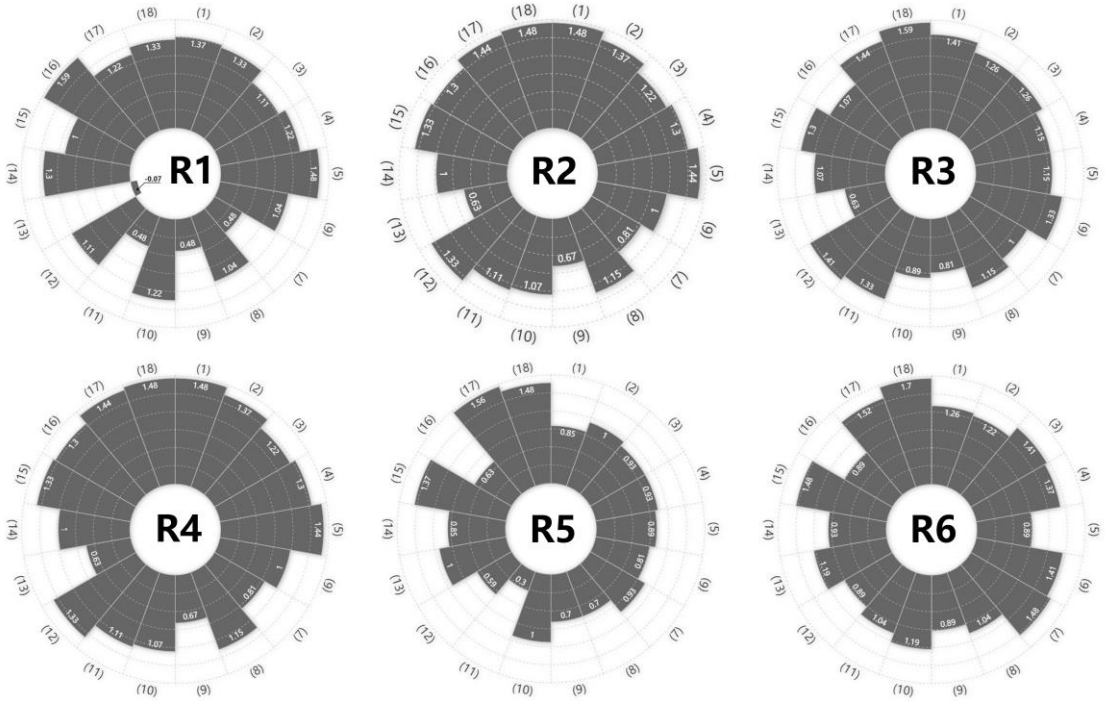

Figure 9. Radar Chart of Average Scores for Lightscape Indicators at R1–R6

This study established 18 lightscape perception indicators, covering multiple dimensions including lightscape, nature, space, history, culture, aesthetics and mountain. The 18 indicators and corresponding numbers are shown in Table 1. The scores of 6 lightscape sites on each indicator were analyzed (Figure 9), and the results were as follows:
(1) R1's advantages are high Cleanliness and Visual Openness. The disadvantages are low Comfort, sense of Change and Nature. The overall assessment is that the space is visually open but provides a rather plain experience. So it is advisable to enhance the landscape layering and natural vegetation.
(2) The advantages of R2 are beautiful Scenery, high scores in Attractiveness, Satisfaction, and Characteristics. While in terms of Coordination and Nature are poor. The overall assessment is that it has strong visual appeal but lacks natural elements and spatial coherence.
(3) R3 excels in Historicity and Cultural Identity, but has lower scores in Color Harmony and Distinctiveness. In general, R3 conveys a strong cultural atmosphere, but color coordination should be improved.
(4) R4 has high Cultural Identity and Spatial Diversity. While the disadvantages are poor Attractiveness and Satisfaction. Overall, the cultural atmosphere is well expressed but lacks significant visual attraction.
(5) The advantage indicators of R5 are that there are many Natures and Undulation Degree, but it has lower scores in Scenic Quality, Satisfaction, Distinctiveness, and Cleanliness. Comprehensive evaluation shows that although they have natural terrain advantages, the overall landscape quality is relatively low, and landscape creation and spatial integration should be strengthened. Overall assessment is that although the site benefits from natural terrain, the overall landscape quality is inadequate and requires enhanced spatial organization and visual design.
(6) R6 has high scores in Pleasantness, Harmony, Comfort Level, Spatial Diversity, and Layers Perception, but with a moderate performance in Cultural Identity and Distinctiveness. In general, R6 offers the best overall spatial experience, but the cultural depth and uniqueness could be further enhanced.

4.3. Correlation Analysis Between Lightscape Indicators and Favorite Site

In order to explore the degree of influence of each lightscape indicator on tourists' preferences, this paper uses Pearson's correlation analysis method to calculate the correlation coefficient between the 18 indicators and the selection frequency of the "favorite site". The results are shown in Table 1:

Table 1. Correlation Analysis Between Indicators and Favorite Lightscape Site

Number	Indicator	Correlation Coefficient(r)	Strength of Correlation	Explanation
(1)	Scenic Quality	0.82	Strong(+)	The level of ligtscape beauty directly affects tourist preferences.
(2)	Attractiveness	0.78	Strong(+)	Interactive and iconic designs significantly improve selection rates.
(3)	Pleasantness	-0.05	Weak (-)	No significant association.
(4)	Satisfaction	0.27	Weak (+)	Tourist satisfaction weakly correlates with selection behavior.
(5)	Distinctiveness	-0.15	Weak (-)	Unique styles may not be sufficiently perceived.
(6)	Harmony	0.65	Moderate(+)	Harmony among lightscape elements has a moderate impact.

(7)	Comfort Level	0.09	Weak (+)	Comfort has little impact on selection behavior.
(8)	Affection Degree	-0.21	Weak (-)	Slight contradiction with selection rates.
(9)	Change Perception	0.25	Weak (+)	Dynamic lighting effects are not clearly perceived.
(10)	Color Harmony	0.47	Weak (+)	Color combinations have limited influence on preferences.
(11)	Historicity	0.12	Weak (+)	Tourists prioritize visual appeal over historical value.
(12)	Cultural Identity	0.19	Weak (+)	Cultural attributes have little influence on preferences.
(13)	Naturalness	-0.58	Moderate (-)	Artificial designs may be more popular.
(14)	Cleanliness	0.31	Weak (+)	Cleanliness is not a core factor.
(15)	Spatial Diversity	0.72	Strong(+)	Diversified spatial forms enhance visitor interest.
(16)	Visual Openness	0.44	Weak (+)	Open sightlines play a minor role.
(17)	Undulation Degree	0.29	Weak (+)	The gap of terrain elevation differences have minimal impact.
(18)	Layers Perception	0.75	Strong(+)	The three-dimensional effects are key drivers.

(1) Strongly positive correlated indicators ($|r| \geqslant 0.7$):
Scenic Quality, Attractiveness, Layers Perception, and Spatial Diversity show strong positive correlations with the frequency of being selected as the favorite lightscape site. This indicates that tourists' preferences are highly influenced by visual aesthetics, terrain hierarchy , and spatial organization.
(2) Moderately correlated indicators ($0.5 \leqslant |r| < 0.7$):
Indicators such as Harmony and Naturalness have a certain degree of influence but are not decisive factors. Notably, Naturalness shows a negative correlation with preference (e.g., R1 had a negative score for Naturalness yet was still well-liked), suggesting that in highly artificial environments, carefully designed artificial elements may be more appealing.
(3) Weakly correlated indicators ($|r| < 0.5$):
Traditional evaluation dimensions such as Historicity, Cleanliness, and Cultural Identity have relatively little impact on visitors' choices. This suggests that contemporary tourists place greater value on immediate spatial experiences rather than historical or cultural context.

5. CONCLUSION AND OUTLOOK

5.1. Research Conclusions

Based on the theory of lightscape perception, this study took Longmenhao Old Street in Chongqing as a case study. Six representative sites (R1–R6) were selected for lightwalk experiments and questionnaire surveys. A systematic analysis was conducted on visitor preferences regarding different types of lightscape and the role of 18 perception indicators in shaping the visitor experience. The main conclusions are as follows:
(1) Preferred lightscape types are primarily concentrated in three categories: architectural scenes with historical and cultural imagery, natural scenes that strongly interact with light elements, and landmark urban facilities. These reflect visitors' high sensitivity to visual aesthetics, cultural identity, and spatial rhythm.
(2) Main sources of disturbance include commercial advertisements, poorly integrated modern facilities (such as glass elevators), and overcrowding. These negative lightscape elements significantly disrupt the spatial atmosphere and perceived quality, suggesting the need for stricter management of commercial elements and the spatial scale of facilities during future

redevelopment.
(3) R6, the highest-rated site, demonstrated comprehensive advantages in spatial layering, comfort, and harmony, offering a model for effective lightscape enhancement. In contrast, R5 received the lowest scores across several indicators and urgently requires improvements in landscape quality and cleanliness.

Future research can expand to include more historical districts in Chongqing, explore night-time lightscape perception, and integrate multi-sensory elements such as soundscapes to deepen understanding of visitor experiences.

SUMMARY
To enhance students' understanding of Indoor Environmental Quality (IEQ), a measurement tool was developed for use in the educational program at Eindhoven University of Technology (TU/e) in the Netherlands. The tool includes sensors to measure air temperature, relative humidity, illuminance, and sound pressure level—factors perceivable by humans. It was designed to be inexpensive, suitable for instant and continuous measurements, robust for student use, compatible with Android and iOS, and capable of local data storage. The "SvS" (Senses versus Sensors) device was created, and following a prototype phase, 300 units were produced. The SvS device was used twice in a first-year bachelor's course at TU/e. After the course, 82% of students reported that the device improved their understanding of IEQ. The sensors were calibrated, and all perform accurately within the normal ranges, except for the light sensor which requires a correction factor of 1.5.

Keywords: Indoor Environmental Quality, education, measurement device

1. INTRODUCTION

As professors at the department of the Built Environment at Eindhoven University of Technology (TU/e) working on Building Physics, we considered it an essential skill for future architects and building engineers to be able to fully comprehend the concept of Indoor Environmental Quality (IEQ). In that sense, we were convinced that only learning the theory and the quantitative values given in, for example building standards, codes, or regulations, is not sufficient. These students will be the ones who in their future professions will have to consider and balance many aspects, among which energy, sustainability and the user's needs. While currently, the building process and buildings have their focus on energy and sustainability, we should not forget that the reason we as human beings build is to facilitate the user's needs. We also know that users spend 90% of their time indoors (e.g. Klepeis et al., 2001; Awbi 2003; WHO 2014), meaning that a good IEQ is essential for the quality of a building; a poor IEQ leads to reduced comfort, health and productivity. We also noticed that Architecture students and Building Engineering students often struggle to grasp the practical applications of typically used aspects to identify IEQ, finding it difficult to discern normal or significant values.
Therefore, we decided to develop a measurement device for all students enrolled in the bachelor program Architecture, Urbanism, and Building Science (AUBS) to use. The device should measure

typical values characteristic of various aspects of Indoor Environmental Quality (IEQ), enabling students to connect their own perceptions (senses) to measurable data (sensors). IEQ encompasses factors such as air quality, temperature, light, and sound, which influence occupant comfort, health, and energy use in buildings. Since air quality is key component of IEQ, we chose to measure relative humidity (RH) because it is easier for humans to perceive than CO_2 or PM concentrations. The measurement device should be paired with a software application (app), providing a hands-on method that enhances students' understanding and integration of these factors into their building designs. By bridging the gap between theoretical knowledge and practical application, this initiative also aims to inspire students to pursue advanced studies in building physics, addressing the growing demand for specialists in this field.

2. METHODOLOGY

2.1 Device requirements

At the start of this project, we explored existing devices for student use. Our initial aim was to develop a smartphone application that would utilize the phone's built-in sensors. This approach offered significant advantages: students would have a personal measurement device readily available, and app maintenance and distribution would be simple and sustainable. However, this option proved impractical due to the wide variability of smartphone sensors (van Duijnhoven et al., 2023) and the challenge of accurately measuring environmental temperature with a device that generates its own heat. Therefore, we decided to develop an external device equipped with four sensors. To minimize costs, we created an app that connects to the device to read sensor data. While momentary measurements are useful, incorporating a logging function to store time series data would further enhance students' understanding of the variability of these environmental values. Therefore, the development requirements were:

1. Sensors for measuring illuminance, sound pressure level, air temperature, and relative humidity;
2. Small device that should be carried in a bag;
3. The device should allow to measure real time (momentarily) and as a data logger (continuously);
4. An app should be developed to read real time measurements and to program the logging schedule for continuous measurements;
5. Powered by internal batteries and by an external power unit (e.g. power bank) or the regular power net;
6. Data should not be stored on the smart phone and should be transferable to a computer for analysis;
7. The device should be robust and intuitive to use;
8. The price for the students should be low (preferably under € 25).

2.2 Development procedure

With the specifications given, the TU/e Equipment and Prototype Center (EPC) developed the first version of the device (version 1, see Figure 1). This version contained a small digital display to be used for real time measurements.

Due to the high costs, the size, and the low visibility of the display, the display function was removed and added to the app. During the development, several setbacks had to be overcome. An important one was that the development of an app for an iOS driven device (iPhone) needs approval from Apple. This was achieved via the board of the University.

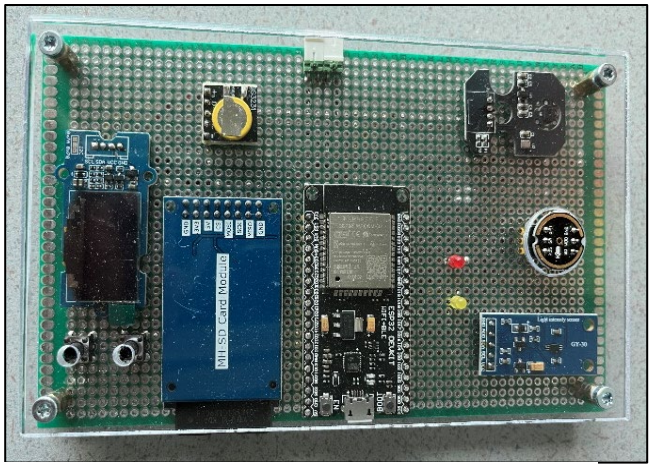

Figure 1 First version of the SvS device (version 1)

Another consideration was the placement of the sensors to ensure they were not obstructed, as this could affect the measurements, while also protecting them from external elements such as dirt, handling, or being tossed into bags. This led to the situation where the light sensor and the microphone are placed on top of the device, while the air temperature and relative humidity sensors are 'isolated' and placed at the bottom of the device. Ten devices of this version were produced (version 2, see Figure 2) and used for testing the design and usability in a pilot test among seven bachelor students.

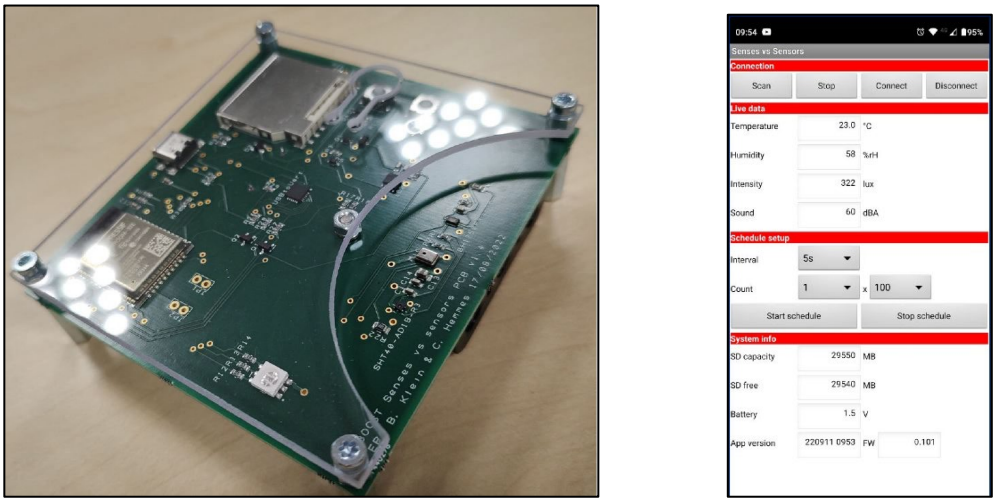

Figure 2 Version 2 of the SvS device (left) and the app (right)

This process led to relevant practical insights, such as the size of the device, the battery life span, the connectivity, and the design.
With these insights, the final version (version 3) of the SvS device was developed as well as the app applicable for people with Android and with iOS smartphones (see Figure 3). After the first round of usage in education, 295 students used the device and also this version was evaluated.

Initially, the selected sensors were identified based on their price, availability and the specified range of accuracy. In a later stage they were calibrated and software wise adjusted. To validate the quality of the sensors the SvS devices (version 3) were calibrated. The calibration results for the four different sensors and both student evaluations are presented in this paper.

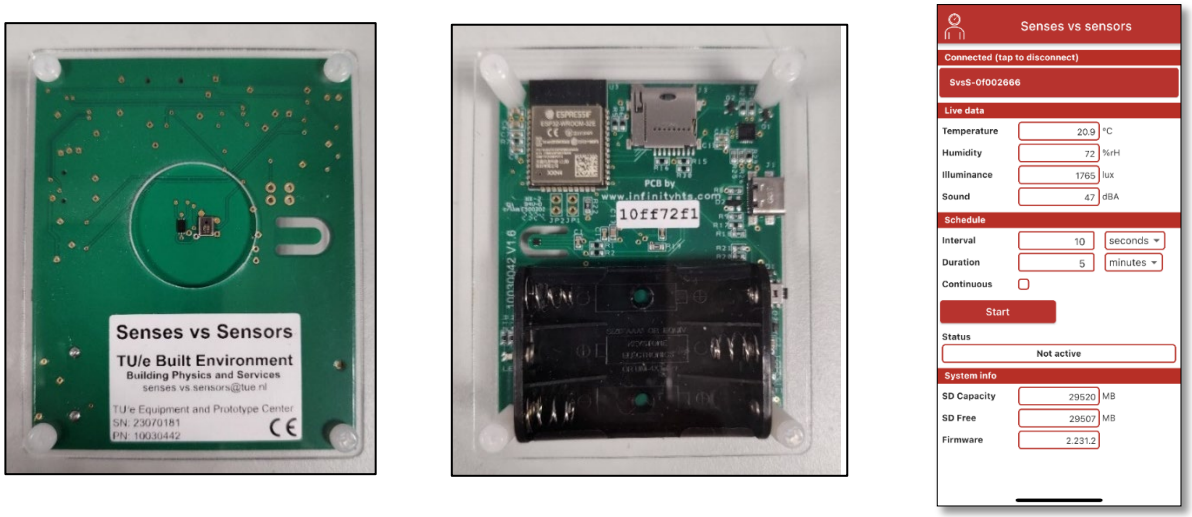

Figure 3 Picture of the SvS device (version 3) front (left), back (middle) and the app (right). Device size is 8.2*6.8*2.0 cm^3

To assess the SvS device and the app, student evaluations were organized in the bachelor program of our department. The two evaluations are outlined in paragraph 2.3 and 2.4 and the calibration is introduced in paragraph 2.5.

2.3 Student evaluation on design and usability of the SvS device (version 2)

To test how students experienced the device, a pilot was conducted among seven bachelor students who followed the third-year bachelor course, *Building Physics and Building Services Engineering*, mandatory for AUBS. These students (3 male, 4 female) were recruited via an announcement on the course page. For the testing purpose, ten devices of the second version were manufactured as well as the first working version of the app. Since the app was only available for Android at that time, students with other smartphones could use an Android phone from our laboratory. The students were given an assignment to measure both real-time values as well as to use the logging function for 24 hours. After one week of use, students provided insights and feedback through an online survey with 19 mostly open-ended questions on the usability of the device. To gather the most comprehensive feedback, the survey results were discussed in a group session with all students, a student assistant, and the project leader.

2.4 Student evaluation on the applicability of the SvS device (version 3) for the intended learning goal.

The SvS device was used in an assignment for the first-year mandatory bachelor course *Healthy and Sustainable Living Environments* in the Architecture, Urbanism, and Building Sciences program. In this group assignment (two students per group), students used the device to measure real-time conditions in their own dwelling and predict values based on their perceptions. They

were also asked to log data for at least 48 hours and explain any differences. The results had to be presented in graphs and be discussed within each group. A total of 295 students used version 3 of the device. To gather feedback, an online survey was conducted during the last lecture using Mentimeter (Mentimeter, n.d.). The survey, focusing on the device's usage and the course's learning objectives, received responses from 35-46 students (not all students answered every question).

2.5 Calibration of the SvS devices, version 3

Since we were interested to know the quality of the sensors, ten randomly selected devices of the SvS were calibrated. See specifications of the sensors in Table 1

Table 1 Specification of the used sensors in the SvS device

Aspect	Sensor type	Manufacturer	Type	Specified range
Illuminance	Ambient light sensor	ROHM Semiconductor	BH1750FVI	1-65535 lx
Sound pressure level	Omnidirectional MEMSmicrophone	CUI Devices	CMM-4030D-261-I2S-TR	38-120dB, 100-10.000 Hz
Air temperature Relative Humidity	Combined air temperature and RH sensor	SENSIRION	SHT4x	-40-125°C 0-100%

For calibrating the illuminance, an Ulbricht Sphere was used (uku 1600) with 12V halogen incandescent lamps, and an Illuminance Spectrophotometer (Konica Minolta, CL-500A). The sound pressure level was measured in a diffuse field measurement room of the TUE Acoustics Lab, using an omnidirectional sound source (Brüel & Kjaer, OmniPower Sound Source Type 4292-L, Acoustics Engineering Power Amplifier and noise generator Type Amphion). For temperature and RH, we used a climate chamber (Memmert, type ICH260) in combination with two research grade air temperature and relative humidity Probes (Vaisala, type HMP1).

3. RESULTS

In this paragraph the results of both student evaluations are presented as well as the results from the calibration.

3.1 Results student evaluation on design and usability of the SvS device (version 2)

In total seven students used the device for one week. The results from the questionnaires indicated potential improvements of the SvS device related to the manual and the process of connecting the device, the logging function, the size of the device (too big), and the pricing (should be less than € 20 if they would need to buy it). Also, a special casing was needed to protect the device and the blinking light indicating that the logging was active, was too bright. As additional IEQ indicators, they would prefer the option to measure air quality (e.g. CO_2 or PM concentrations). The students were pleased with all the different features, the look of the device ('what you see is what you get'), the options for both logging and real-time measurements, and the IEQ insights it provided to them. Most students would have liked to have such a device at the beginning of their studies. The insights obtained from this survey led to an adjustment in the size (half the size and as consequence battery pack of 3* AAA), improvement of the app (more intuitive), reducing the brightness of the blinking LED, and adding a case to the device. In September 2023, a total of 300 SvS devices (version 3) were produced and implemented in our educational program.

3.2 Results student evaluation on the applicability of the SvS device (version 3) for the intended learning goal.

Since we wanted to know more about how students experienced the SvS device and whether it contributed to their comprehension of IEQ in buildings, a survey was conducted during the final lecture of the course *Healthy and Sustainable Living Environments,* leading to 35-46 respondents. The results showed that 50% of the students encountered some technical difficulties, however, these were all solved along the way. These difficulties were related to the connectivity and limited life span of the batteries. In addition, 75% of the technical problems were not related to the device, but with experienced problems when working with Microsoft Excel for processing the logged data. When asking for their gained insights, 82% indicated that using the device added to their comprehension of IEQ aspects. Although the students considered all four aspects insightful, illuminance was considered most insightful (30%). When asked if they would like to use the SvS device more often, 60% answered positively and 45% would like to buy the device (average suggested price € 22).

Some of the results led to an improved assignment in the following year, i.e. a short instruction on how to work with MS Excel to process the measurement data and dimming of the blinking. Also, some problems occurred with the limited lifespan of the batteries. Therefore, we decided to discourage the use of batteries but suggest using an external power supply when possible.

3.3 Calibration of the SvS devices

3.3.1 Illuminance

By using the Ulbricht sphere, the linearity of the results was tested against a calibrated device. In addition to the 'no light' situation, four light conditions with a similar spectral power distribution (SPD) were tested. The light sources were halogen incandescent lamps. From the graph in Figure 4, the linearity is near to perfect (R^2=1) but the SvS largely underestimates the illuminance by a factor of 1.5 (calibration factor y = 1.5x-1.6). An explanation is that the illuminance sensor is not omnidirectional and therefore also not cosine corrected. This means that predominantly, the illuminance incident to the device is measured and much less towards the other angles.

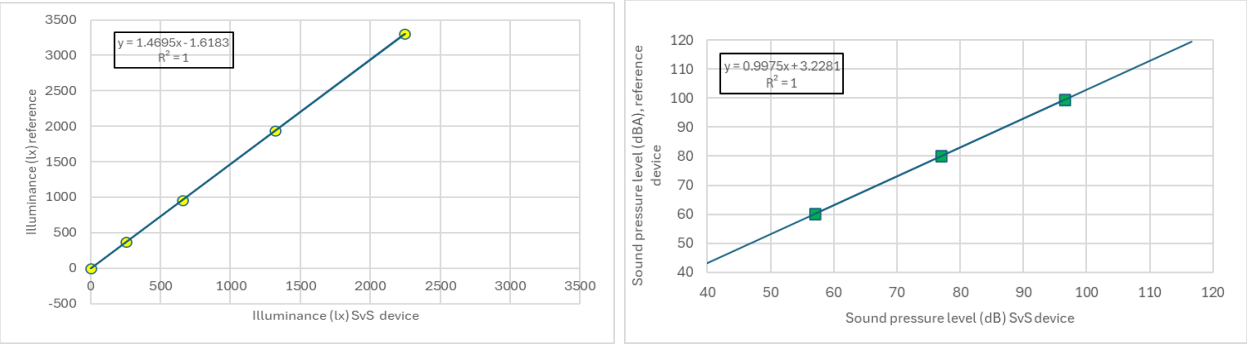

Figure 4 Calibration of the illuminance (left) and sound pressure level (right)

3.3.2 Sound pressure level

In the acoustic room with an omnidirectional sound source, the responses of the SvS device are compared to a calibrated measurement device for three different white noise levels. In addition, a fourth level is introduced, namely the 'no sound' situation where only background noise is

available. Since the minimum threshold for the SvS device is 38 dB, this value is not included in the graph. From the graph (Figure 4) both values align within 3dB ($y = 1.0x - 3.2$, $R^2 = 1$). It must be noted that the response of the SvS device closely aligns with the A-weighted values for white noise, indicating the human perception correction.

3.3.3 Air temperature and Relative Humidity (RH)

Since air temperature and RH are closely related, these will be discussed in one paragraph. In the climate cabinet, temperatures between 12-32 °C and RH between 28-77 % were assessed.
In Figure 5 the differences between the SvS device and the reference device are given over time. Since the SvS requires a few minutes to stabilize, the data after stabilization are used. When calculating the differences, ignoring the peaks due to stabilization, the SvS device slightly underestimates the air temperature by 0.3 °C ($y = 1.0x + 0.3$, $R^2 = 1.0$), while the RH is slightly overestimated by 8.3 % ($y = 1.1x – 8.3$, $R^2 = 1.0$).

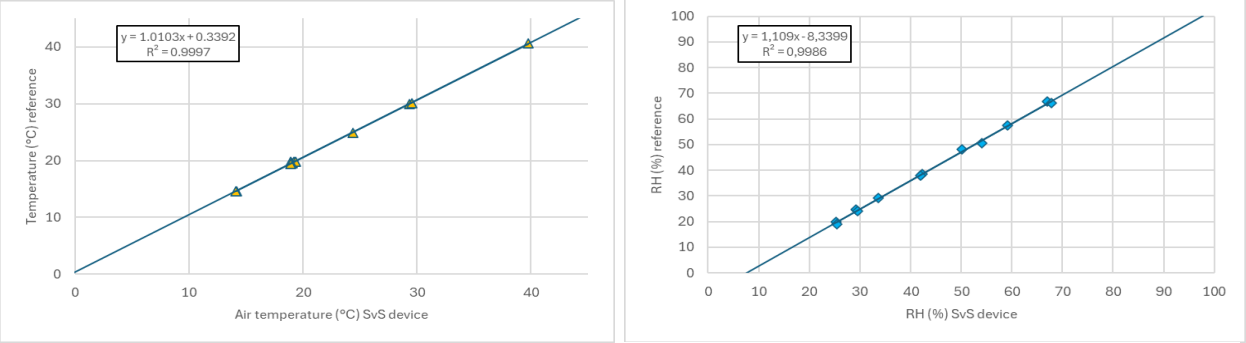

Figure 5 Difference between the SvS device and the calibrated reference device over time. Air temperature (left); and the RH (right)

4. CONCLUSIONS

The device is sufficiently robust to be used in education, meeting the envisioned learning outcome as to contribute to a better understanding of IEQ and the related measurable values. The device is sufficiently user friendly, and the user instructions are of such quality that additional teacher support is hardly required. The sensors perform very well with only minor differences for temperature (underestimation of 0.3 °C), RH (overestimation of 8.3 %) and sound level (underestimation of 3 dB). The difference in illuminance is a factor of 1.5, which can be explained by the absence of a 'cosine diffuser' in the sensor. For the next version, adding sensors to assess the air quality (e.g. CO_2 sensor) is considered as well as improved versions of the sensors, especially the light sensor. A contract for maintenance is needed to check the functioning and performance of the app on new smartphones and with new updates of mobile operating systems. To make the device more accessible, the option to make it cheaper, the sensor quality better, making the specifications of the device open, and the maintenance less time-consuming will be explored.

ACKNOWLEDGEMENTS

This project was supported by the TU/e BOOST! funding. We want to thank Kees Hemmes from the TU/e Equipment and Prototyping Center (EPC) for developing the device and the app and his inexhaustible dedication to solving any potential issue. In addition, we want to thank the Building Physics and Services lab for their help in calibrating and handling the SvS devices. Finally, we want to thank Rijn Jo Kersten for calibrating the different devices.

SUMMARY
Modern residential and commercial buildings often feature automatic shading devices (ASDs). However, these systems frequently underperform and are often manually overridden. This issue arises mainly because current ASD control systems focus primarily on reducing cooling energy and enhancing indoor thermal comfort by blocking solar radiation. Typically, these systems monitor outdoor irradiance, activating shades only when specific thresholds are reached. In addition to energy conservation, ASDs also aim to ensure visual comfort for occupants. Glare is traditionally measured using indicators like daylight glare potential (DGP) and daylight glare index (DGI), which require computational analysis of wide-angle indoor images. This necessitates installing several cameras indoors, leading to significant drawbacks: it disrupts interior layouts and limits the connection between indoor and outdoor environments when shades are deployed. Consequently, a more comprehensive control algorithm for ASDs is essential. This study aims to establish the relationship between indoor glare indicators and external climatic conditions. Field measurements were conducted, utilizing cameras and illuminance meters within a model room to evaluate glare. Additional meters will be placed with fisheye lenses to monitor outdoor daylight conditions. Random forest (RF) is a good tool in predicting the indoor glare levels while the use of traditional pattern recognition approach by convolutional neural networks (CNN) might not be a good solution and more works is required.

Keywords: Automatic shading control system, daylight glare control, sky image.

1. INTRODUCTION

Natural lighting is one of the crucial elements in modern green architectural designs. It provides a healthy indoor environment and offers an enormous amount of energy-saving opportunities through the adoption of daylight-linked lighting control (DLLC) systems. A good daylighting design admits the maximum amount of natural light without compromising visual comfort. Most designers are interested in daylight availability rather than visual comfort. Hirning et al. (2014) collected 493 responses from a survey conducted in Brisbane and found that 49% of occupants reported that uncomfortable glare was found in green buildings equipped with automatic shading devices (ASDs) control. A poorly installed and commissioned ASDs control system affects both occupants sitting in the perimeter zones and the interior zones. Both the design and installation of ASD control should not reduce the functionalities of the DLLC system or sacrifice human visual comfort.

Automatic shading device control and the DLLC are two major systems in daylighting designs. The DLLC aims at reducing lighting energy consumption and maintaining suitable lighting levels. While ASD control prevents excessive glare and cooling load, it should not worsen the indoor

daylight availability. Unlike DLLC can use both open- and closed-loop controls, ASD control usually uses open-loop controls only (Jain and Grag, 2018). Common controlling parameters for ASD control are indoor temperature, cooling and heating loads, outdoor daylight level, glare and solar irradiance. When a shading device is switched on, the connection between the indoor and outdoor is lost due to blockage of glazings by shading devices. Hence, feedback (closed-loop) control cannot be formed. Meerbeek et al. (2014) used vertical illuminance as a threshold to switch the blind on and off which can minimize the number of switching. However, the performance of the control device could not fulfil occupants' expectations since occupants tend to operate shading devices depending on weather conditions, the demand for sunshine and the prevention excessive of glare. Hence, a shading control links glare and climatic parameters is needed.

Recently, high dynamic range (HDR) imaging techniques have been widely adopted for glare evaluation. Camera sensor has a dynamic range of 7-8 exposure values (EV) which is far less than 14-16 EVs for human eyes. To study indoor daylight measurement, 20 EVs or higher are needed. HDR image comprises images with different EVs. Well-prepared HDR images have been widely used to assess discomfort glare (Wolska and Sawicki, 2020). Hirning et al. (2014), Jakubiec et al. (2015) and Jakubiec & Reinhart (2015) reported that different types of glare index perform nearly the same but have their own limitations. Mahić et al. (2017) also showed that luminance values correlate well with occupant responses. A RADIANCE build-in program, "evalglare" calculates different glare indices such as daylight glare index (DGI) and daylight glare potential (DGP) from HDR images.

This study aims to develop a method for determining the interior glare level by exterior weather and solar geometrical relationship. The study will form a basis for filling the gap in current ASD controlling system responses to indoor visual comfort environments when the shading systems are actuated.

2. METHODOLOGIES

This study is mainly focused on developing the relationship between the outdoor parameters and the glare and illuminance levels. In this section, the details of the experimental setup, glare index calculation and the training of machine learning are presented.

2.1. Case studies

A low-rise residential building was selected for the field measurement. One of the reasons for selecting a low-rise building instead of a high-rise one is that the building is under single ownership and hence, measurement can be performed in the room and on the roof. The building being studied is a three-storey height residential building located in the countryside of Hong Kong.

Figure 1 shows the site layout plan. As indicated on the plan, the residential block was in Shatin, New Territories. The window is facing west-southwest viewing an open car park with around 120° free of heavy obstruction.

(a) (b)

Figure 1. Location plan (a) and exterior fisheye view (b) of measuring location.

2.1.1. Experimental setup

Figure 2 depicts the plan and section of the room together with the equipment setup. The measured room is approximately 2.3m (W) x 4.74m(L) x 2.3m (H) and is located on the second floor. Inside the room, 2 locations were selected namely 1 and 2. Those two locations are near the room are located far from the windows as it can represent indoor environment with high contrast in term of luminance distribution. Location 1 is in about 75% depth of the room. Location 2 is in the middle of the room. At each point, one camera and one illuminance meter were mounted facing vertically toward the window direction. The focal length of each camera is set to about 24mm equivalate in 135-film format to capture wide-angle images. Minolta T-10MA was used to measure the vertical illuminance and two cameras, Nikon Z 8 and Pentax Q were used to capture photos in the room. On the windows, another Minolta T-10MA was also used to measure the outdoor vertical illuminance. While an Insta360 X4 camera was used to capture the High dynamic range image of the vertical outdoor view. Similarly, another Insta 360 X4 and illuminance meter were installed on the roof to capture horizontal illuminance and sky images. The surface reflectances within the room were measured by Minolta Spectrophotometer CM-25cG.The spectrophotometer measures the reflectance between wavelengths from 360nm to 740 nm covering the near-infrared, visible light and ultraviolet regions. The transmittance of the window was measured by an illuminance meter T-10MA according to Fontoynont (1999). The relevant reflectance and transmittance are shown in Table 1. In general, the surface of the room has a light colour but the transmittance of the window is a little low making the room look gloomy. Inside the room, there are some windows for installing air conditioning units and ventilation purposes. Those small windows were covered by an opaque surface during measurement.

Table 1. Room surface characteristics

Item	Reflectance / Transmittance
Ceiling	70.47%
Wall	76.34%
Floor	18.34%
Window	13.39%

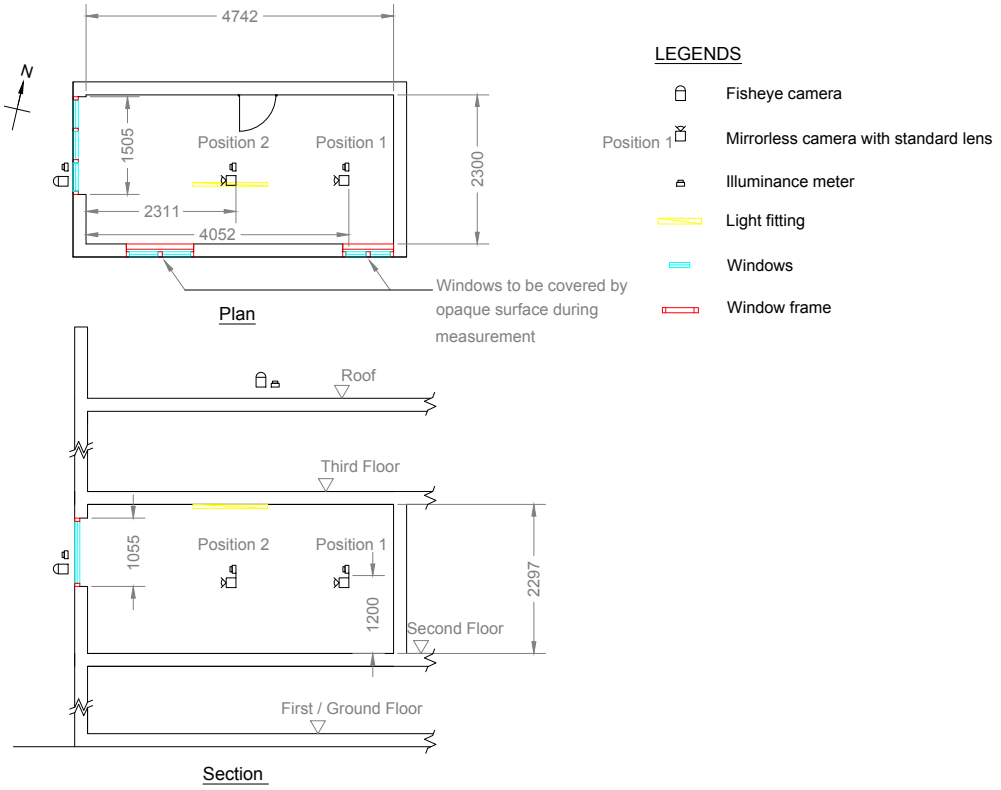

Figure 2. Plan and section of studied room and arrangement of measuring equipment.

2.2. Glare Measurement

One of the aims of shading control is to limit the glare and hence an adequate method for determining the glare is needed. This section outlines the method of glare measurement and calculation. There are several indicators quantifying degree of glare, among all of them, Daylight glare index (DGI) has better reflection on high contrast environment (Quek et al., 2021). DGI is calculated according to Eq. (1) and it is commonly used in determining glare related to daylighting applications.

$$\mathrm{DGI} = \frac{10\ log \sum_{i=0}^{n} 0.478\left(L_s^{1.6} \times \Omega^{0.8}\right)}{L_b + 0.07 \times \omega^{0.5} \times L_s} \quad (1)$$

Where,

L_s = luminance of glare source (cd/m^2)

Ω = solid angle subtense of the source at the eye of the observer modified for the effect of position of the observer in relation to the glare source (sr)

ω = solid angle of the source at the eye of the observer (sr)

L_b = luminance of the background (cd/m^2)

n, i = total and current number of light sources

Bellia et al. (2008) compared a few glare indexes and listed the degree of perceived glare as Table 4. The classifications are as follows: 'Below 16 – unaware'; '16 to 20 – perceptible'; '20 to 22 – acceptable'; '22 to 24 – between acceptable and discomfort'; '24 to 28 – discomfort'; 'over 28 – intolerable'. The British Standard Institution (2017) stated that a DGI of 22 should be set as the threshold for activating of shading device. Although the DGI is commonly referred to in many standards and guidebooks, however, the measurement of glare is extremely complicated (Wolaks and Sawicki, 2020). In reference to Eq. (1)., it can find that many instruments and precious location setting up are needed. And it makes using these complicated setups in field measurement is infeasible. With the advancement of digital cameras in the late 80s, Rea and Jeffrey (1990) suggest using digital devices to conduct fast and practical measurements in assessing the indoor visual environment.

In this study, two cameras as described in 2.1.1 were used to analyze the indoor visual environment. Both cameras were calibrated according to Wolska and Sawiociki (2020). The aperture and shooting mode of these cameras were set to f/14 and aperture priority. The auto exposure bracketing was set to ±2 EV. A total of 5 pictures were captured for each set of measurements and these pictures were combined into HDR images with Photoshop. Glare sources were identified by the "evalglare" program in RADIANCE. Finally, the information was passed to the Aftab Glare Analysis program to calculate the DGI.

2.3 Machine learning training approach

The measurements were conducted from December 2024 to Feb 2025 and 7-day measurements were conducted. However, the winter of Hong Kong is dominated by clear skies and nearly clear skies which makes the current study can only cover a few sky conditions and low solar altitude situation. After applying quality control to the weather and indoor measurement data (Li et al., 2008), there were about 100 sets of valid data for this analysis.

2.3.1. Modelling with outdoor illuminance data and relative solar position by random forest

Over the years, machine learning (ML) models have gained traction as a preferred approach for daylight prediction due to their high accuracy when compared to conventional regression models (Ayoub, 2019). In particular, ensemble models which combine several ML models to build a single and more powerful model than its original constituents have been widely explored (Mohammed and Kora, 2023). Compared with the traditional decision tree process, random forest (RF) can build the decision tree on a random sample of data and provide an average result. RF is a tree ensemble that grows several decision trees for reducing the variance and bias of a model which was used in this study. Ensemble models are known for their efficiency and ability to prevent overfitting (Khan et al., 2024). Previous studies have shown that RF has a strong learning ability, and the model is robust enough to handle regression problems (Ao et al., 2019). Due to the nature of RF, it is still one of the most commonly used machine learning methods in study fields related to climate and weather (Rozante et al., 2023; Wen et al., 2024).

Four (4) RF models for the DGI and indoor vertical illuminance were proposed. The model inputs were vertical illuminance at the window, horizontal illuminance on the roof, solar altitude, relative solar azimuth, and scattering angle. Each RF model predicts the middle and rear DGI and indoor vertical illuminance, respectively. For model development, the split data were separately scaled

using the min-max method to prevent data leakage. Then a splitting ratio of 80 to 20% dividing the data into training and testing datasets. Also, the Grid search method was used to optimize the model. Finally, the model was assessed using correlation of determination (R^2), and % root mean square error (%RMSE).

2.3.2. Modelling with outdoor illuminance data, relative solar position and outdoor images by convolutional neural networks

Computer vision is one of the research directions of deep learning and it can be used for image processing tasks, like image classification, image segmentation, and object detection (Lecun et al., 2015). For daylight predictions, reference planes are evenly divided into grids thereby becoming an array of data. Such divisions are like an image structure composed of pixels, making it possible to apply such models in daylighting analysis (He et al., 2021). Specifically, convolutional neural networks (CNN) have enhanced research in computer vision. CNN can make mostly correct assumptions about image data, and it requires fewer connections and parameters than traditional neural networks (Krizhevsky et al., 2012). Moreso, they can extract features from geometries and construct non-linear models to predict the required daylight performance metrics (He et al., 2021). Therefore, in this study, CNN was adopted to handle the image data of the daylighting from the sky and through the window. Two CNN models were proposed for the mid (Position 2) and rear (Position 1) DGI. The structure of both models was the same with the major difference being in the output file. For a model, the structure consists of numerical inputs made up of the outdoor vertical and horizontal illuminance, solar altitude, relative solar azimuth, and scattering angle. While the image inputs were daylight illuminance from the roof and the window captured by the fisheye camera lens. All numerical data were scaled using the Min-Max method while the images were rescaled to 32 by 32 pixels before normalizing between 0 to 1. The image input layer accepts inputs with a shape of 32, 32, and 6 which represent the pixel height, width and channels, respectively. Also, the CNN had three convolutional layers and a RELU activation function was used. The size of the filters for the three convolutional layers were 32, 64 and 64, respectively. Furthermore, a 64-neuron dense layer was used together with a RELU activation function and cross-validation of the data was also conducted to prevent overfitting. Importantly, the model was split into training and testing datasets using a ratio 80 to 20% and Adam optimizer was used to optimize the process. Unfortunately, this method seems not able to reproduce the data for indoor vertical illuminance values, further works are required in coming studies.

3. ANALYSIS AND DISCUSSION

The training and testing results for the ML including the RF and CNN modeling are presented in Table 2. The result is generally considered as good in terms of field measurement data. In general, it is very interesting that the use of RF approach which without any image as input provides a better result than the CNN approach. Only under the mid of the room, the use of CNN slightly outperforms the RF approach. One of the reasons is that RF using multi-model structure seems more appropriate in selecting different set of equations in determining the DGI values. Unfortunately, normal RF approach cannot use images as input directly, hence adding additional input parameters seems cannot improve or maintain the same accuracy. Another reason may be the pictures were taken in auto exposure mode. This approach is acceptable in predicting glare as glare is a sensation of relative luminance. However, for acting as input features in ANN, undefined relative values might often misleading. Furthermore, during the resizing pre-process, the resized pictures were suffered from a lost in picture's Exif data. Hence, the use of sky image not only

could not provide additional weather information, but more noises for modeling training was introduced.

Table 2. Performance of random forest model in predicting indoor DGI and illuminance level

		RF				CNN			
		Training set		Testing set		Training set		Testing set	
		r^2	%RMSE	r^2	%RMSE	r^2	%RMSE	r^2	%RMSE
Position 1 (Rear of the room)	DGI	0.905	12.09%	0.887	6.28%	0.020	24.81%	0.095	29.43%
	Vertical illuminance	0.951	20.22%	0.873	15.10%				
Position 2 (Middle of the room)	DGI	0.848	6.18%	0.259	12.19%	0.104	12.68%	0.033	11.20%
	Vertical illuminance	0.991	6.36%	0.644	36.87%				

Comparing the DGI and illuminance data, the ability of RF in predicting the DGI is far better than the illuminance values. It may due to the order of magnitude for DGI is smaller than that of the vertical illuminance. Hence smaller errors were recorded for DGI compared with illuminance values. While the RF model performs better in the rear part of the room (Position 1) than the middle of the room (Position 2). A plausible explanation is that the view of exterior environment from the rear part of room is smaller than that of the middle of the room then the variations of DGI and illuminance values in the rear part is larger. For example, the DGI in Position 1 is ranged from 1.23 to 25.52 while the range is 15.47 to 31.52 for Position 2.

3. CONCLUSIONS AND FUTURE WORKS

In this study, a field study is conducted to study the feasibility of estimating the indoor glare and interior illuminance by climatic parameters. It is found that using the random forest can estimate the indoor DGI and vertical illuminance based on real-time weather data and basic solar geometrical relationship. Additional feasibility study on employing sky and obstruction images were carried out. CNN, a commonly used tools for pattern recognition was employed. Unfortunately, basic CNN models cannot further improve the accuracy of the ANN model and sometimes, it introduces noises in model training. With this technique, it is expected that the use of ML (especially RF) can fulfill the gap that ASD controller cannot have any feedback when the shading devices is lower down.

This work is an improvement work for the ASD controlling system. Even the performance of using CNN in predicting DGI or indoor illuminance seems not promising, however, there are still some improvements work can be done by using multi-modality model. Works such as appropriate number of pixels in the image, changing the angle of view in fisheye view image, including Exif information as input to better represent the daylight climate. Apart from imaging aspect, indoor glare index is highly affected by indoor environment. Both natural and artificial lights are presented inside normal occupied space. It makes the prediction of glare is harder. Needless to say, the difficulty will be increase if the DLLC controller is incorporated. To have a completed picture,

more scale-model & field measurements and simulation works are required.

ACKNOWLEDGEMENTS

Work described was fully supported by a Faculty Development Scheme from the Research Grant Council of HKSAR [Project no. UGC/FDS16/E07/23] and Research Matching Grant Scheme from the Research Grant Council of HKSAR [Ref. no. 2021/3006]. The authors would also like to express their thanks to student helpers, Mr. Chris K.S. IM, Mr. Philip P.F. KONG, Phelim C.Y. LAI and Mr. Jackson W.Y. WONG for conducting field measurement. The authors would like to thank the late Prof Danny Li who was Co-I of one of the research projects and giving valuable advice to the authors.

SUMMARY
Despite existing energy efficiency measures, the building sector is responsible for around 30-40% of global energy demand. Sensors can help to improve energy efficiency. However, their use involves additional energy consumption, complex hardware installations and therefore critical installation and operating costs, all of which become more important as additional or higher resolution information is collected. Implicit sensing methods, like Bluetooth detection or computer activity, can provide occupancy data without the use of dedicated sensors. To demonstrate the benefits of implicit sensing in terms of energy efficiency, reliability and accuracy, a technical-functional system evaluation was conducted with 60 participants as part of a structured laboratory study. The results of the study show that a passive approach can provide sufficiently accurate information to maintain overall control reliability without the need to install additional sensors. The detection methods were evaluated for user acceptance via a questionnaire.

Keywords: Sensor technology, occupancy detection, implicit detection, user acceptance.

1. INTRODUCTION

To achieve the current energy policy goals, it is essential not only to transition to renewable energy sources but also to improve the energy efficiency of existing consumers (Byun et al., 2013). In the building sector, particularly regarding artificial lighting, there is significant potential as 20% to 45% of electrical energy consumption in commercial buildings are due to lighting (Madias et al., 2016). In addition, reducing lighting energy consumption can also reduce internal heat gains, which in turn reduces a building's cooling load (Ryckaert et al., 2010). This indirect effect means that lighting energy savings contribute to overall energy efficiency and climate targets not only directly, but also indirectly. There is also great potential for heating, ventilation and air conditioning (HVAC) to contribute to climate goals by improving the energy efficiency of these technical systems. In commercial buildings, controls and sensors are primarily used to achieve energy savings in lighting and HVAC. One possibility is to use illuminance sensors to regulate artificial light depending on the availability of daylight. A central approach is the occupancy-based control of lighting and HVAC systems, which only activates devices when the room is actually being used. Compared to manual controls, occupancy-based solutions achieve on average around 30% higher energy savings for lighting, regardless of building type and application scenario (Galasiu et al., 2007). The combination of daylight and occupancy controls reduces running costs while maintaining comfort and supporting sustainability.

Information about real occupancy patterns at the workplace can also be used for further energy efficiency measures, such as deriving optimised user distributions in offices with zoned lighting concepts (Hammes et al., 2022), or as a basis for evaluating the comfort and health of occupants. In order to take user-related influences on energy performance into account and to meet user-related comfort requirements in the best possible way, a high resolution of occupancy data at the workplace proves to be essential (Hammes et al., 2024). Occupancy data is therefore considered to be one of the key variables for the success of set control strategies. The role of occupancy detection for lighting controls and for controls of other building actuators was already investigated in multiple reviews (Salimi and Hammad, 2019; Shen et al., 2017).

Occupancy control is usually based on passive infrared sensors (PIR), as the hardware costs are low and implementation is simple. The disadvantage is the need for a direct line of sight (Guo et al., 2010). CO_2 sensors offer the possibility of deducing the number of occupants in a room in addition to receiving binary information. However, there is a certain inertia associated with CO_2 sensors, which prevents real-time detection capability, as well as interference from unmonitored ventilation (Salman et al., 2024). Camera systems offer high resolution, but associated applications for occupancy detection are computationally intensive, usually lead to low acceptance in terms of data protection and require a direct line of sight (Salimi and Hammad, 2019; Salman et al., 2024).

Ultimately, occupancy detection in these approaches is always linked to the use of dedicated sensors, which usually have permanent energy consumption. Standby times rarely exist. Therefore, it should be checked first whether net energy savings during operation justify the use of additional hardware and the associated grey energy. The energy consumption of sensor-based lighting control systems can outweigh the energy savings, especially in individual offices with high user absence (Gentile et al., 2014). In addition, these sensors are associated with other costs and require maintenance (Salman et al., 2024). The alternative use of wireless sensor networks and energy harvesters shows great potential for energy-efficient operation (Hidalgo-Leon et al., 2022).

Implicit detection methods are another promising solution. Existing hardware is used to derive occupancy information. This includes timestamp clocks as well as computer activities (e.g., via keyboard and mouse tracking) and network activities (e.g., WiFi and Bluetooth-based detection of mobile devices). A conceptual approach to live-position detection of Bluetooth Low Energy (BLE) devices is offered by (Daniş et al., 2023). The framework is based on a hidden Markov model that uses Received Signal Strength Indicator (RSSI) data and heuristically modelled movements to determine positions from sequential RSSI measurements using probabilistic filtering. A hybrid approach to locating building occupants using WiFi and BLE networks is provided by Chen et al. (2019). The system integrates a conventional k-nearest neighbour positioning algorithm with a stochastic random walk algorithm to derive high-resolution occupancy data. The challenges of implicit detection methods are efficient algorithms, data semantics, interoperability, privacy, and reliability in wireless communication (Shen et al., 2017).

The use of implicit recording methods theoretically offers the possibility of recording additional application-relevant information without the use of dedicated sensors or direct user input, e.g., testing of health-effective light doses. It has also been shown that interaction speeds with the mouse and keyboard can provide information on fatigue (Natnithikarat et al., 2019). The objective of the study is to investigate whether implicit detection methods can provide a practical, reliable and

accepted alternative to conventional sensor-based occupancy detection. The use of implicit occupancy detection methods was therefore evaluated as part of a structured laboratory study.

2. METHODOLOGY

2.1. Study Design

For the structured laboratory study, an approximately 30 m² corner office at the University of Innsbruck was set up so that 4 people could carry out typical office activities at the same time (Fig 1a). The study stations were located in the corner of each side of the table. The personal computers (PC) in the center of each desk, shown in Fig. 1a, were used exclusively for monitoring and conducting the study and were not occupied by study personnel during the testing phase.

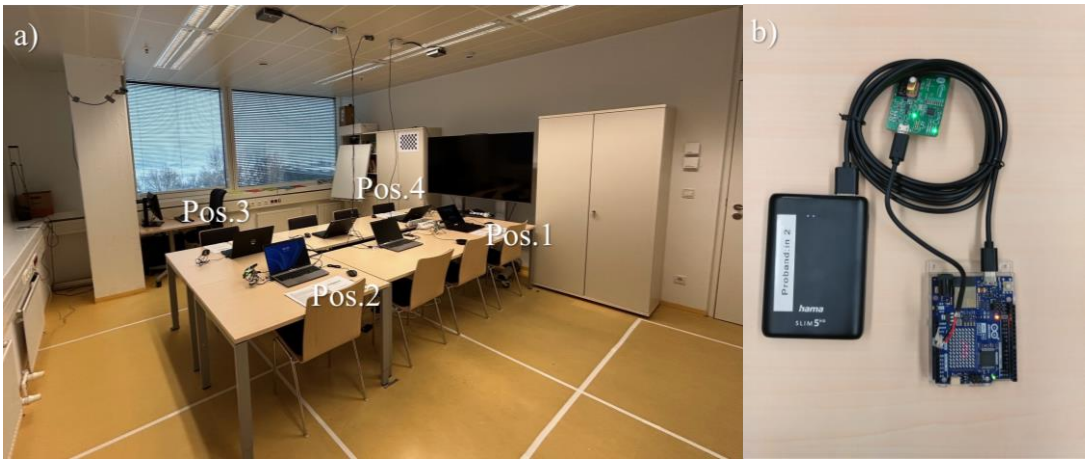

Figure 1. a) Display of the study site, occupied by a maximum of 4 participants at the same time. b) A Bluetooth device that the study participants carried in their pockets, which tracked their movements.

Four different tasks were defined to simulate typical office work: Task A required participants to type a given text, simulating screen and desk work. In Task B, participants had to watch a video that simulated passive PC work, such as online meetings. Task C required participants to sort sheets of paper. This required directional movement around the room. Task D simulated absence. This required the participants to leave the room. The order of the tasks was randomly assigned to each participant to reflect all possible task combinations. Each person completed a total of 16 tasks, lasting 3 minutes each. All tasks occur equally frequently. There was a 10-second transition period between tasks to prepare for the next one. Task changes were automatically indicated by an acoustic signal and automatically recorded. The controlled study setting represents the ground truth for evaluating the accuracy of implicit recording methods.

To avoid distortions due to individual behaviour and to ensure the reliability and validity of the data, the group size was chosen accordingly to ensure a representative sample (Rosenthal and Rosnow, 2008). 60 people took part in the present study (40 female, 20 male). Of these, 44 were students, 13 had a professional focus on office work and 3 had no focus on office work. A total of 17 sessions took place (12 sessions with 4 people and 5 sessions with 2-3 people). The study was conducted from 29 November 2024 to 6 December 2024.

A Python-based desktop app that mimics a time clock was installed on the study laptops at the

workstations. A graphical user interface made it possible to choose between ‘Come’ and ‘Leave’ with a button click (required for Task D). In addition, a self-written Python script was used to implement mouse and keyboard tracking (Python 3.12). The primary libraries used were pynput (version 1.7.7) and requests (version 2.32.3). All measurement data collected during the measurement campaign was saved including a timestamp in an InfluxDB. BLE devices were taken out of the room by the study participants when performing Task D (Fig. 1b) to track movement. The RSSI of the known device addresses was collected using a Python script (Python version 3.10.12, Bleak library version 0.22.3) and was also stored with a timestamp in another InfluxDB. RSSI-based passive detection uses the received signal strength of BLE devices as an indicator for occupancy detection. The RSSI decreases with distance in this case from the operating laptop in the middle of the workplaces. Limits for RSSI with devices in the room are in the range of less than -80dBm. RSSIs correspond to an integer measurement of a received radio signal that follows the IEEE 802.11 standard (Chen et al., 2019). All measurements were carried out with high resolution in time steps of a few seconds. This resolution is also the basis for the analysis.

The implicit methods were evaluated in terms of accuracy and reliability. Accuracy represents the percentage of correctly identified presences and absences in relation to the task-specific ground truth (presence at the workplace for tasks A and B; absence for tasks C and D). The 50% split in the ground truth for accuracy is to avoid favouring any sensor technology. Reliability reflects the consistency of occupancy detection for a technology within a specific task.

2.2. User Acceptance and Ethics

The participants also completed a questionnaire (Limesurvey, version 3.22.4+200212), in which they rated the acceptance of various occupancy detection technologies. Selected results on implicit detection methods from the questionnaire are presented in this study. There are 53 complete responses to the questionnaire. On average, participants took 5:52 minutes to complete the questionnaire. In the case of Likert-type questions, care was taken to ensure a symmetrical distribution of complementary characteristics. To avoid bias in the answers due to their predetermined order, the order of the answers was randomized for ranking questions and closed questions with a fixed choice option. Participants were usually given the option of selecting 'not assessable' to avoid biased responses.

All participants took part in the study voluntarily. The study participants were informed in advance about the purpose of the study and were free to leave the study at any time. None of the study participants chose this option. All participants signed an informed consent before participation and were compensated with €30 for full participation in the study. All aspects of data protection were considered when conducting the study.

3. RESULTS

3.1. Accuracy and Reliability

Compared to ground truth, occupancy detection at the workplace via RSSI measurement has an overall accuracy of (52.91±6.64) % across all tasks and users. The virtual time clock (desktop app) achieves (64.85±2.17) %, the mouse and keyboard tracking (63.28±3.58) % accuracy. In combination via logical-or linking with the desktop app, BLE tracking can achieve (52.16±3.32) % accuracy and BLE tracking with mouse & keyboard tracking (52.96±4.01) %. The PC-related

applications can achieve (58.31±1.76) % in combination. All three variants together in logical-or linkage achieve an accuracy of (52.17±3.04) %. Fig. 2a shows the accuracies depending on the task. The reliability of the occupancy detection is shown in Fig. 2b. The consistency of the values obtained is always high (Fig. 2b), regardless of whether the value is correct or not (Fig. 2a).

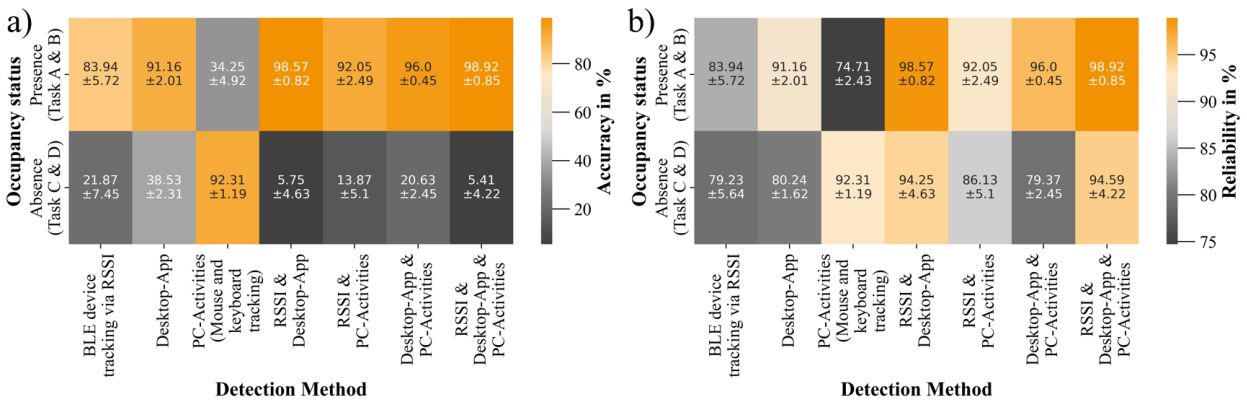

Figure 2. a) Accuracy of occupancy detection at the workplace and b) reliability of occupancy detection of the implicit detection methods as a function of the tasks (Task A: active PC work, Task B: passive PC work, Task C: movement in the room, Task D: leaving the room).

While deviations between the study participants are balanced out by the sample size (Rosenthal and Rosnow, 2008), slight deviations can in principle occur in the BLE device detection with regard to the position, even though the receiver PC was positioned as centrally as possible. This results in an accuracy (total of absence and presence) of 62.40% for BLE device detection at position 1, 51.46% at position 2, 49.10% at position 3 and 48.51% at position 4 (see positions in Fig. 1a). There were no position-dependent influences for the other recording methods.

False negatives, i.e., incorrectly recognised absences, are the biggest obstacle to a satisfactory technology implementation, as they can have a disruptive effect on the user experience. Tab. 1 therefore shows the proportion of correct detections, false absences and incorrect attendances across all users and tasks in relation to attendance at the workplace (attendance Task A & B and absence Task C & D). While the study participants always took the BLE devices with them during Task D, there was a frequent operating error with the virtual time clock via the desktop app. It could be observed that leaving and returning to the work space was not indicated properly 22 times and 13 times, respectively.

Table 1. Identified false absences and false presences at the workplace in relation to the ground truth.

Detection method	Correct detection	False absence	False presence
BLE device tracking (via RSSI)	52.91%	8.03%	39.06%
Desktop-App	64.85%	4.42%	30.73%
Mouse & keyboard tracking	63.28%	32.87%	3.85%

3.2 Questionnaire

The recording of workplace-centred information proves to be valuable in ensuring that the technical building systems are controlled as energy-efficiently as possible and that user-related comfort requirements are implemented in the best possible way (Hammes et al., 2022, 2024). Collecting workplace-centred information via wall and ceiling mounting can prove to be complex

or involve the use of technologies that meet with low acceptance, such as cameras (Salimi and Hammad, 2019). In the questionnaire, most people also find the use of cameras indoors unacceptable (Fig. 3). It can be seen that visible sensors positioned close to the workplace meet with a low level of acceptance compared to wall and ceiling mounting (Fig. 4). Implicit sensors, as non-physically dedicated recording devices, can be excluded from this category as they are primarily background processes in existing IT infrastructure. The time clock as a desktop app shows a comparatively high level of acceptance compared to other sensor types (Fig. 3). Mouse and keyboard tracking is viewed rather critically, although 32% of participants had no knowledge of implicit detection methods and 45% had heard of them but knew no details. Only 23% were aware of this technology.

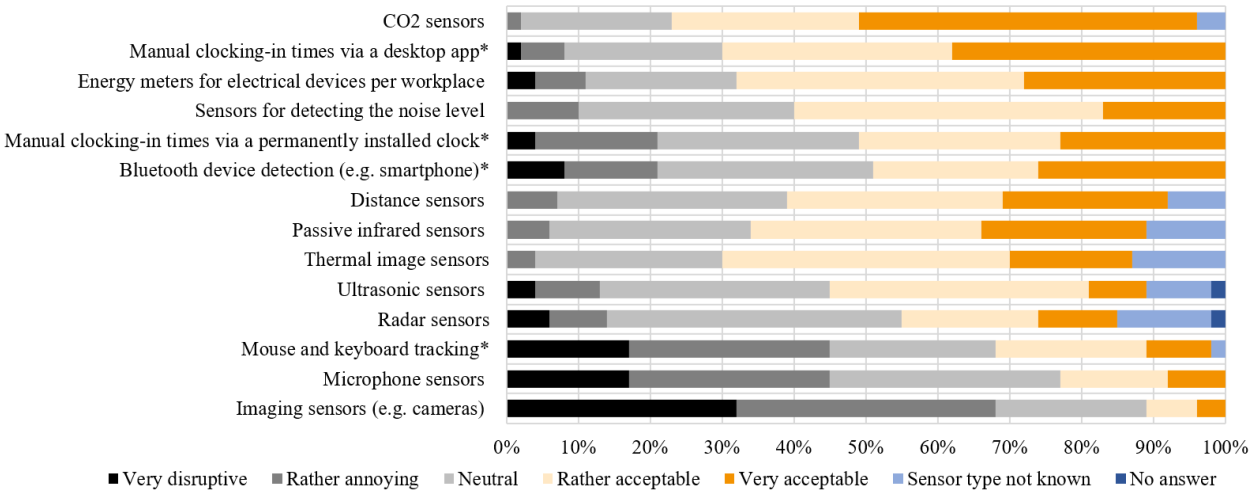

Figure 3. Feedback from study participants on the question of how acceptable they find the use of individual sensor technologies in indoor spaces (Question type: 5-point Likert scale). The implicit recording methods relevant to the study are marked with *.

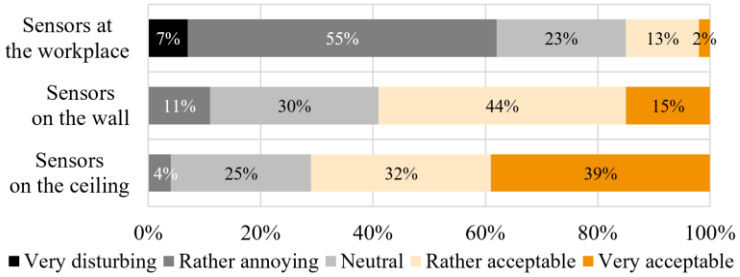

Figure 4. Feedback from participants on the question of how they rate visible sensors in indoor spaces (Question type: 5-point Likert scale).

4. DISCUSSION

4.1 Reflection and implication of the results

The results show that BLE device tracking via RSSI delivers the lowest accuracy. With Bluetooth device detection, reflections, refraction and scattering in particular can strongly influence the signal strength. Room size, building materials and interior of the building and the presence of obstacles, such as uncontrolled extraneous movements, can have a detrimental effect on detection

accuracy (Salman et al., 2024). Applying device detection in practice can be difficult because people use multiple Bluetooth devices, Bluetooth is often turned off, or the occupant does not have a device with them. An approach that takes advantage of both Bluetooth and Wi-Fi networks could maximise positioning accuracy. Determining a suitable Bluetooth signal strength threshold to infer presence poses a significant challenge. Complex and dynamic characteristics compromise the use of a fixed threshold, such as the study setting with numerous obstacles and high dynamics due to the study design. Salman et al., (2024) present a self-adaptive system based on WiFi for occupancy monitoring and thus without the use of dedicated sensors. In particular, it is based on a data mining algorithm for cluster analysis (DBSCAN algorithm) to ensure self-adaptation of the control limit threshold for dynamic environments. Based on the increase in WiFi-based infrastructure, such approaches to occupancy detection are gaining in importance.

BLE detection and the desktop app display the comparable data, so the combination has the same uncertainties. Mouse and keyboard tracking shows high accuracy in absence detection at workstation level and the desktop app in terms of presence detection. The desktop app is also rated with high acceptance (Fig. 3). By combining these implicit methods, accuracy and reliability can be significantly improved overall (Fig. 2). While they were logically OR-linked in this study, future research should investigate whether a rule-based linking of the technologies could further improve reliability. This is because the recorded interactions with the desktop application and the mouse and keyboard tracking provide reliable evidence of presence at the time of interaction compared to many other technologies. This creates an accurate ground truth, whereas many comparable sensors generally operate with the risk of false absences and presences. It should be noted that no interaction with the PC does not provide verified absence. The media used for implicit data collection also has the great advantage of already being present and being able to communicate due to another primary reason for use (Shen et al., 2017), which saves energy and costs as no dedicated sensors are required. The results from Fig. 2a show improvements in accuracy by combining the methods with regard to presence detection and this with high reliability Fig. 2b. Although the accuracy of absence detection is consistent across all methods and combinations, with the exception of mouse and keyboard tracking, it does not sufficiently represent the correct target value, which is evident from the high reliability.

4.2 Limitations

The study setting is limited to office applications. Further investigations are necessary to validate the data for other applications. The signal-based processing of work tasks was used as ground truth. Even if the degree of error was reduced by transition times, the tasks are not necessarily carried out at the exact times. This can lead to unwanted pauses, particularly in Task A, the PC work. A remedy could be a switch-off time, analogous to PIR sensor technology (Guo et al., 2010), which reduces false-off rates during mouse and keyboard tracking, e.g., according to the methodology of Hammes et al., (2021), in order to derive the cumulative probability of the minimum absence duration from periods of inactivity.

Although multiple Bluetooth receivers can be used to locate the position in the room, this study is limited to recording the Boolean presence status at the workstation in order to maintain comparability between the different recording methods. While limited accuracy was achieved using RSSI in the given study setting, its use in other scenarios, such as larger rooms with fewer obstacles, should be tested.

5. CONCLUSION

Implicit occupancy detection offers the potential for acceptable accuracy, lower costs and lower energy consumption compared to conventional explicit concepts. A combination of several implicit detection methods may prove beneficial to capture presences for the control system. The results of the study show that while attendances are correctly captured with high consistency, absences do not achieve sufficient accuracy. Direct processing of the information in compliance with data protection regulations is considered a suitable option. Implicit occupancy detection is used not only to optimise artificial lighting, but also to control HVAC systems.

2. Department of Respiratory Medicine, St. James's Hospital, Leeds, UK.

SUMMARY

The contribution of airborne microorganisms to surface bioburden in indoor environments is an important factor in infection control and hygiene. This study conducted air and surface microbiological sampling in a 4-bed naturally ventilated respiratory ward to measure total aerobic colony count (ACC) and to identify the present of *Staphylococcus spp*. Results show a positive strong significant relationship between airborne ACC and *Staphylococcus spp* r=70 (0.60-.078), p=<0.001, n=120. A linear regression equation to describe surface microbial load ($cfu.cm^{-2}.h^{-1}$) based on the airborne microbial load ($cfu.m^{-3}$) showed the contribution of the airborne microorganisms to the total surface load was 65% ± 18 after cleaning. This study provides valuable insights into the relationship between airborne microorganisms and surface contamination, with implications for improving hygiene practices in hospitals.

Keywords: Airborne Microorganisms, Surface Bioburden, Hospital Infection Control, Ventilation and Microbial Load Deposition.

1 INTRODUCTION

Airborne microorganisms are removed through ventilation or deposition onto surfaces, and the number of deposited microorganisms over a period of time correlates to the number of airborne microorganisms. A qualitative link between air and surface microbes has been shown as a percentage of positive sampling. More recently, researchers found a tenuous quantitative correlation of *P.aeruginosa* and total fungal load in the air and on surfaces (Bonnal 2015). However, a study on the total fungal flora and *Aspergillus spp* shows no significant correlation between airborne fungal and surface fungal (Gheith 2015). The quantitative relationship between microorganisms measured through active and passive sampling is still unclear and needs to be supported with empirical evidence. Despite the number of studies that have sampled the hospital environment, there have been few attempts to evaluate any relationships between microorganisms in the air and on surfaces. This study measures the transient relationships between air and surface bioburden in a hospital ward to: (i) to investigate the quantitative relationships between both airborne aerobic colony count (ACC) and *Staphylococcus spp*, hospital environment; (ii) to provide a mathematical model that relates airborne microorganisms' concentration and surface load; and (iii) to quantify the contribution of airborne microorganism load on the surface load in the healthcare environment.

2 METHODOLOGY

The study was performed in a 4-bed adult respiratory ward in a hospital in Leeds (in England) during February (17th and 21st) and March (3rd and 10th) 2020, from 8:00 am to 4:00 pm. The ward is naturally ventilated, bed occupancy ranges from 75 – 100%, each patient is nursed on a 1:1 basis. Domestic and near-patient sites are cleaned once daily around 12:00 midday.

Active air sampling was performed using a single-stage impactor Microbio MB2 bioaerosol sampler (Fred Parrett, UK) at an airflow of 100 l/min and placed between beds at 1.5 m height. Air was sampled onto Tryptone Soya Agar plate (TSA) (Oxoid, UK) to determine an Aerobic Colony Count (ACC) and onto Mannitol Salt Agar plate (MSA) (Oxoid, UK) for *Staphylococcus spp* for 5 minutes every 15 minutes. For passive air sampling, two TSA and two MSA agar settle plates (90 mm) were placed on a 1 m high trolley that is 0.75 m away from the active sampler and at the center between the four beds. Passive sampling was performed every 30 minutes for ACC and every 1 hour for *Staphylococcus spp*, for the first day and then every 30 minutes for the rest of three study days. ACC and *Staphylococcus* spp were the most interesting target for researchers as it is related to the standard hygiene recommendations (Dancer 2004). Surface screening was performed using 55 mm contact plates at five high hand-touch surfaces (bedside cabinet, overbed table, patient's note, right side bed rail and left side bed rail). Screening was carried out in the morning (9:00) and in the evening (16:00) to allow comparison with previous work (Dancer 2004).

Pearson's correlation assessed the relationship between airborne ACC and Staphylococcus spp., reporting r and 95% CI for precision. Significance was set at $p<0.05$, with $p<0.001$ highly significant. Analyses were conducted in R 4.4.2. To quantify the contribution of airborne microorganism load on the surface load, we compared the accumulated deposited load on petri dishes (12pm-4pm) with the surface evening screening using contact plates (at 4pm). The loss rate of airborne microorganisms due to deposition onto floor surfaces ($\lambda_{d.f}$) can be calculated according to equation.

$$\lambda_{d.f} = \frac{C_{sf}\, A_f}{C\, V} \qquad 1$$

Where C_{sf} is the deposited microorganisms' concentration on the floor ($cfu.m^{-2}.h^{-1}$). A_f is the surface area of the floor (m^2). and V is the volume of the room (m^3). Most standard hospital wards are rectangular rooms with uniform height so A_f/V is equal to 1/H, where H is the height of the room.

3 RESULTS

Figure 1 shows time-series data for active and passive samples over the 4 days. Across all samples the average concentration of airborne ACC and *Staphylococcus spp*. were 196 ± 103 and 158±86 cfu.m^{-3}, respectively, and there is a positive strong significant relationship between airborne ACC and *Staphylococcus Spp* r=70 (0.60-.078), p=<0.001, n=120. The average concentration of airborne deposited microbial concentration measured as ACC and *Staphylococcus spp*. were 18±10 (cfu. Plate^{-1} .h^{-1}) and 8±6 (cfu. Plate^{-1}.h^{-1}) respectively. The mean of $\lambda_{d,f}$ calculated from the sample data is 3.38 (h^{-1}) and 1.97 (h^{-1}) for ACC and *Staphylococcus spp.*, respectively **(Figure 2).**

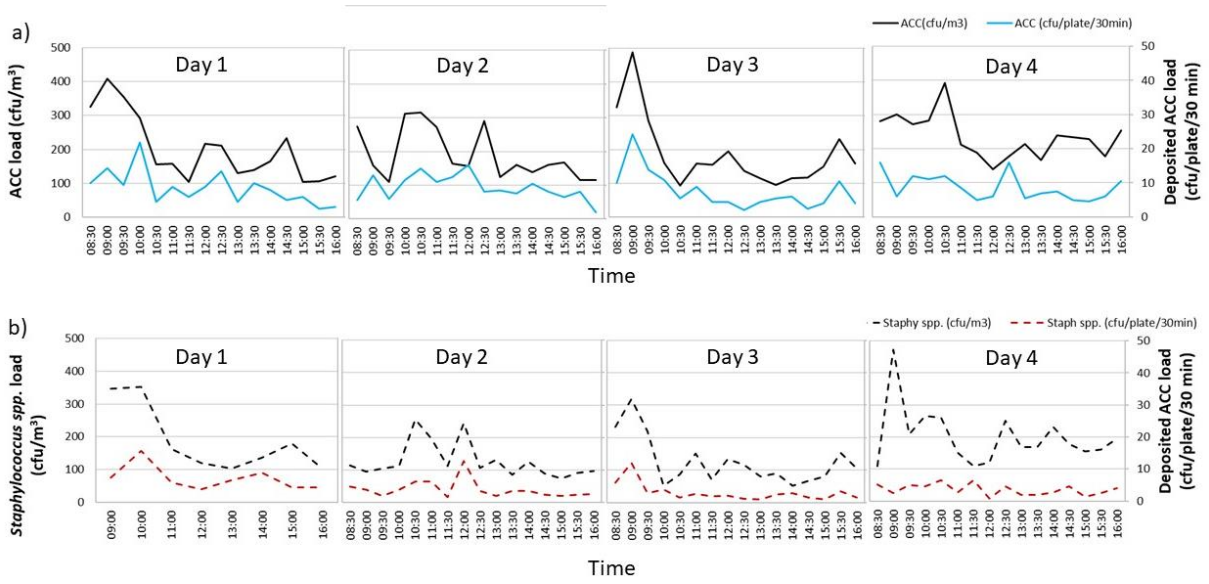

Figure 1: Active and passive air sampling results for four days on the time series a) microbial concentration measured as ACC and b) *Staphylococcus spp.* load.

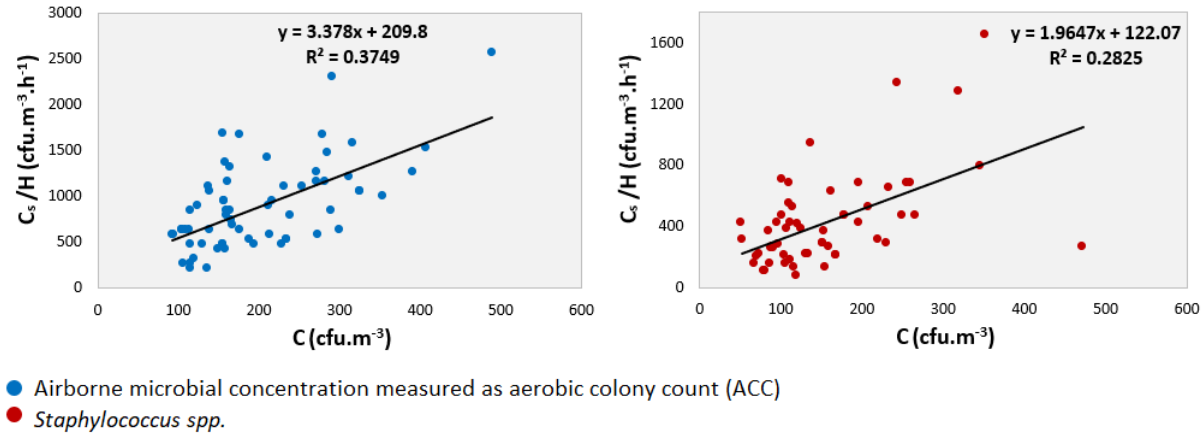

Figure 2: The scatter plot of the concentration of microorganisms on Petri dishes divided by the room height against the mean indoor airborne microorganism's concentration $\lambda_{d,f}$.

The contribution of the airborne microorganism load to the total surface load was calculated based on the passive samples and the surface screening data to be 65% ± 18% (range 39% - 82%) for the first four hours after cleaning (**Table 1**).

4- DISCUSSION AND CONCLUSIONS

This research establishes a quantitative evaluation of airborne microorganisms that influence surface contamination in healthcare facilities with natural ventilation. Airborne microorganisms maintained a strong positive relationship to surface contamination. A high percentage of surface contamination (65% ± 18%) comes from deposited airborne microorganisms. The average concentration of airborne deposited microbial concentration measured as ACC and *Staphylococcus spp*. were 18±10 (cfu. Plate^{-1} .h^{-1}) and 8±6 (cfu. Plate^{-1}.h^{-1}) respectively.

Table 1: The contribution of airborne ACC on surface contamination in a four-bed ward for 4 hours (12 pm - 4 pm).

	Day 1	Day 2	Day 3	Day 4	Average
	mean ± SD (Min-Max), sample size				
Surface ($cfu/cm^2/4h$)	1.49 ± 1.04 (0 - 4.08), n=20	0.83 ± 1.05 (0 - 3.62), n=20	1.58 ± 1.19 (0.25 - 4.46), n=20	0.99 ± 0.94 (0.25 -2.99), n=16	1.36 ± 1.07 (0 - 4.46), n=75
Petri dishes ($cfu/cm^2/4h$)	0.83	0.93	0.62	0.98	0.7
Contribution	56%	82%	39%	82%	65% ± 18% (39% - 82%)

Different microorganism deposition rates existed probably because the particles showed various sizes and airborne characteristics. ACC tends to deposit faster because of its wider microbial content and larger particle groups. The rates at which microorganisms deposit change based on ventilation conditions as well as ward occupancy. A limitation is that the study lacks time-series data on the transient relationship between airborne and surface microbial load, with considerations to the presence and activity level of patients and healthcare workers. Overall, the study demonstrates the potential to develop quantitative correlations between air and surface microorganisms which support the approach for using surface screening as a broader hygiene marker (Smith, et al. 2018). Future research should include monitoring tools or interval time series monitoring such as AMPAS (automatic multiplate passive air sampler, (Hiwar, et al. 2022) to maintain continuous microbial measurement capabilities. Improved time-sensitive monitoring of microorganisms in healthcare environments is likely to be important for better infection prevention systems (Smith, et al. 2018).

SUMMARY
Understanding the emission and persistence of aerosols in enclosed spaces is critical for mitigating airborne transmission of pathogens. In this controlled chamber experiment (volume = 12 m³), six graduate students (three males, three females) performed four 20-minute tasks: natural breathing and reading aloud, each with and without a surgical mask. Aerosol concentrations (ranging from 0.25–33 µm) were recorded every 6 seconds using a GRIMM 11D spectrometer placed 1 m from the participant. Data were segmented into 3.4-minute intervals and analysed using weighted least squares regression and a mixed-effects model at the 5% significance level. Results indicate that speaking increases aerosol emissions by 26% compared to breathing ($p < 0.001$) and that mask usage reduces emissions by 63% ($p < 0.001$). Moreover, male participants produced 38% more aerosols than females, though this difference was not significant ($p = 0.079$). These findings underscore the importance of integrated mitigation strategies to manage indoor air quality and reduce transmission risks effectively.

Keywords: Airborne Transmission, Respiratory Aerosols, COVID-19

1. INTRODUCTION

Respiratory aerosols, generated through breathing, speaking, and coughing, stay suspended in the air for longer periods compared to larger droplets, which fall quickly due to gravity. This makes them particularly important when considering airborne disease transmission. Studies have confirmed that viruses such as SARS-CoV-2 can spread through aerosols, remaining in the air for extended durations and traveling significant distances, increasing the likelihood of inhalation and infection (Chia et al., 2020; Green et al., 2023). Accurately quantifying individual aerosol emissions in enclosed spaces remains a significant challenge, as the total aerosol level depends on multiple factors, including individual variation in emissions, room ventilation, and particle interaction with the surrounding air (Nicas et al., 2005; Zhang & Bluyssen, 2022).

Most current methods measure exhaled aerosols at the source, typically just a few centimetres from the mouth. While this provides useful data on particle size and concentration, it does not account for the behaviour of aerosols after exhalation. Once released, these particles undergo evaporation, mix with ambient air, and interact with airflow patterns, all of which influence their airborne lifetime and spatial distribution (Asadi et al., 2020; Morawska & Cao, 2020). Consequently, direct measurement of aerosol persistence and accumulation in indoor spaces is necessary for a more accurate estimation of exposure risk (Chia et al., 2020).

This study focuses on respiratory aerosols in a controlled environment, specifically examining the effects of mask usage, gender, and speaking. Instead of just measuring exhaled particles near the source, it considers how aerosols accumulate and persist in the air over time. This approach allows for a better assessment of how much each individual contributes to the overall aerosol concentration and provides insight into effective airborne disease mitigation strategies. Additionally, recent research highlights that individual differences in aerosol production can be substantial. Some individuals, referred to as "superemitters" consistently release orders of magnitude more particles than others during the same expiratory activities (Asadi et al., 2020; Gregson et al., 2021).

2. METHODOLOGY

2.1. Experimental Setup

The controlled chamber experiments were conducted in a sealed chamber designed to minimize external influences on aerosol dispersion. The chamber, measuring 3 m × 2 m × 2 m with a total volume of 12 m^3, was constructed using structural lumber and enclosed with heavy-duty clear plastic sheeting to ensure airtight conditions. This setup provided a controlled environment, free from external airflow and ambient particulate matter, allowing for accurate aerosol emission assessments.

Participants containing of 3 male students and 3 female students completed four experimental scenarios: natural breathing (unmasked), speaking (unmasked), breathing (masked), and speaking (masked). All participants submitted consent forms approved by the McGill University Ethics Committee. In speaking scenarios, the participants were asked to read "The Rainbow Passage", a standardized script widely used in voice studies, ensuring consistency in phonation effort across experiments. Each experiment scenario lasted 20 minutes, followed by a 15-minute air exchange period. Figure 1 shows a photograph of an experiment session with a participant.

Figure 1. Photograph of an ongoing session.

To ensure consistent conditions between different experiment scenarios, an IQAir HealthPro air purifier equipped with high-efficiency particulate air (HEPA) filtration system was placed inside the chamber. This system removed residual aerosols between sessions, restoring the background concentration to below 50 particles per Liter (P/L) within 15 minutes. Continuous monitoring of temperature, relative humidity and carbon dioxide (CO_2) concentrations was conducted using TSI AirAssure 8144-6 and 8144-2 sensors. Aerosol measurements were performed using a GRIMM 11D aerosol spectrometer, positioned 1 m from the participants. This instrument recorded real-time size-resolved aerosol concentrations every 6 s, covering 31 size bins ranging from 0.253 µm to 35.15 µm. The spectrometer detection limit is 50 P/L for small aerosols and 10 P/L for larger particles. Figure 2 shows the experimental setup and plan view of the controlled chamber.

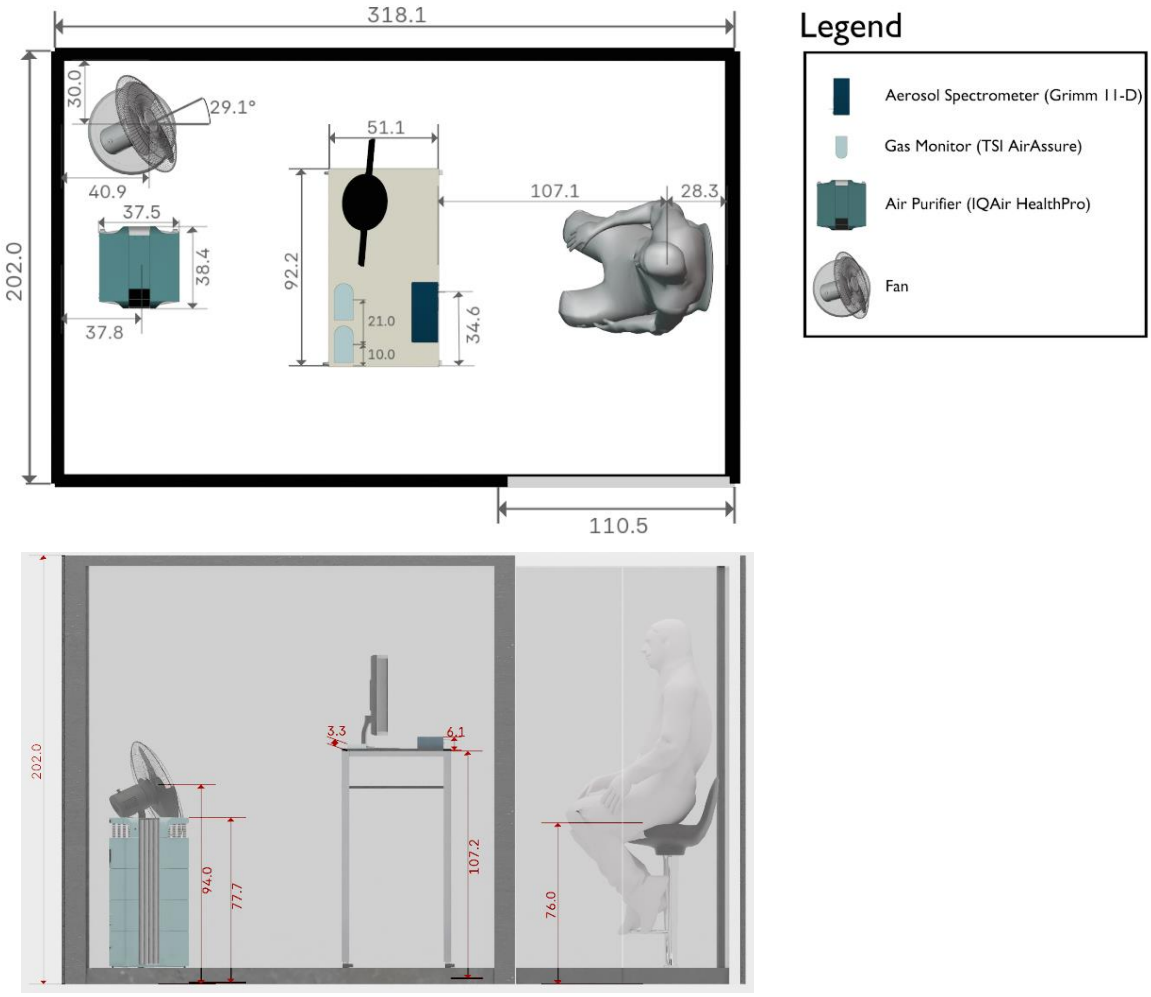

Figure 2. Experimental setup and plan view (top) and sideview (bottom) of the controlled chamber. Dimensions are in cm.

2.2. Data Analysis

Aerosol concentration data were collected continuously throughout each experimental session and divided into six intervals of 3.4 minutes each to capture short-term fluctuations. Before analysis, the raw concentration data were log-transformed to stabilize variance and allow for the interpretation of model coefficients in terms of relative percentage changes rather than absolute

differences. Baseline corrections were applied to each participant's dataset to ensure that aerosol emissions were analysed independently of the conditions from previous experimental scenarios.

To analyse how aerosol concentrations changed over time, weighted least squares (WLS) regression was first applied to estimate trends in aerosol increase and decay, accounting for measurement uncertainty across different particle sizes. A linear mixed-effects model was then used to quantify the effects of mask usage, speaking, and gender on aerosol emissions while controlling for time. In this model, mask condition (with mask versus without mask) and activity type (breathing versus speaking) were treated as fixed effects, while time-dependency was modelled as a random effect, incorporating random intercepts and slopes for each participant group. Interaction terms were included to determine whether the effects of speaking and mask usage simply added together or if they influenced each other in a more complex way.

To improve the reliability of effect size estimates, bootstrap resampling (1,000 iterations) was performed to generate robust 95% confidence intervals. All statistical tests were two-tailed, and significance level was set at $p < 0.05$.

3. RESULTS

Figure 3 displays the mean aerosol concentration (aggregated across all particle sizes) for each condition, stratified by gender and activity type. Error bars indicate measurement precision, rather than inter-participant variability. In all experimental conditions, aerosol concentrations increased over time. Speaking produced higher aerosol emissions than breathing under the same mask condition, confirming that speech-generated aerosols contribute to airborne particle levels. However, aerosol concentration trends for breathing without a mask were comparable to those observed for speaking with a mask, suggesting that wearing a mask during speaking effectively reduces aerosol emissions to levels similar to breathing without a mask.

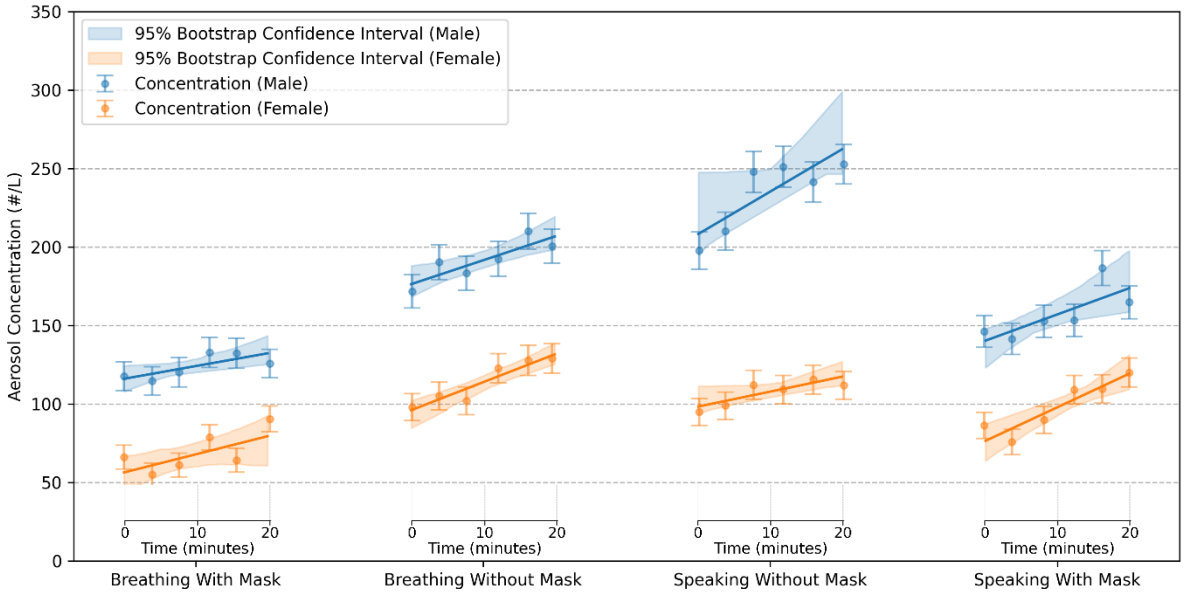

Figure 3. Aerosol concentration (#/Liter) for males and females across four activities (breathing and speaking,

with and without surgical masks). Each activity lasts 20 min and is divided into 6 intervals, with each data point representing the average aerosol concentration over a time interval. Trend lines fitted using Weighted Least Squares show changes in aerosol concentration over time, error bars indicate measurement precision, and shaded regions represent 95% bootstrap confidence intervals for the trend lines.

The data also indicate that male participants exhibited higher aerosol emissions on average compared to female participants. To quantify the effects of each experimental variable while controlling for time, a linear mixed-effects model was applied to the log-transformed aerosol concentration data. The results from this model are presented in Table 1.

Table 1. Mixed-Effects Model Regression Results.

Variable	Coefficient	Std. Error	z-value	p-value	95% Cl
Intercept	4.109	0.225	18.295	<0.001	(3.669, 4.550)
Without Mask (vs. With Mask)	0.490	0.039	12.575	<0.001	(0.414, 0.567)
Speaking (vs. Breathing)	0.230	0.048	4.807	<0.001	(0.136, 0.323)
Male (vs. Female)	0.324	0.184	1.758	0.079	(–0.037, 0.686)
Without Mask × Speaking Interaction	–0.241	0.055	–4.371	<0.001	(–0.349, –0.133)
Speaking × Male Interaction	0.112	0.055	2.029	0.042	(0.004, 0.220)
Time (Scaled)	0.495	0.175	2.826	0.005	(0.152, 0.838)

The estimates for percentage changes were derived by exponentiating the regression coefficients and expressing them as relative differences. The coefficient for "Without Mask" condition is 0.490 ($p < 0.001$), which translates to an estimated 63.28% increase in aerosol concentration when a mask is not worn. Similarly, the coefficient for "Speaking" condition is 0.230 ($p < 0.001$), corresponding to a 25.80% increase in aerosol emissions when participants engage in speech rather than passive breathing. While the coefficient for "Male" is 0.324 ($p = 0.079$), suggesting a 38.31% increase in aerosol emissions for male participants, this effect does not reach significance level ($p > 0.05$), meaning the gender-based differences observed may not be entirely generalizable.

There is a significant negative interaction between "Without Mask" and "Speaking" (–0.241, $p < 0.001$), indicating that the combined effect of not wearing a mask and speaking is less than the sum of their individual effects. In other words, while both factors increase aerosol emissions, their combined effect is not simply additive. Additionally, the interaction between "Speaking" and "Male" (0.112, $p = 0.042$) suggests that male participants experience a further increase in aerosol emissions when speaking.

The model also identifies time as a significant predictor of aerosol concentration. The coefficient for time (0.495, $p = 0.005$) translates to a 64.01% increase in aerosol concentration per unit increase in the time scale, confirming that emissions accumulate over time.

These findings highlight that mask usage and speech activity play dominant roles in determining aerosol emission levels. The interactions indicate that the combined effects of these factors are not strictly additive, suggesting a more complex relationship between speaking and the protective effects of masking. The time-dependent increase in aerosol concentration underscores the importance of extended exposure periods in indoor environments, particularly in settings where masks are not worn.

Figure 4 shows the size distribution of aerosols during the breathing without mask scenario, based on the number concentrations averaged across all participants. The size distribution, presented on

a logarithmic scale, reveals a primary peak below the detection limit of the instrument (<0.25 µm) and a secondary peak at approximately 2.5 µm. This pattern is consistent with previous studies reporting a primary mode at around 0.5 µm or within the 0.2–0.5 µm range (Bagheri et al., 2021; Holmgren et al., 2010). The observed shift to smaller diameters could be due to particle evaporation or interactions with indoor air, which alter the size distribution of respiratory aerosols after being exhaled into the room environment.

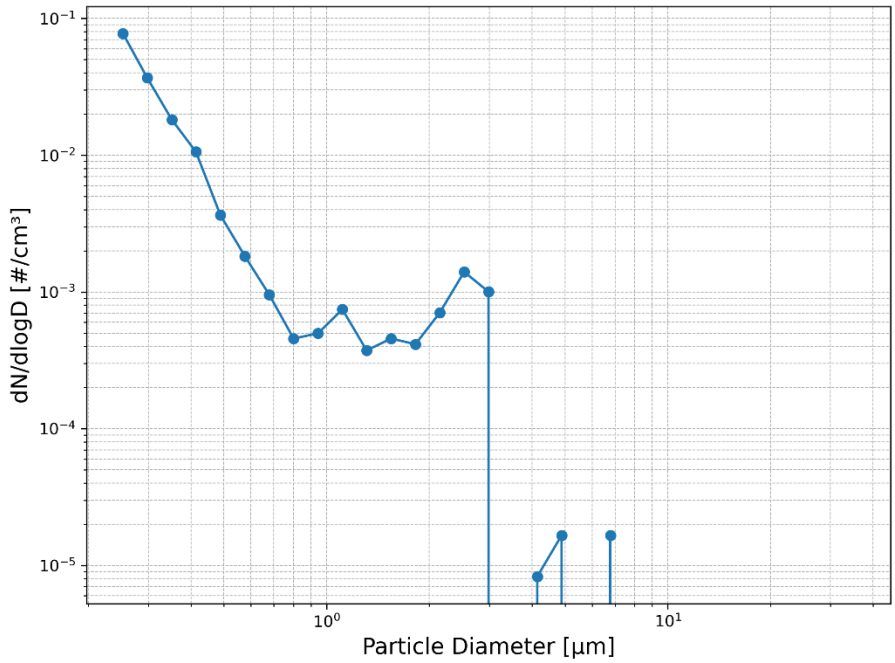

Figure 4. Size distribution of aerosols during the breathing without mask scenario, based on number concentration averaged across all participants

The secondary peak at 2.5 µm aligns with findings by Morawska et al. (2009), who identified a similar peak at approximately 4 µm in the log-normal size distribution of exhaled particles. The difference in peak location can be attributed to the fact that Morawska's study involved direct measurement of exhaled droplets, whereas the present study assessed particles that had interacted with indoor air over time. The shift toward smaller particle sizes suggests that processes such as evaporation and aerosol aging may influence the persistence and transformation of exhaled particles in indoor settings.

4. Conclusions

This study provides quantitative evidence on how mask usage, speech activity, and gender influence aerosol emissions in a controlled indoor environment. The results demonstrate that speaking increases aerosol concentration by approximately 26% compared to breathing, while not wearing a mask leads to a 63% increase in emissions. The interaction between these factors suggests that the combined effect of speaking without a mask is not strictly additive, implying a complex relationship between speech-driven aerosol generation and the protective role of masks.

Although male participants emitted, on average, 38% more aerosols than female participants, this

difference was not statistically significant at the 5% level. However, the interaction between speaking and male gender suggests that men may experience a greater increase in aerosol emissions when speaking, potentially due to physiological differences in vocalization. These findings suggest that gender-related variability should be considered in exposure assessments, though further research with larger sample sizes is needed to confirm this trend.

Aerosol concentrations increased steadily over time, confirming that particles accumulate in enclosed spaces when ventilation is limited. This reinforces the need to consider not just emission rates but also how long aerosols persist in indoor environments. Without adequate air exchange, even relatively low emission rates can lead to significant aerosol buildup over time, especially in settings where multiple people are present for extended periods.

These findings highlight the importance of masking and ventilation as complementary strategies for managing indoor air quality. While masks effectively reduce emissions at the source, ventilation plays a key role in preventing long-term accumulation. Future studies should investigate how these patterns hold in real-world environments with varying ventilation rates, larger populations, and different types of face coverings, particularly in shared indoor spaces where exposure risk is highest.

SUMMARY

Indoor volatile organic compounds (VOCs) not only include formaldehyde, toluene, etc. which are harmful to human health, but also include odor-producing compounds, causing smell discomfort to occupants. Decorated wooden panels are one of the main sources of indoor VOCs, but the odor components released by them are not clear. In the study, acetic acid and hexanal were utilized as odor compounds, and actual material samples of odor emission sources were employed. An environmental chamber was used to assess the odor reduction capabilities of air purifiers. By leveraging Weber-Fechner's law, a correlation was established between odor concentration and perceived intensity. Additionally, the study analyzed the impact of air purifiers on reducing odor intensity and introduced a novel general odor purification performance index. Propose a subjective-objective hybrid evaluation method to establish a connection between the objective indicators of the air purifier and the subjective odor evaluation of personnel.

Keywords: Odor intensity, Indoor air quality (IAQ), Purification efficiency, VOCs.

1 INTRODUCTION

As awareness about indoor air quality grows, the need for creating a comfortable and healthy indoor environment has become increasingly important. Indoor volatile organic compounds (VOCs), acknowledged for their elevated levels and potential health risks, have drawn significant attention. Common sources of VOCs include decorative materials such as wood, adhesives, and paints, which can emit harmful substances like formaldehyde and benzene (Dong et al., 2019). While measures such as source control and mechanical ventilation techniques have succeeded in reducing VOCs concentrations below the threatening levels; however, indoor odor problems persist, especially during renovation processes (Liu et al., 2024). Odors are not just unpleasant; they can initiate adverse health reactions including emotional stress, respiratory issues, and cognitive impairments.

Despite the prevalence of air purifiers in mitigating indoor pollutants, especially in newly renovated spaces, their effectiveness varies based on their technology – ranging from adsorption and catalytic oxidation to plasma treatments. However, the challenge remains in establishing a standard method to evaluate their performance on odor-causing VOCs. Current market indicators like the total volatile organic compound (TVOC) removal rate are too broad, failing to specify which VOCs are reduced and not directly correlating with changes in odor intensity. This lack of

specificity in TVOC measures calls for more targeted research for odor removal.

2 METHOD

The evaluation of the removal effect of air purifiers on pollutants in current standards is limited to objective indicators. Especially in a real environment, odors have companionship and hybridity characteristics, and it is difficult to establish a connection between objective indicators of individual odors and subjective evaluations of a specific environmental odor by personnel. We propose a new method to establish a connection between the objective indicators of the air purifier and the subjective odor evaluation of personnel. Using personnel odor recognition experiments to obtain personnel stimulation calculation models for various elemental odor substances, and establishing a comprehensive odor intensity model (Wang et al., 2023). Moreover, monitoring and evaluating the effectiveness of air purifiers on odors by detecting typical irritants and establishing a connection between subjective and objective indicators.

2.1 Air purifier and experimental setup

Table 1 shows the details of the PACs measured. The air purifier tested was fitted with a composite filter that sandwiched granular coconut shell activated carbon (average particle size: 0.3 mm) between the HEPA filter media. The surface of activated carbon is treated with chemical reagents to improve the adsorption performance of formaldehyde. The manufacturer did not provide details of the surface modification. The air purifier with multiple purification technologies is used for the purification experiment of odor compounds released by the medium density fiberboard (MDF).

Table 1. Basic information on the tested air purifier in the laboratory

Sample No.	Filter information					Rated Airflow (m^3/h)	CADR (m^3/h)	
	Size (mm)	Number	Pleat Number	Filtering Area (m^2)	Rating & Materials		HCHO	TVOC

[a] Equipped with amino acid aldehyde removal crystals and negative ion purification technology.

The experimental system consists of two parts: an environmental chamber with accessories, and a sampling and analyzing system. The environmental chamber used in the experiment was built following the requirements of the Chinese national standard GB18801-2022, and the volume of the environmental chamber was 30 m^3. The surface of the environmental chamber (6 sides of the wall and the ground) is composed of stainless-steel boards, to avoid the deposition or chemical reaction of gaseous compounds on the surface of the environmental chamber, which endangers the health of the experimenters and increases the experimental error. Next to the environmental chamber is the observation room, one of which is equipped with transparent glass as an observation window. Figure 1 provides a schematic diagram of the environmental chambers for the experiment (Figures 1a, b). In the center of the environmental chamber (3.5m×3.4m×2.5m), Air conditioners are placed to control the temperature and humidity in the cabin. Table 2 shows the environmental conditions of the chamber used for the experiment. Throughout the test, the temperature and relative humidity of the environmental chamber were recorded by an automatic recorder (HOBO, Onset, USA). Before testing, indoor surfaces were scrubbed with deionized water and air-dried in

ventilation mode. When the indoor and outdoor air properties were balanced, the valves in all sampling pipes were sealed and the background concentration of gaseous pollutants was measured.

2.2 VOCs emissions

Medium-density fiberboard, which is widely used in building decoration, is the main sources of indoor VOCs. Acetic acid, hexanal, and pentanal were found to be odor compounds common to these materials. As one of the main compounds released by human skin, acetic acid is commonly present in indoor environments. At the same time, acetic acid and hexanal have a low threshold value of exposure, which are easy to cause poor perceived air quality. According to the above characteristics, acetic acid and hexanal were used as typical odor compounds in building materials to carry out the pollutant purification experiment.

The medium density fiberboard (MDF) stored for two years, which released pollutants at a slow stable rate, was utilized to simulate the release of odorous VOCs from building materials in residential environments. Compared with the high-release state of the newly renovated building, the slow-release state of the decoration board accounts for a higher proportion of the actual building life cycle. Therefore, it is more practical to select MDF that has been aged for two years to test the purification performance. Six MDF panels with dimensions of 2.4 m×1.2 m × 0.015 m was evenly arranged in the environmental chamber, and the air purifier was placed in the middle of chamber. The loading rate of the panels in the environmental chamber is 1.17 m^2/m^3, which is close to the arrangement of materials in the actual building interior.

2.3 Sniffing Discrimination Experiments

A cohort of four odor evaluators (gender-balanced; 2 males, 2 females) aged 20-26 years, in good health and without a history of smoking or olfactory impairments, were recruited from the university campus. The evaluators underwent a rigorous training program adhering to the ISO12219-7 standard, spanning four sessions within a month. Odor intensity (OI) assessments were conducted utilizing a standardized 6-point scale methodology. To represent varying odor intensities, aqueous solutions of 1-butanol were prepared at distinct concentrations, as guided by previous research, with detailed parameters outlined in Table S1. According to the ISO13725 standard, the experimental environment was carefully controlled, ensuring an odorless room with constant ventilation and a temperature maintained at 23 ± 2° C. The test room was devoid of any non-essential items capable of emitting odors.

Odor evaluation and compound characterization were performed using GC-O-MS. The operating principle of GC-O-MS is shown in Figure 2. The Supelco tube was installed on the thermal desorption instrument of the GC-O-MS. Before odor evaluation, a blank Supelco tube was run to rinse the VOC impurities trapped in the GC-O-MS to eliminate background errors. The qualitative method is the same as that of GC-MS. Some VOCs took a long time to elute from the column, for example, acetic acid eluted between 7.56 and 8.08 min. In the characterization of odor compounds, the allowable deviation between the time of smelling the odor and the retention time was ± 0.1 min.

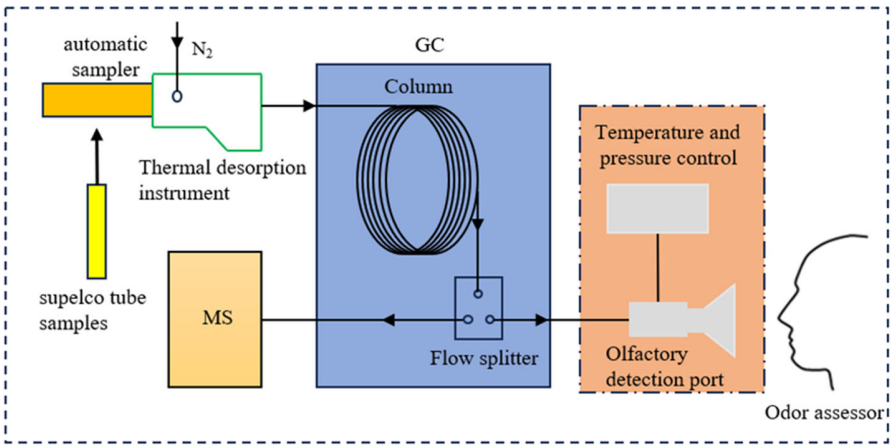

Figure 2. Schematic diagram of the operation of GC-O-MS.

Preceding the experiment, evaluators were instructed to abstain from pungent odor sources, including perfumes and strongly flavored foods, for 24 hours. Upon arrival, participants acclimatized to the test environment for 5 minutes prior to analysis, with each sample assessment taking approximately 45 minutes. To mitigate olfactory fatigue, evaluators alternated sniffing sessions in three 15-minute cycles, as detailed in Table S2. During the formal experiment, evaluators sniffed through a designated olfactory port and promptly recorded the retention time (RT), odor intensity (OI), and odor descriptors (such as rubber, fruity, cucumber, sour, rosin) upon perception. Following this, the OI values were averaged across all evaluators' scores. The odor

threshold was defined as the concentration at which at least 50% of the evaluators could detect the odor, with the presence of the odor being confirmed if detected by two or more evaluators.

2.4 Experimental Procedure

The purification experiment of odor compounds released by the plate was divided into two stages: gas release and purification. After the initial environment of the environmental chamber was adjusted, 6 MDF boards were evenly placed in the chamber, the circulating fan and stirring fan were turned on, and the environmental chamber was sealed for 8 h. The purification phase was divided into 4 steps and lasted 120 minutes as show in Figure 3. First, turned off the stirring fan and proceed to the initial 20-minute concentration sampling. After that, turned on the air purifier and took 3 concentration samples in a row for 20 minutes each, according to the Chinese national standard GB/T 18801–2022.

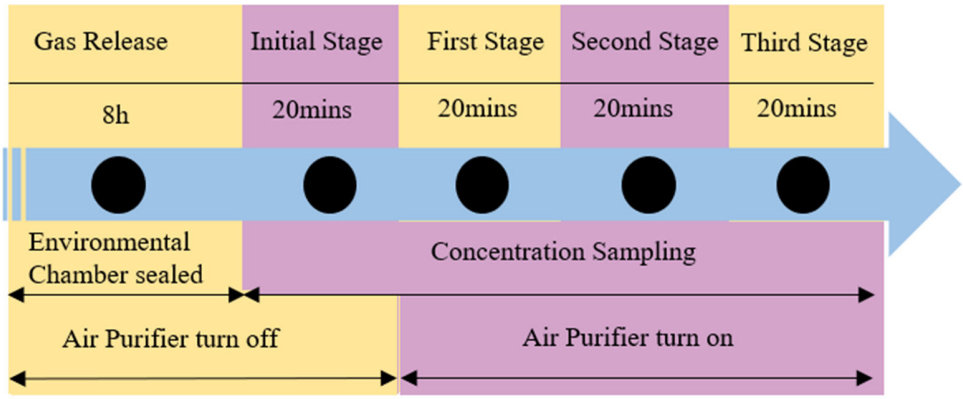

Figure 3. Sampling in the concentration of odor compounds at each stage

In both natural attenuation and total attenuation experiments, the variation of pollutant concentration with time conforms to the trend of exponential function, as shown in Eq. (1).

$$C_t = C_0 e^{-kt} \quad (1)$$

Where, t is time, min, C_0 is the concentration of gaseous pollutants at the initial moment in ppm, C_t is the concentration of gaseous pollutants at time t in ppm and k is the pollutant concentration attenuation index in min^{-1}.

Ventilation efficiency η defined as the ratio of the amount of air involved in diluting pollutants to the amount of ventilation sent into the room, expressed by Eq. (2). In this study, we used the evaluation formula of ventilation efficiency to evaluate the purification performance of air purifiers.

$$\eta = \frac{CADR}{Q} \quad (2)$$

Where, η is the purification efficiency of the air purifier and Q is the circulating air volume of the air purifier in m^3/h.

Due to the limited number of data points for offline sampling, CADR cannot be calculated, so the purification effect is evaluated by the concentration purification efficiency index, and the definition of concentration purification efficiency η' is shown in Eq. (3).

$$\eta' = \frac{C_0 - C_t}{C_0} \quad (3)$$

Where, η' is the purification efficiency of pollutants at time t, C_t is pollutant concentration at time t and C_0 is a concentration of contaminants at the initial moment

Weber-Fechner's law is one of the most widely used concentration-odor intensity transformation models and is, therefore, the model that is the focus of this study. Based on the Weber-Fechner law, this study proposes to evaluate the odor purification performance of air purifiers by using odor intensity reduction ΔOI index. Based on the GC-MS results of the actual odor activity value OAV_i of the panel, combined with the sensory evaluation results as per our previous study, to obtain a constant a_i, the odor intensity (OI_i) and odor intensity reduction (ΔOI) can be obtained, and finally, the comprehensive odor intensity SOI of the mixed gas can be obtained .

$$OAV_i = \frac{C_i}{C_{Ti}} \quad (4)$$

$$OI_i = a_i log OAV_i + b_i \quad (5)$$

$$\Delta OI = OI' - OI'' \quad (6)$$

$$SOI = log \sum 10^{OIi} \quad (7)$$

3 RESULT

3.1 Purification effect of odor compounds released from the MDF boards

The offline analysis method was used to obtain the average concentration over four time periods. The concentration changes of the odor compounds detected in the experiment are shown in Figure 4, and the concentration values of the compounds have been subtracted from the background concentrations in the environmental chamber. The odor compounds detected in this experiment included acetic acid, toluene, and hexanal, and there may still be compounds with odor but concentrations below the detection limit of GC-MS instruments, which cannot be characterized. Toluene concentrations below the odor threshold concentration do not produce odor in the environmental chamber, but toluene remains a potential odor compound when the loading rate of the material increases, so the variation in toluene concentration is listed here.

In Figure 4, the concentrations of the three odor compounds showed a decreasing trend when the purifier was turned on. The initial concentration of acetic acid was 8.51 μg/m^3, and after 40 minutes, the concentration of acetic acid decreased to 0.03 μg/m^3, and the purification efficiency was 99.6%. The initial concentrations of toluene and hexanal were 23.45 μg/m^3 and 25.86 μg/m^3, respectively, and the concentration purification efficiency η' after 1 h was 64.5% and 40.0%.

Filters are typically tested for efficiency and lifetime using ppm levels of contaminants. The initial concentration of VOCs detected in the environmental chamber was very low compared to the initial concentration of the compound used in the single-pass efficiency of the filter or the test of the air purifier CADR. The purification efficiency of the filter varies with the initial concentration, so it is of little significance to compare the purification efficiency at different initial test concentrations. The experimental object in this research is a two-year MDF with a load factor of 1.17 m^2/m^3. The experimental conditions are in accord with the real residential buildings, which can better reflect the actual odor compound purification effect. This is instructive for the establishment of a test method for the odor purification performance of air purifiers. In the next

step of the study, it was necessary to use panels with updated production times to simulate the odor emission conditions of newly renovated buildings.

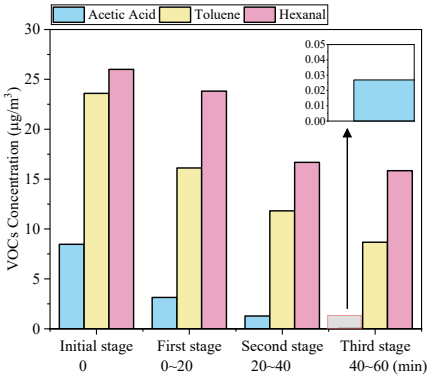

Figure 4. Changes in the concentration of odor compounds at each stage

3.2 Reduction in odor intensity

It is important to note that the Weber-Fechner law applies to moderately intensive stimuli. For compounds with a concentration equal to the odor threshold, it has been assumed that bi=0.5. This is because the odor threshold concentration is defined as the concentration at which 50% of the group members perceive a faint odor and others do not, so the theoretical odor intensity OI should be 0.5, i.e., 0.5 for bi. To obtain the coefficient a_i of Weber-Fechner's law, an odor evaluator must evaluate the odor at the scene. Detailed data on this can be found in Table S3. According to the principle of the GC-O-MS instrument, the odor evaluator smells the gas after the gas in the gas bag is concentrated 40 times more at the olfactory port, and the compound concentration corresponding to the odor intensity given by the odor evaluator can be calculated. According to Eq. (5), the odor data are fitted to obtain the coefficient a_i of Weber-Fechner law. There are 6 data points for both acetic acid and hexanal, and the concentration of toluene in the purification experiment does not contribute to the odor, so no fitting is done here. Figure 5 show the fitting results of acetic acid and hexanal. The fitting correlation coefficients R^2 of acetic acid and hexanal were 0.998 and 0.981, respectively, which were higher than 0.98, indicating that the fitting effect was good. The transition relationship between acetic acid and hexanal concentrations and odor intensity is as follows in Equations 8 and 9:

$$OI_{Acetic\ acid} = 1.9375 * logOAV_{Acetic\ acid} + 0.5 \quad (8)$$

$$OI_{Hexanal} = 0.8832 * logOAV_{Hexanal} + 0.5 \quad (9)$$

By substituting the concentrations of acetic acid and hexanal detected in the environmental chamber, respectively, the corresponding odor intensity can be calculated. The odor intensities of acetic acid and hexanal at different stages are shown in Figure 6. The initial odor intensity of acetic acid released by MDF is 1.33, indicating a weak odor. After turning on the air purifier, the odor intensity of acetic acid gradually decreased, and after 1 hour, the odor intensity of acetic acid decreased to 0. The initial odor intensity of hexanal released by MDF was 1.66, and the odor intensity of hexanal slowly decreased after 1 h operation of the air purifier. From the perspective of odor characteristics, the sour taste characteristics of acetic acid gradually decreased to 0 after

the air purifier was turned on for 1 h, and the grassy flavor characteristics of hexanal changed slightly. In this study, the odor intensity reduction ΔOI index was proposed to evaluate the odor purification performance of air purifiers.

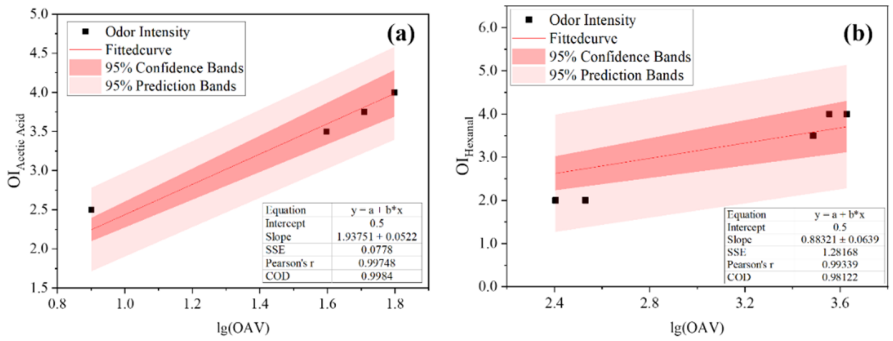

Figure 5. Linear fitting results of logOAV and OI of (a) acetic acid and (b) hexanal

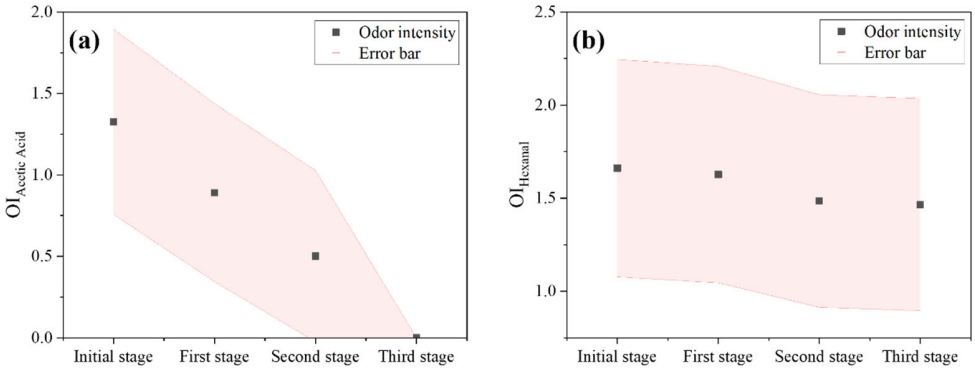

Figure 6. Changes in odor intensity when the air purifier is turned on (a) in acetic acid and (b) hexanal odor intensity

It should be noted that the odor intensity calculated in Figure 5 and Figure 6 is at a weak stage, and the accuracy of the prediction of the Weber-Fechner law at this stage needs to be verified. The main goal of this study is to preliminarily explore the evaluation method of odor purification performance, and the analysis of the applicability scope of the model will be carried out in future research. This study provides reference directions for the establishment of an evaluation method for the purification odor performance of air purifiers. In addition, according to the experimental results, it is recommended to increase the intensity of the air release source based on this experiment to achieve more accurate odor intensity prediction when evaluating the odor purification effect of the air purifier on the MDF.

SUMMARY
This study used a wind tunnel experiment to measure the flow field under conventional and twist wind profiles and employed steady Reynold-Averaged Navier-Stoke equations with standard $k-\varepsilon$ model, coupled with the discrete ordinate (DO) model to investigate the impact of twist wind on wind environment and air temperature around two prevalent building configurations: tandem and side-by-side arrangements. The results indicated that the twist wind can generate asymmetrical flow fields around both the tandem and side-by-side arrangements, with the effects of twisting flows being more pronounced in densely urbanized areas characterized by narrow street widths. The twist winds have cooling effects on air temperature because the weakened downwash flow is unable to resist the buoyancy flow, thus facilitating the rise of heated air within the street canyon.

Keywords: Twist wind profile, Computation fluid dynamic, Pedestrian-level wind comfort, Air temperature.

1. GENERAL INSTRUCTIONS

As urbanization progresses, the urban heat island (UHI) effect has become increasingly pronounced, leading to a yearly rise in temperatures across an expanding number of regions (Perkins-Kirkpatrick and Lewis, 2020). An increasing body of research has focused on strategies to reduce urban temperatures, mitigate the heat island effect, create comfortable pedestrian wind and thermal environments, and promote outdoor activities among residents (Weerasuriya, et al., 2020). In addition, an uncomfortable thermal environment tends to encourage residents to remain indoors during hot weather, thereby leading to a significant increase in energy consumption due to the use of air conditioning (Giridharan and Emmanuel, 2018). Hence, investigating the impact of architectural design on urban wind and thermal environments holds significant importance.

As the scarcity of land resources becomes increasingly apparent, an expanding number of structures are being constructed not only within urban centers but also in proximity to mountainous regions. This trend is particularly pronounced in cities characterized by their mountainous terrain, such as Hong Kong and Chongqing. For buildings situated in these areas, the influence of the wind field exhibits significant differences compared to that observed in flat terrains, this phenomenon has been addressed in the previous literature (Yuan, et al., 2023). Twisted wind profile (TWP), defined as the variation in wind direction along the vertical axis due to terrain effects, has been extensively examined in prior research. The complex topography in mountainous areas has been proven to induce helical wind patterns, therefore affecting the ventilation, structural stability, and

pollutant dispersion. Through wind tunnel experiments, Tse, et al., (2017) successfully simulated twist wind using twist vanes and discovered that it significantly influences the position of the downstream low wind velocity areas. Yuan, et al., (2022) conducted RANS simulations to examine the modification of the flow field under twisted winds while considering horizontal homogeneity. They concluded that the asymmetry in the flow field is influenced by the twist angle varying with height. Therefore, the flow characteristics under the conventional wind profile (CWP) and twist wind profile (TWP) exhibit significant differences and warrant further investigation.

Nowadays, the Computation Fluid Dynamics (CFD) approach has emerged as a robust and indispensable tool for investigating wind flow patterns and air temperature distributions within street canyons (Toparlar, et al., 2015). The thermal forcing plays a crucial role in determining the flow field structures within street canyons (Hang, et al., 2024). Li, et al., (2020) highlighted the significance of modelling the solar radiation in urban wind and thermal environments, noting that solar radiation serves as the primary thermal forcing in urban areas. In this study, the Discrete Ordinate (DO) model in FLUENT was utilized to simulate solar radiation and sunlight exposure. The pedestrian-level wind environment and air temperature around two distinct building configurations (tandem and side-by-side arrangements with varying gaps) were simulated using the steady Reynolds-Averaged Navier-Stokes (RANS) equations with standard $k-\varepsilon$ turbulence models.

2. METHODS

2.1. Wind tunnel experiments

The wind tunnel experiment was conducted in the Aerodynamics and Acoustic Facility (AAF) at the Hong Kong University of Science and Technology. The twisted wind profile has been replicated by the twist vanes, which induce varied wind directions along the vertical axis. The maximum twist angle at ground level was measured to be 25° (Figure 1). The pedestrian-level wind velocity was measured using the KANOMAX Model 0965-07 anemometer at a height of 1 cm above ground level across 72 distinct locations (Li, et al., 2024).

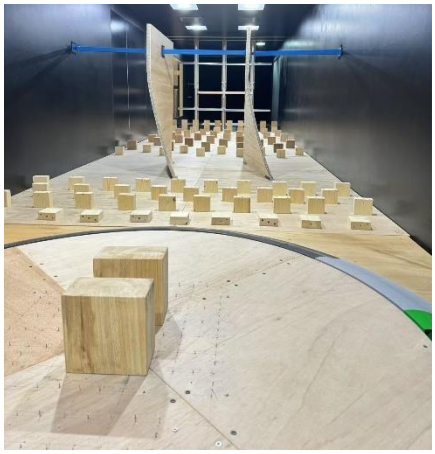

Figure 1. Inside view of wind tunnel experiment.

2.2. CFD simulations

The inlet conditions, encompassing wind velocity, turbulence intensity, and twist angle profile, were consistent with the data obtained from the wind tunnel experiment (Figure 2). The distances from the building edges to the computational domain boundaries (inlet, lateral, outlet, and top) were set at 5 *H*, 5 *H*, 15 *H*, and 5 *H*, respectively (Table 1). The boundary conditions for the computational domain are detailed in Table 2. Lateral 1 and lateral 2 were modified to velocity inlets under TWP conditions to accurately simulate the twisted wind profile phenomenon. The reference velocity is determined to be 7.23 m/s at a building height of 600 mm, while TWP 25 represents the twist wind profile where the maximum twist angle measured at the ground level is 25 degrees.

In this study, various configurations of neighboring buildings, including tandem and side-by-side arrangements, were simulated to represent the diverse building layouts commonly found in urban environments. The flow field under conventional wind profile (CWP) and twist wind profile (TWP) were simulated using the steady Reynold-Averaged Navier-Stoke equations with standard $k-\varepsilon$ models. Air temperature was evaluated under realistic solar radiation conditions, which were simulated using the Discrete Ordinate (DO) model in FLUENT, the radiation simulations were conducted at LSTs (local solar times) of 1500 LST (3. p.m) on a summer day in Hong Kong. This time was selected to simulate the hottest period of the day in Hong Kong, representing the most severe conditions.

$$u_{(z)} = \frac{u^*_{ABL}}{\kappa} \ln\left(\frac{z+z_0}{z_0}\right) \quad (1)$$

$$\theta_{(z)} = \theta_0 \exp\left(\alpha \times z/\beta\right) \quad (2)$$

$$v_{(z)} = u_{(z)} \tan\left(\theta_{(z)}\right) \quad (3)$$

$$k_{(z)} = \frac{3}{2}\left(I_{(z)} u_{(z)}\right)^2 \quad (4)$$

$$\varepsilon_{(z)} = \sqrt{C_\mu} k_{(z)} \sqrt{\left(\frac{\partial u}{\partial z}\right)^2 + \left(\frac{\partial v}{\partial z}\right)^2} \quad (5)$$

where frictional velocity u^*_{ABL} =0.37 m/s; dynamic roughness height z_0 =0.00025 m; von Karman constant κ =0.4187 and the model constant C_μ =0.09; $\theta_{(z)}$ is the twist angle along the vertical height; θ_0 is the yaw angle measured at the lowest height; The constants α and β, derived from the line fitted to the twist angle profile of the incident flow, were –3.06 and 1.43 respectively. The turbulence intensity profile ($I_{(z)}$) was obtained by fitting the wind tunnel data and the inlet turbulence kinetic energy ($k_{(z)}$) was derived from Blocken, et al., 2012. The inlet turbulence dissipation rate ($\varepsilon_{(z)}$) can be calculated based on the above Equations. The pedestrian-level wind environment was assessed based on the mean wind velocity ratio (*MVR*), which is defined as the mean wind velocity at the pedestrian level height (z=2 m) and the wind velocity at the reference height (z=200 m in prototype scale). The air temperature near the tandem and side-by-side building arrangement was presented by T-T_{ref}, where T_{ref}=273.15 K.

3. RESULTS

3.1 Grid sensitivity test and Validation

The mesh was a structured hexahedral mesh generated by ANSYS ICEM CFD using the blocking technique. Grid sensitivity was evaluated for three distinct grid arrangements: Coarse (minimum cell size of 4 mm), Medium (minimum cell size of 2 mm), and Fine (minimum cell size of 1 mm). The number of cells was 1,649,376, 3,425,424, and 4,931,538 for coarse, medium, and fine cell sizes, respectively. These arrangements were compared, and the computational results between the medium and fine grid arrangements exhibit negligible differences (Figure 3). The medium mesh was selected for optimal balance between computational resource utilization and simulation accuracy. The simulation results were compared with the wind tunnel results at several different horizontal lines (x=-0.225 m, 0 m, 0.075 m, 0.31 m, 0.385 m, and 0.535 m). While high consistency was observed in most regions, discrepancies were noted in the location of wake areas relative to wind tunnel experiment results (Figure 4). This is due to the well-known drawback of RANS models in predicting the wind conditions in the building wake (Yoshie, et al., 2007). The temperature simulation results were compared with the reference data and agreed with the on-site measurement results (Idczak, et al., 2006) in Table 3.

Table 3. Comparison of the wall temperature between CFD and on-site measurement.

Location	On-site measurements (Idczak, et al., 2006)		Present study	
	0800 LST	1600 LST	0800 LST	1600 LST
x/H=0.21	21.4 ℃	29.2 ℃	21.7 ℃	29.5 ℃
x/H=0.84	24.9 ℃	28.9 ℃	23.8 ℃	28.6 ℃

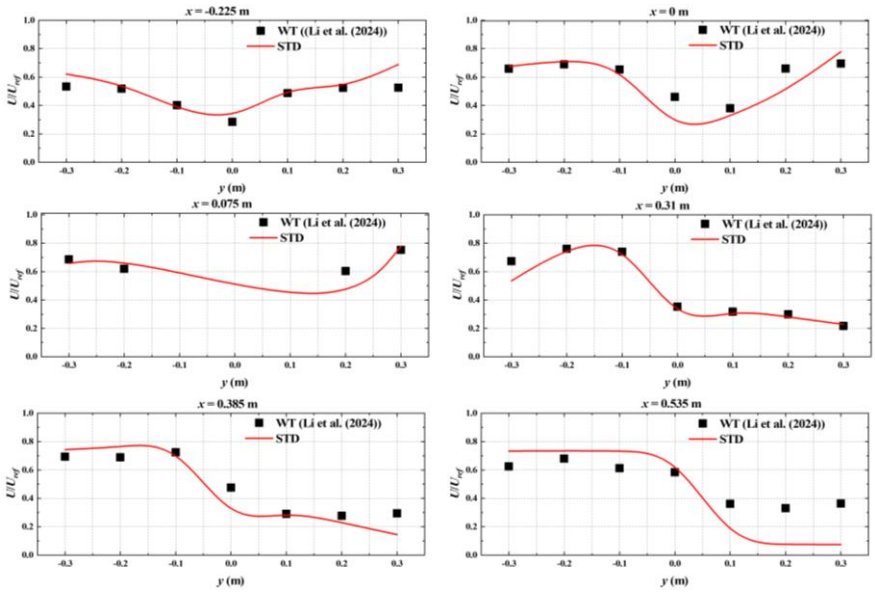

Figure 4. Comparison of the U/U_{ref} results between the CFD and the wind tunnel experiment results under TWP.

3.2 Effect of twist wind on wind comfort

Figure 5 describes the flow field distribution under CWP and TWP for varied building configurations. The twisted wind affects the creation of an asymmetrical flow field distribution around building arrays. For the side-by-side arrangement of the building array, when the gap spacing is small (SBS1), vortices behind the two buildings tend to interact with each other. Conversely, when the gap spacing exceeds the building widths, the two buildings behave as independent entities, each with its own inclined flow field. In addition, when the gap spacing is small, the Venturi effect was observed. The corner vortex on the right side of the building tends to be located downstream of the passages due to the acceleration phenomenon. This indicates that the influence of twist winds is more pronounced in narrow building arrangements. The twisted wind clearly enhances the vortex shedding on the side surface in the direction of its approaching flow. Upon analyzing adjacent structures with varying inter-building distances, it becomes apparent that the wider the spacing between buildings, the more accurately the deviation angle aligns with the wind's angle of incidence.

For the tandem arrangement, the wind velocity magnitude was lower than that in the flow field surrounding the side-by-side arrangement due to the wake effect caused by the upstream buildings. With the increasing gap between buildings, a vortex was observed in the passage between the two structures, and its intensity increases as the building separation widens under TWP conditions.

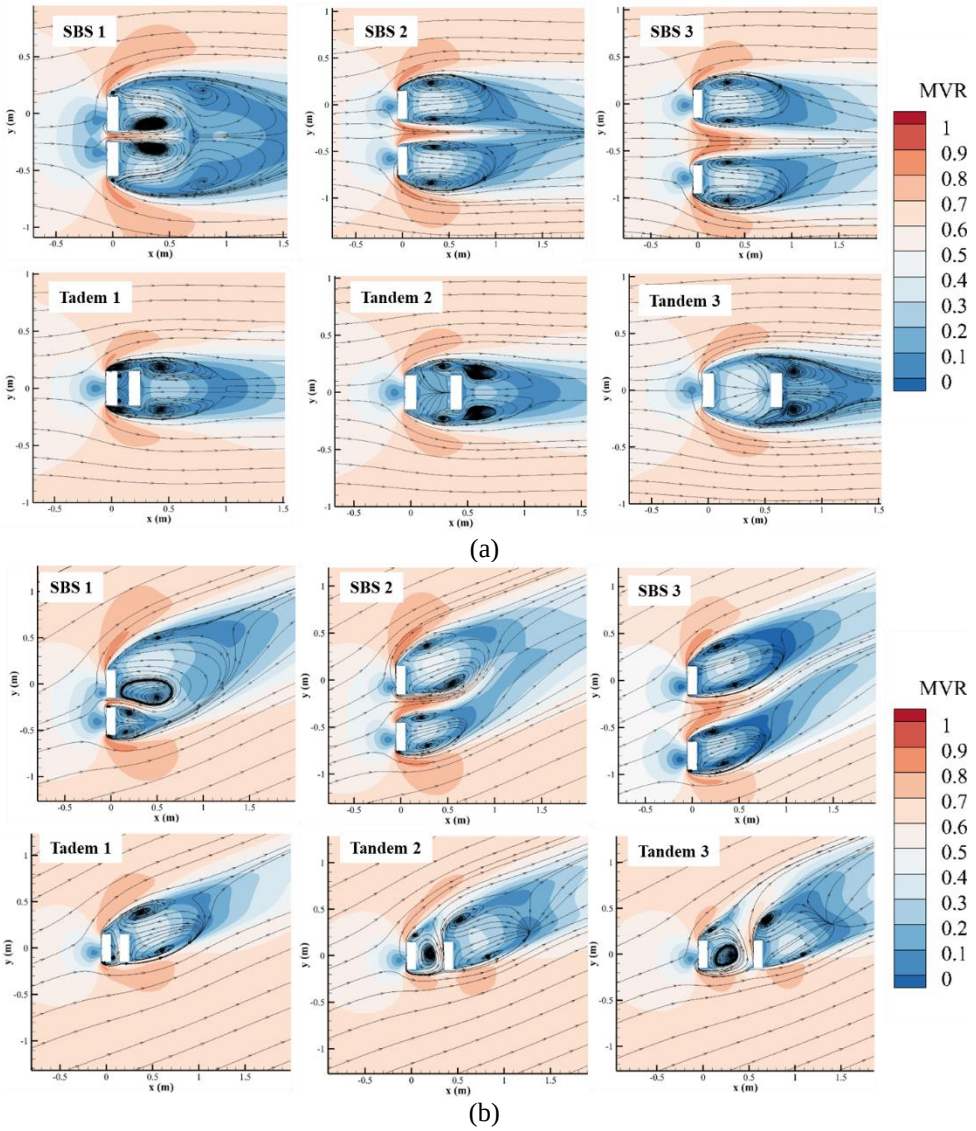

Figure 5. *MVR* distribution at the horizontal plane (z=0.01 m) under (a) CWP and (b) TWP.

3.3 Effect of twist wind on air temperature

Twisted winds can significantly alter the air temperature in the passages between two buildings, with more noticeable changes occurring in tandem arrangements compared to side-by-side arrangements (Figure 6 and Figure 7). For side-by-side arrangements, unlike the symmetric temperature distribution observed under CWP, the air with higher temperatures tends to flow toward the approaching twist wind directions. This phenomenon was more pronounced with narrower gaps between the two buildings. For buildings in tandem arrangement, high temperatures were observed near the leeward façade under CWP due to direct solar radiation. However, under TWP, high temperatures were observed near the windward façade because the weakened downwash flow cannot effectively counteract the buoyancy flow. The impact of twist wind on air temperature distribution was more significant in buildings arranged in tandem compared to those arranged side-by-side.

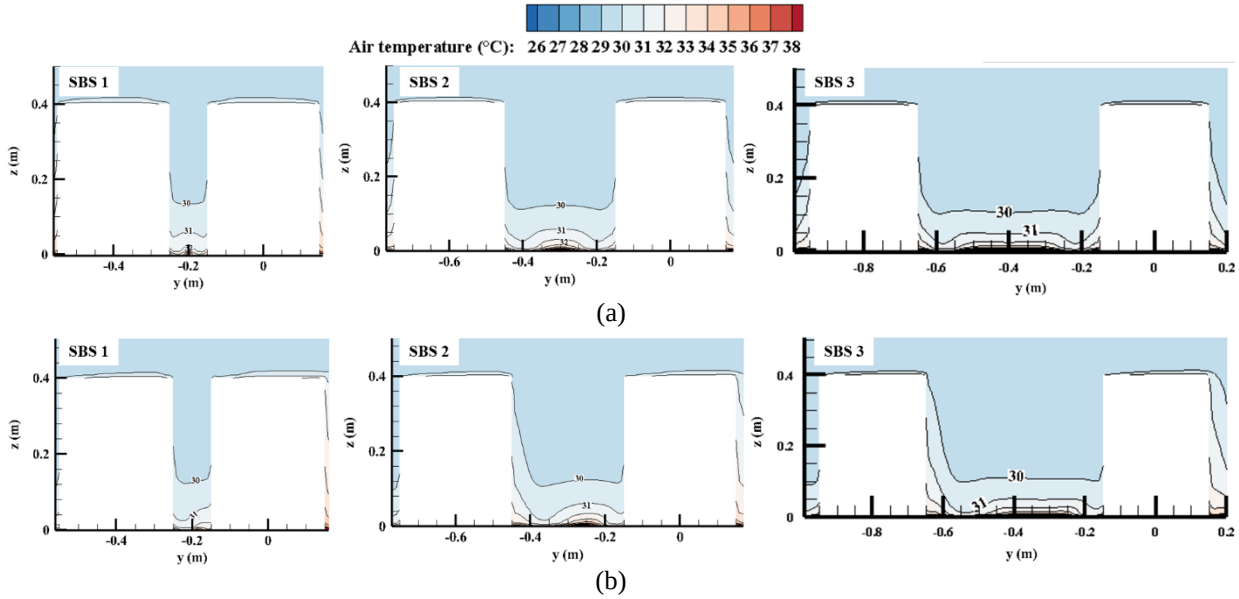

Figure 6. Air temperature contour in the vertical plane at x=0 for the side-by-side arrangement under (a) CWP and (b) TWP.

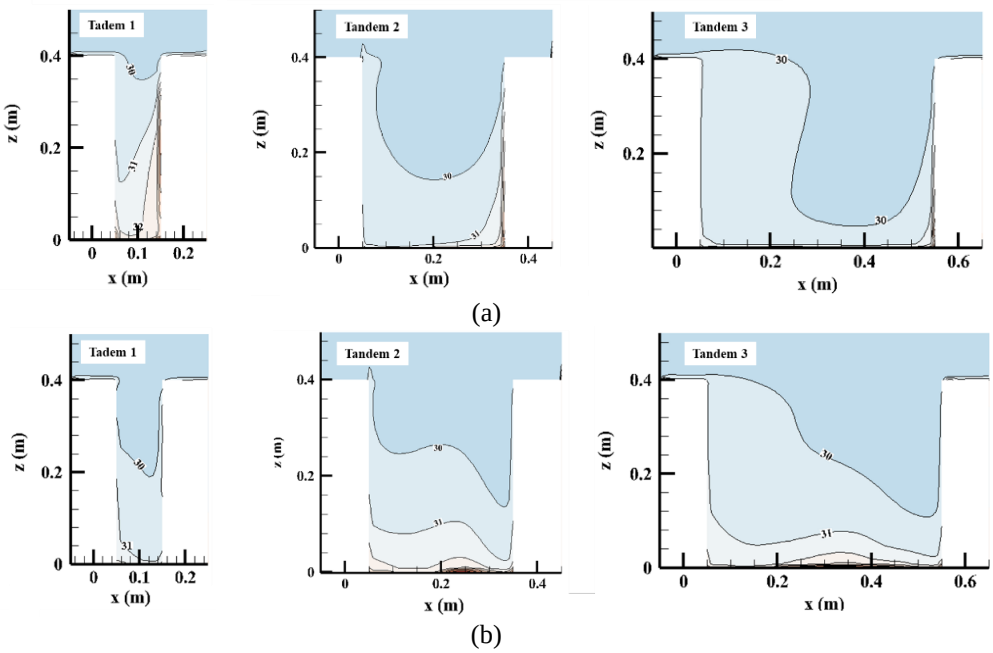

Figure 7. Air temperature contour in the vertical plane at y=0 for tandem arrangement under (a) CWP and (b) TWP.

4. CONCLUSION

CFD simulations were conducted to investigate the impact of twist wind on pedestrian wind

environment and air temperature around two commonly observed building configurations: tandem and side-by-side arrangements. The results demonstrate that the twist generates an asymmetrical flow field, enhancing the corner stream in the direction of the approaching twisted wind flow while weakening the corner stream on the opposite side of the building. For the side-by-side building configuration, the effect of twist winds is more pronounced with narrow spacing. When the building gap exceeds twice the building depth, the two buildings behave as independent structures, and complete vortex shedding phenomena are observed behind each building. For the tandem building arrangement, the inclined corner flow of the upstream building tends to be redirected into the passages between the two tandem buildings, forming a significant counterclockwise street canyon vortex. The twist wind altered the air temperature distribution within the street canyon. The weakened downwash flow was unable to counteract the buoyancy-driven flow, thereby facilitating the removal of heated air from within the street canyon.

ACKNOWLEDGEMENTS

This work was supported by a grant from the Research Grants Council of Hong Kong Special Administrative Region, China (Project No. T22-504/21-R). The authors of this paper would like to express their gratitude to the staff of AAF in HKUST for supporting the wind tunnel experiment.

ABSTRACT

Is bigger always better when it comes to urban green spaces (UGS)? How large should urban green spaces be to effectively mitigate urban heat? This study develops a temperature and humidity regulation model for UGS, exploring the optimal size from the perspective of the threshold value of efficiency (TVoE) required to counteract heat from upwind built-up areas. The results show that TVoE for green spaces to effectively mitigate urban heat is around 1000 m. As the building density in the upwind built-up area increases, the required size of the UGS also increases. The TVoE is generally higher at night, indicating a reduced cooling effect during nighttime. The analysis of heat index (HI) levels shows that UGS can significantly reduce extreme heat conditions (Danger levels) and increase more comfortable temperature ranges (Caution levels), especially near UGS boundaries. However, they may also slightly increase extreme danger levels in areas with lower building densities. This research provides theoretical support for the strategic planning and management of urban green spaces, helping cities better adapt to the challenges of climate change.

Keywords: Urban green space, Threshold value of efficiency, Cooling effect

1 INTRODUCTION

Urban greening is considered a highly promising measure for improving the urban heat environment (Wong et al., 2021), with vegetated urban green spaces (UGS) exhibiting higher cooling efficiency (Kumar et al., 2024). At both micro and macro scales, UGS can alleviate the negative impacts of the urban heat island by altering the surface energy balance (Zölch et al., 2024). The cool island effect created by UGS, along with the infiltration of cool air into surrounding urbanized areas, plays a key role in improving local thermal environments and enhancing human thermal comfort (Bie et al., 2020).

The role of UGS as a "regulator" of the urban microclimate has been confirmed by numerous studies (Hwang et al., 2015; Algretawee et al., 2019). Previous studies have shown a nonlinear relationship between the size of the UGS and cooling intensity (Monteiro et al., 2016). So how big does the UGS need to be in order to effectively regulate the urban microclimate? Yu et al. (Yu et al., 2017) proposed the concept of the threshold value of efficiency (TVoE) from the perspectives of "law of diminishing marginal utility". TVoE considers the trade-offs that exist between the size of the UGS and the cooling effect from the principle of cost-effectiveness (Yang et al., 2020). TVoE has been applied in several studies to determine the minimum size required for UGS to sustain the cooling effect (Fan et al., 2019).

These studies typically determine the TVoE at the UGS size in terms of the cooling effect of the UGS on the surrounding built-up area, and are primarily focused on satellite imagery-based surface temperatures (LST). However, remote sensing of LST is not applicable to capture the effects of UGS on air temperature and pedestrian-scale thermal climate (Sun et al., 2015). How large does UGS need to be as a "buffer" against heat in upwind built-up areas? This study will base on the numerical modeling to determine the TVoE of the UGS that resists heat from the upwind built-up area from the perspective of the UGS cooling the air temperature.

2 METHODOLOGY

2.1 STUDY AREA AND BACKGROUND CLIMATE

This study was conducted in Guangzhou, Guangdong province, China (22.3°N to 24.1°N, 112.8°E to 114.2°E). Guangzhou is a megacity in southern China with a population of over 18 million, and classified as Cfa (C: warm temperate; f: fully humid; a: hot summer) (Chen et al., 2023) according to Köppen Geiger climate classification, Guangzhou.

Meteorological data above the urban canopy were collected from a weather station installed on the roof of the Building Energy and Environment Laboratory at South China University of Technology, as shown in Figure 1. This weather station will provide data on solar radiation, long-wave radiation, air temperature, relative humidity, wind speed, and rainfall above the urban canopy. Meteorological data within the urban canopy were provided by a Bowen station located in an unmanaged green space at the South China University of Technology, as shown in Figure 1. The Bowen station will provide air temperature, relative humidity, and soil water content within the urban canopy. The distance between the two sites is about 350m.

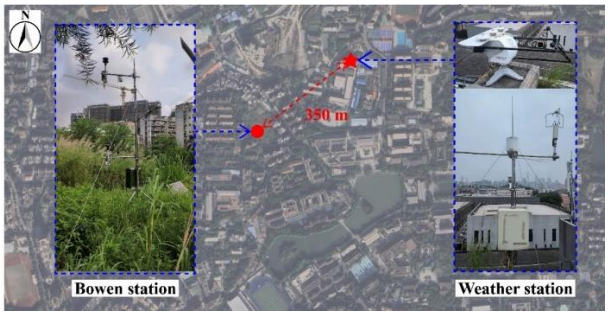

Figure 1. Study area and weather station

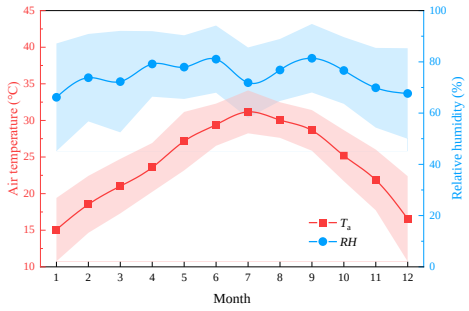

Figure 2. Background climate

The monthly variations of air temperature and relative humidity in urban canopy are shown in Figure 2. The average monthly maximum air temperature is observed from June to August, while the average monthly minimum air temperature is recorded from December to February. The warm period, comprising June, July, and August, is defined as the three months with the average monthly maximum air temperature.

2.2 MODEL DESCRIPTION

We developed the Upark model for the common vertical composition of "trees + shrubs + soil" in the UGS. The Upark model considers the vertical combination of "trees + shrubs + soil" and its effects on radiative transfer, turbulent energy exchange, and ET. The Upark model solves the energy and hydrology budget to calculate the air temperature, surface temperatures of vegetation leave and soil, and relative humidity. The tree canyon air space is subdivided into two layers. T_a and RH are calculated at the tree crown layer and human height layer, and the modeled energy and water vapor fluxes.

The air temperature is obtained by solving the energy budget. The energy balance equations (Equations 1 and 2) are solved separately for the tree crown layer and human height layer to calculate the air temperatures at the tree crown layer (T_{at}) and human height layer ($T_{a1.5}$):

$$QH_{atm} + QH_{1.5\to t} + QH_t + QH_{adv} = 0 \quad (1) \qquad QH_{t\to 1.5} + QH_{sh} + QH_s + QH_{adv1.5} = 0 \quad (2)$$

where QH_{atm} is the turbulent exchange of sensible heat flux between the atmosphere above the tree crown and tree crown layer (W m^{-2}); $QH_{1.5\to t}$ and $QH_{t\to 1.5}$ are the turbulent exchange of sensible heat fluxes between the tree crown layer and human height layer (W m^{-2}), where the direction of heat flux is the opposite, $QH_{1.5\to t} = -QH_{t\to 1.5}$; QH_t, QH_{sh}, and QH_s are the sensible heat fluxes from tree, shrub, and soil (W m^{-2}), respectively; and QH_{adv} and $QH_{adv1.5}$ are the sensible heat transport

by advection at the tree crown layer and human height layer (W m^{-2}), respectively.

$$T_{a1.5} = \frac{\left[T_{at} + \left(\frac{R_{nsh} - LE_{sh}}{\rho c_p} + \frac{R_{ns} - LE_s - G}{\rho c_p} + \frac{T_{r1.5}}{r_a^{adv1.5}}\right) r_a^{1.5t}\right] r_a^{adv1.5}}{r_a^{1.5t} + r_a^{adv1.5}} \quad (3)$$

where $T_{a1.5}$ is air temperature at 1.5 m above ground (°C); T_{at} is air temperature at the tree crown layer (°C); R_{nsh}, and R_{ns} are the net radiant fluxes for the shrub, and soil (W m^{-2}); LE_{sh}, and LE_s are the latent heat fluxes for the tree, shrub and soil (W·m^{-2}) calculated by the three-layer model (Li et al, 2024); $T_{r1.5}$ are the air temperatures near the UGS at 1.5 m above ground (°C), calculated using the UT&C model (Meili et al, 2020); $r_a^{adv1.5}$ is the resistances of sensible heat transport by advection at 1.5 m above ground (s m^{-1}); $r_a^{1.5t}$ is the aerodynamic resistances from 1.5 m to the tree crown (s m^{-1}); G is the soil heat flux (W m^{-2}).

The specific humidity of air is obtained by solving the water vapor budget. The water vapor balance equations (Equations 4 and 5) for the tree crown layer and human height layer are solved to calculate the specific humidity of the tree crown layer (q_{at}) and human height layer ($q_{a1.5}$):

$$QE_{atm} + QE_{1.5\to t} + QE_t + QE_{adv} = 0 \quad (4) \qquad QE_{t\to 1.5} + QE_{sh} + QE_s + QE_{adv1.5} = 0 \quad (5)$$

where QE_{atm} is the turbulent exchange of water vapor flux between the atmosphere above the tree crown and tree crown layer (kg m^{-2} s^{-1}); $QE_{1.5\to t}$ and $QE_{t\to 1.5}$ are the turbulent exchange of water vapor flux between the tree crown layer and human height layer (kg m^{-2} s^{-1}), respectively; QE_t, QE_{sh}, and QE_s are the water vapor flux from tree, shrub, and soil (kg m^{-2} s^{-1}); and QE_{adv} and $QE_{adv1.5}$ are the water vapor transport by advection at the tree crown layer and human height layer (kg m^{-2} s^{-1}).

The specific humidity is calculated based on air temperature and relative humidity:

$$q_{sat}(T_i) = 0.622\frac{e_{sat}(T_i)}{p_{atm} - 0.378e_{sat}(T_i)} \quad (6) \qquad e_{sat}(T_i) = 0.611\exp\left(\frac{17.27T_i}{T_i + 237.3}\right) \quad (7)$$

where i represents the tree crown layer or human height layer; $q_{sat}(T_i)$ is the saturated specific humidity at location i (kg kg^{-1}); T_i is the air temperature at location i (°C); RH_i is the relative humidity at location i (%); $e_{sat}(T_i)$ is the saturation vapor pressure at temperature T_i (kPa) calculated by using the Clausius–Clapeyron relation (Brutsaert, 2023); and p_{atm} is the atmospheric pressure (kPa).

The relative humidity is calculated based on the specific humidity:

$$RH_{1.5} = \frac{q_{a1.5}}{q_{sat}(T_{a1.5})} \times 100 \quad (8)$$

where $RH_{1.5}$ is the relative humidity at 1.5 m above ground (%); $q_{a1.5}$ is the specific humidity at 1.5 m above ground (kg kg^{-1}); and $q_{sat}(T_{a1.5})$ is the saturated specific humidity at 1.5 m above ground (kg kg^{-1}).

2.3 CASE SETTING

Based on the urban morphology classification of 141,375 urban blocks in 63 major cities in China, the primary urban block types in Chinese cities are predominantly medium-rise, high-density areas (3 < number of floors < 7, building density > 0.25) (Long et al. 2019). Specifically, in Guangzhou, medium-rise high-density (33%), low-rise high-density (number of floors < 3, building density > 0.25; 27%), and high-rise high-density areas (number of floors > 7, building density > 0.25; 22%) dominate. In this study, the buildings in the upwind urbanized area are modeled with six floors, each having a floor height of 3 m, resulting in a building height (h_b) of 18 m. Additionally, the building density in most urban blocks in China ranges between 0.22 and 0.52 (Long et al. 2019). To account for the impact of varying building densities, this study sets the

building density (ρ_b) between 0.2 and 0.6. The building width (w_b) is set at 10 m. The road width (w_r) under different conditions is calculated based on ρ_b and w_b, $w_r = w_b/\rho_b - w_b$.

The built-up area will be simulated using the UT&C model (Meili et al, 2020), with material parameters configured as shown in Table 1.

Table 1. Parameters in the UT&C model.

Parameter description	Values	Parameter description	Values
α_g, albedo of ground (-)	0.2	E_t, emissivity of tree canopy (-)	0.95
α_w, albedo of wall (-)	0.35	λ_g, thermal conductivity of impervious ground (W K^{-1} m^{-1})	1.2
α_t, albedo of tree canopy (-)	0.2	λ_w, thermal conductivity of wall (W K^{-1} m^{-1})	0.57
E_g, emissivity of ground (-)	0.95	Cv_g, volumetric heat capacity of impervious ground (MJ K^{-1} m^{-3})	1.5
E_w, emissivity of wall (-)	0.95	Cv_w, volumetric heat capacity of wall (MJ K^{-1} m^{-3})	1.0

The UGS in this study consisted of trees and shrubs. The morphological parameters of trees and shrubs were derived from field measurements conducted in a small park on the Wushan Campus of South China University of Technology. Specifically, the heights of trees and shrubs were set at 15 m and 0.6 m, respectively, with corresponding leaf area indices of 4.5 m^2 m^{-2} and 3.5 m^2 m^{-2}. The size of the UGS (windward distance) was varied from 100 m to 2000 m. The UGS microclimate model is described below, with temperature and humidity data calculated by the UT&C model for the built-up area serving as boundary conditions for advection source terms.

2.4 THRESHOLD VALUE OF EFFICIENCY (TVOE)

The TVoE is a metric designed from a cost perspective to evaluate the trade-off between microclimate regulation efficiency and the size of UGS (Epstein et al. 2017). In the microclimate regulation efficiency curve, the cooling and humidifying effects initially increase significantly as the scale of UGS expands. However, beyond a certain point, the growth in cooling and humidifying effects becomes marginal with further increases in UGS size. This critical point, referred to as the TVoE, is defined as the point where the slope of the microclimate regulation curve equals 1 or -1, as illustrated in Figure 3. To calculate the TVoE: First, the variables (air temperature/relative humidity and UGS scale) are non-dimensionalized. The non-dimensionalized data are then fitted to a function to determine the microclimate regulation efficiency curve and identify the point where the slope equals 1 or -1. Finally, the identified point is re-dimensionalized to determine the TVoE.

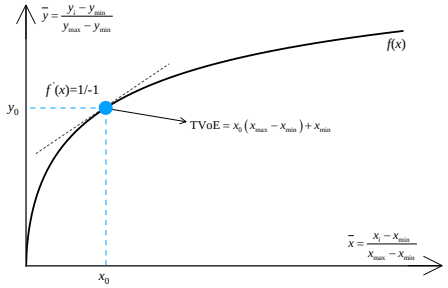

Figure 3. Schematic diagram of TVoE.

3 RESULTS AND DISCUSSION

3.1 AIR TEMPERATURE IN THE UGS AND THE TVOE

During the daytime in the warm period (defined as the period when the monthly mean hourly solar radiation exceeds 15 W m^{-2}, corresponding to 7:00~19:00), the relationship between air temperature and distance from the UGS boundary is shown in Figure 4(a). The solid lines represent the average air temperature under five different building density cases, with the shaded areas indicating ±1.5 standard errors (SE). As the distance from the UGS boundary increases, air temperature decreases rapidly at first but gradually stabilizes. Within the initial 100 m from the UGS boundary, the temperature decreases by 0.9 ℃~1.3 ℃, while at 2000 m, the reduction is only

0.003 ℃~0.01 ℃. This indicates that UGS has an optimal threshold for mitigating heat from surrounding built-up areas.

The cooling effect of UGS is also influenced by the building density (ρ_b) of the upwind built-up area. At a distance of 100 m from the UGS boundary, the temperature difference between the cases of ρ_b = 0.6 and ρ_b = 0.2 is 1.3 ℃, whereas at 2000 m, the difference is only 0.05 ℃. This suggests that the area near the UGS boundary is more affected by the urban morphology of the upwind built-up area. At 100 m, UGS in the ρ_b = 0.6 case exhibits a higher cooling effect of 1.3 ℃. This is because the high-density built-up area (ρ_b = 0.6) provides warmer and drier air, which enhances the transpiration effect of vegetation within the UGS.

Following the method outlined in Section 2.4 for determining the TVoE, the trade-off value of UGS in mitigating heat from upwind built-up areas was identified, excluding fitting formulas with R^2 < 0.8 and anomalous TVoE values, as shown by the boxplot in Figure 4(a). The TVoE exhibits some variability due to background climate conditions but is relatively concentrated. For the ρ_b = 0.2 case, 10%~90% of TVoE values range from 482 m to 644 m. Higher building density cases result in higher TVoE values, indicating that larger UGS scales are needed to mitigate heat. However, the differences between TVoE values under varying building density cases are relatively small, with averages ranging from 569 m to 617 m and medians between 565 m and 606 m. A value of 600 m is selected as the TVoE for mitigating heat from upwind built-up areas. At this distance, air temperature decreases by 2.2 ℃~3.3 ℃, with differences between cases of up to 0.6 ℃.

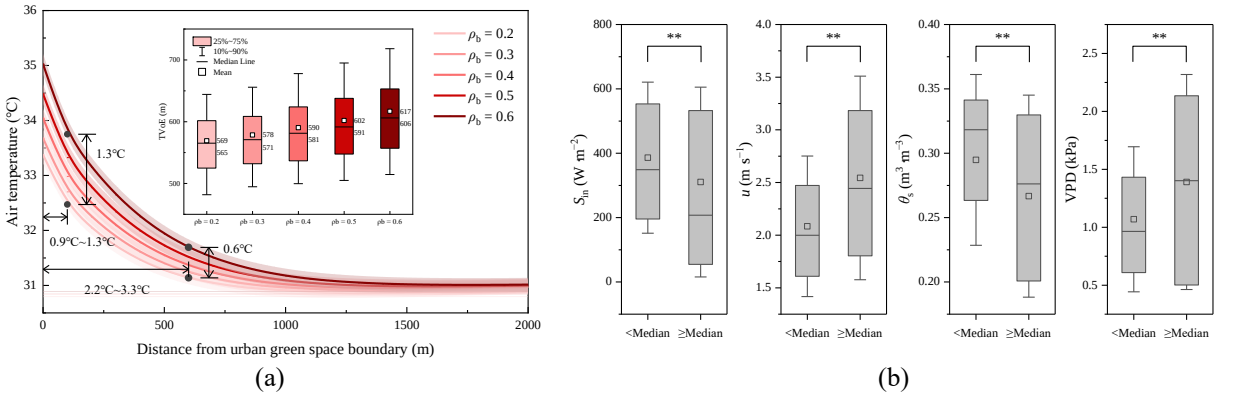

Figure 4. Daytime urban green space mitigation of hot air in upwind built-up areas. (a) changes in air temperature and TVoE within urban green spaces; (b) impact of background meteorological conditions on TVoE.

The TVoE values were divided into two groups based on the median: TVoE < Median and TVoE ≥ Median. A Mann-Whitney U test was conducted to analyze whether the background climate conditions differed significantly between the two groups, as shown in Figure 4(b). The results revealed that solar radiation and soil moisture content were significantly higher for TVoE < Median compared to TVoE ≥ Median ($P<0.01$). Higher solar radiation and soil moisture content promote vegetation transpiration, which enhances cooling effects, leading to lower TVoE values under such background climate conditions. Conversely, wind speed was significantly higher for TVoE ≥ Median compared to TVoE < Median ($P<0.01$). Under higher wind speeds, advection effects become more pronounced, making UGS more susceptible to the influence of upwind built-up areas, thereby resulting in higher TVoE values. It is noteworthy that the vapor pressure deficit (VPD) for TVoE ≥ Median was also significantly higher than for TVoE < Median ($P<0.01$). Although higher VPD generally enhances vegetation transpiration, similar to solar radiation and soil moisture, thereby promoting cooling effects, the VPD in this study represents that of the upwind built-up area. This elevated VPD near the UGS boundary facilitates transpiration in vegetation located in the first 100 m grid of the UGS, leading to more pronounced cooling and

humidifying effects in this zone. Given that the model considers the influence of preceding grids on subsequent grids, stronger cooling and humidifying effects in the initial grid reduce the VPD in subsequent grids. This reduction weakens vegetation transpiration, resulting in higher TVoE values under such conditions.

During the nighttime in the warm period, the TVoE of UGS in resisting heat from upwind built-up areas is shown in Figure 5. Similar to daytime conditions, upwind built-up areas with higher building densities exhibit higher TVoE values. However, the influence of building density on TVoE is more pronounced at night compared to during the day. The average TVoE values at night range between 720 m and 928 m, with a difference of 208 m, whereas the daytime difference is only 48 m. The median TVoE values at night range between 669 m and 919 m, with a difference of 250 m, compared to a daytime difference of 41 m. Due to reduced transpiration by vegetation at night, the TVoE values for nighttime temperatures in UGS are higher than during the day. The difference in average TVoE values between day and night across various building density cases is between 151 m and 311 m, with median differences ranging from 104 m to 313 m. This is particularly evident in the case of a building density of 0.6, where the day-night disparity in TVoE is more significant.

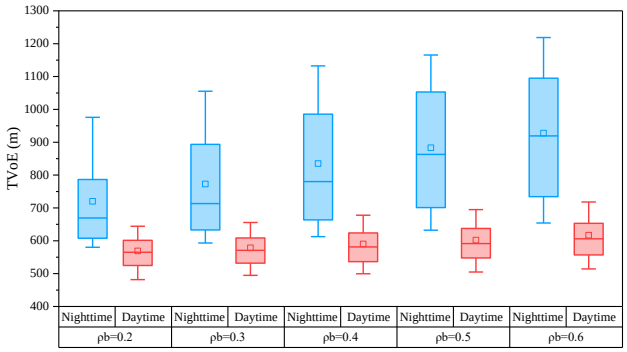

Figure 5. Efficiency thresholds for mitigating hot air from upwind built-up areas in urban green spaces during daytime and nighttime.

3.2 HEAT INDEX OF THE UGS

The analysis indicates that UGS have significant potential for mitigating heat, especially in areas near the boundaries of UGS. This capability is beneficial for reducing heat exposure and improving the outdoor thermal environment. However, RH is also a critical factor influencing thermal comfort. Unfortunately, while UGS rapidly cooling air temperature, this phase is also accompanied by a sharp increase in RH, which may negatively impact the outdoor thermal environment. To evaluate the combined effects of air temperature and RH on human thermal comfort, we selected the heat index (HI) for analysis. HI is an indicator used to assess the risk of heat exposure, which accounts for the combined effects of air temperature and RH, thereby quantifying the human perception of temperature. The HI is a function of T_a and RH. The formula to calculate HI is commonly given as:

$$\begin{aligned} HI = {} & -8.784695 + 1.61139411 \times T_a + 2.338549 \times RH - 0.14611605 \times T_a \times RH - 1.2308094 \times 10^{-2} \times T_a^2 \\ & -1.6424828 \times 10^{-2} \times RH^2 + 2.2211732 \times 10^{-3} \times T_a^2 \times RH + 7.2546 \times 10^{-4} \times T_a \times RH^2 - 3.582 \times 10^{-6} \times T_a^2 \times RH^2 \end{aligned} \quad (10)$$

HI is classified according to Ref. (Blazejczyk et al. 2012), as shown in Table 2.

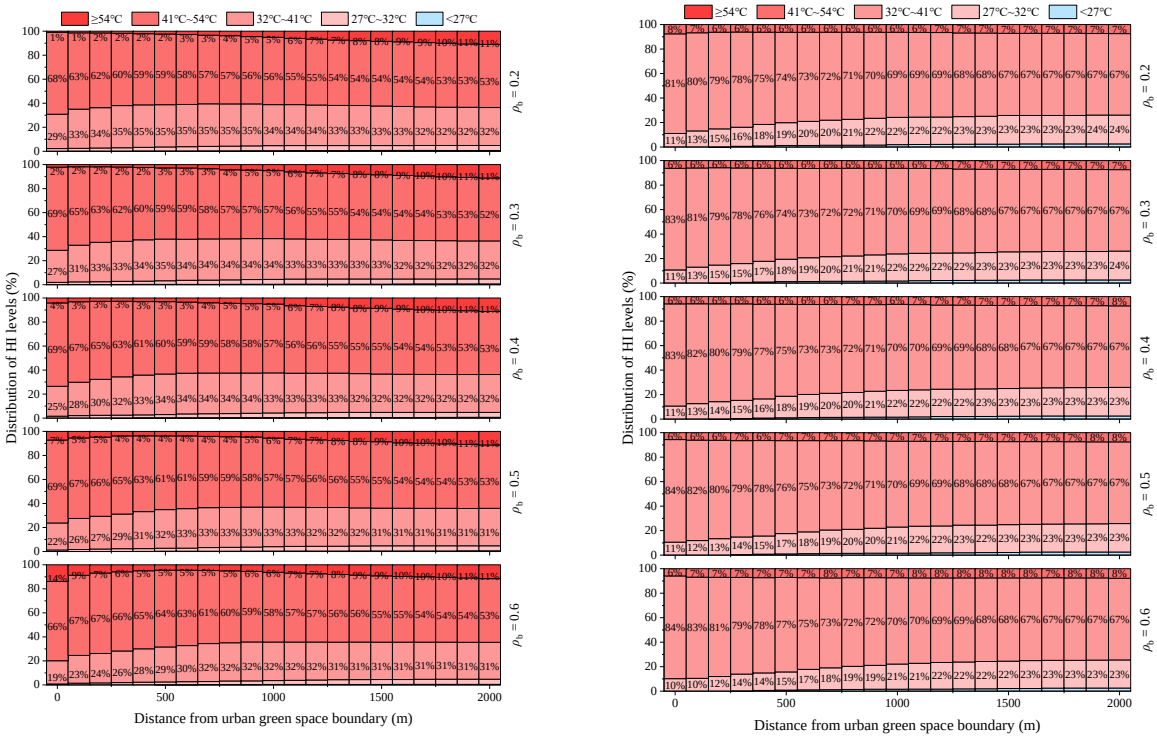
Table 2. Classification of HI levels.

Classification	Caution	Extreme caution	Danger	Extreme danger
Extreme caution	27–32 ℃	32–41 ℃	41–54 ℃	≥54 ℃

The daytime distribution of HI levels is shown in Figure 6(a). In all five cases, instances of HI < 27 ℃ were observed, but the duration was limited to a maximum of 8 hours, accounting for

only 0.7% of the total warm period daytime hours (1196 hours). Among all HI levels, the Danger category (41 ℃~54 ℃) had the highest proportion, exceeding 50% in all cases, followed by the Extreme Caution category (32 ℃~41 ℃), which accounted for 20%–30%. This highlights the harsh outdoor thermal environment in Guangzhou during the warm period. UGS significantly mitigate the outdoor thermal environment, primarily by reducing the proportion of the Danger category. At a distance of 0 m from the urban green space boundary, the proportion of Danger ranged from 66% to 69%. This proportion decreased to 58%~63% at the thermal vegetation offset effect (TVoE, 600 m) and further dropped to 52%~53% at 2000 m. However, the proportion of Extreme Caution increased correspondingly, particularly under the case with a building density of 0.6. Unfortunately, urban green spaces also increased the proportion of the Extreme Danger category, especially under the building density case of 0.2, where the proportion rose from 1% to 11% at a distance of 2000 m from the green space boundary.

The nighttime distribution of HI levels is shown in Figure 6(b). The frequency of HI < 27 ℃ was slightly higher at night than during the daytime, with a maximum duration of 26 hours, accounting for 2.6% of the total nighttime hours (1012 hours). At night, HI levels predominantly fell within the Extreme Caution category, accounting for 70%–80%, reflecting a pronounced "hot night" phenomenon in Guangzhou. Urban green spaces primarily reduced the proportion of the Extreme Caution category and increased the proportion of the Caution category (27 ℃~32 ℃). Across the five cases, at a distance of 2000 m from the green space boundary, the Caution category increased by 12%~13%, while at the TVoE, the proportion increased by 7%~9%. However, urban green spaces also slightly increased the proportion of the Danger category, though the increment was relatively small. UGS effectively reduce HI levels and contribute positively to improving the outdoor thermal environment. However, it is important to note that the rapid cooling effect of urban green spaces is accompanied by a rapid increase in RH, which may lead to intensified heat stress.



(a) (b)

Figure 6. The distribution of HI levels. (a) daytime; (b) nighttime.

4 CONCLUSION

Urban green spaces (UGS) play a crucial role in mitigating urban heat, with the cooling effect being most pronounced near the UGS boundary. The optimal threshold for UGS to effectively counteract heat from surrounding built-up areas is around 600 m. At this distance, air temperature decreases by 2.2 ℃–3.3 ℃, with variations of up to 0.6 ℃ depending on building density. The cooling effect is more effective during the day, with average temperature differences between high-density (ρ_b = 0.6) and low-density (ρ_b = 0.2) areas reaching up to 1.3 ℃ at 100 m, while the difference decreases to 0.05 ℃ at 2000 m. The TVoE values for mitigating heat range from 482 m to 644 m for lower-density areas, while they range from 569 m to 617 m in higher-density areas. At night, the TVoE increases by 151 m to 311 m compared to daytime values, with higher building densities contributing to more significant differences. Additionally, UGS reduce the proportion of extreme heat (Danger levels) from 66%–69% at 0 m to 52%–53% at 2000 m. However, in low-density areas, UGS may slightly increase the proportion of extreme danger levels.

SUMMARY

This study evaluates urban microclimates using a modelling chain that integrates the MLUCM BEP+BEM parameterization with the ENVI-met CFD model. A case study in a residential district of Lecce, Italy, examines three simulation scenarios with varying meteorological inputs. Cases 1 and 2 use urban meteorological station data, while Case 3 employs outputs from the MLUCM BEP+BEM model. Results indicate that Case 3 effectively captures daily temperature trends, improving accuracy in built-up areas, though discrepancies persist in open spaces. The study confirms that enhanced urban parameterization improves microclimate simulations but highlights challenges in spatial variability. This approach provides a scalable framework for assessing urban microclimates and evaluating climate mitigation strategies.

Keywords: Urban Microclimate, MLUCM BEP+BEM, ENVI-met.

1. GENERAL INSTRUCTIONS

Cities are facing extreme heat phenomena such as Heat Waves (HWs), exacerbated by the Urban Heat Island (UHI) which is linked to issues such as thermal discomfort and various health problems (Oke, 2017; McRae et al., 2020). These effects are caused by the urban geometry composed of tall buildings, limited green areas and a dense urban fabric (Pappaccogli et al., 2018). Mitigating these effects through urban planning is difficult, especially due to the complexity of the interaction between the built urban environment and the surrounding atmosphere (McRae et al., 2020). In this context, numerical models capture key urban effects by linking urban geometry characteristics with energy, mass, and momentum exchanges within the Urban Boundary Layer (UBL). These models, known as Urban Climate Models (UCMs), are used to simulate the coupled evolution of atmospheric and urban surface climates. They are conventionally classified into micro/local-scale and mesoscale models, though they can be coupled, with one being used to provide boundary

conditions for the other. Computational Fluid Dynamics (CFD) models, for example, simulate airflow around obstacles at the micro/local scale, while mesoscale UCMs focus on the evolution of the UBL due to interactions with the underlying urban surface. The domain of mesoscale models extends both vertically into the Atmospheric Boundary Layer (ABL) and horizontally beyond the city edge, with grid cells typically between hundreds of metres to 1km.

This study aims to analyse the microclimate of a typical Mediterranean city, Lecce (southern Italy), using a modelling approach that bridges mesoscale dynamics and microscale effects. To achieve this, a modelling chain is proposed, integrating the ENVI-met model with data from ground meteorological stations and the recently released MLUCM BEP+BEM urban parameterization scheme. BEP+BEM scheme coupled with a 1-D column model of the urban canopy flow, describes the vertical arrangement of the urban fabric considering the distribution of heat, humidity and momentum sources in the urban canopy but also provides a perspective on the urban energy balance by estimating the internal energy consumption of buildings through heating and cooling (Pappaccogli et al., 2024). The modelling chain, combining MLUCM BEP+BEM with ENVI-met, assesses whether mesoscale model outputs can replace in-situ observations as inputs for CFD models to better represent urban microclimates. This approach enhances microclimate modelling through result validation while ensuring scalability for broader applications.

2. METHODOLOGY

2.1. Study area

The study area is in the city of Lecce (southern Italy), specifically in the San Pio district. Lecce (UTM coordinates: 40°21.0’7.24” N, 18°10.0’8.9” E) is a city of about 95,000 inhabitants (http://demo.istat.it/pop2019/index.html), and is situated on a flat territory approximately 40-50m above sea level (Fig. 1a). The city experiences a warm Mediterranean climate, classified as Csa according to the Köppen–Geiger system. The urban morphology of the San Pio district consists primarily of two- to three-story buildings and narrow street canyons (Gatto et al., 2020). The area is predominantly residential buildings, with some schools and a few commercial establishments. Urban green spaces are limited, while private green areas are prevalent. Impervious surfaces, which cover a larger area than green spaces mainly consist of concrete sidewalks, asphalt roads and parking lots. Temperature and humidity measurements are recorded by a waterproof data-logger (Tinytag Plus 2-TGP-4505, Gemini Data Loggers Ltd., Chichester, West Sussex, UK), which is equipped with air temperature and relative humidity probes with an accuracy of ±0.3°C and ±3%, respectively, at 25°C. The thermo-hygrometer is installed approximately 4m above ground level on the balcony exposed to SE, surrounding a small concrete-paved square (Fig. 1b). Here, numerous trees, primarily *Quercus ilex* L. and *Pinus pinea* L., ranging from 5 to 8m in height and planted in flowerbeds with sandy-clayey soil. The measurements recorded by the thermo-hygrometer are used to validate the output meteorological results from the microclimate simulations performed with ENVI-met.

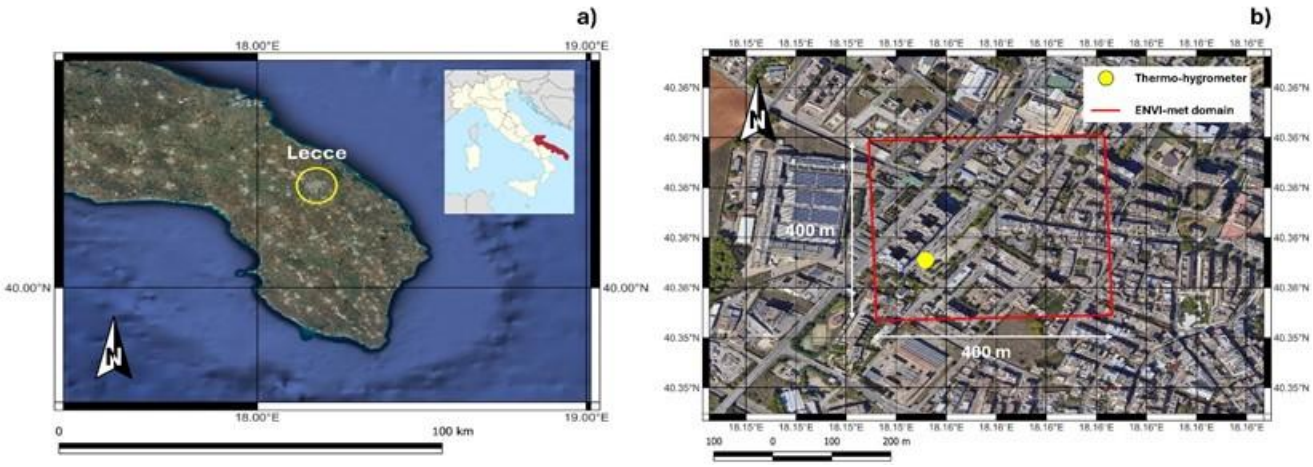

Figure 1. a) Salento Peninsula. b) Study area with the 400 x 400 m domain represented and the position of the thermo-hygrometer.

2.2. Meteorological data and modelling setup in ENVI-met

Meteorological data were collected from two stations in Lecce. The Ateneo station, operated by Fondazione OMD Osservatorio Meteo Milano Duomo, is located 11m above ground level (40°21'22.22"N, 18°10'4.59"E) and records temperature, relative humidity, wind speed and direction, and precipitation. The ARPA station, managed by Environmental Protection Regional Agency, is positioned 13ms above ground level (40°20'44"N, 18°10'37"E) and measures solar radiation. The two stations are 1.1km and 2.2km away from the study area in the E and SE directions, respectively. Measurements from 15 July to 15 August 2024 were processed to obtain a mean daily cycle of a typical summer day for each meteorological variable based on data recorded at 30-minute intervals. These processed data were then used as meteorolgical input for ENVI-met 5.1.0. August 1st was selected as the representative day of the chosen period; the first 6 hours were considered as initialization time (spin up). A geometric model of the 400 × 400 m study area was created in QGIS and imported into ENVI-met, where the grid was set to 225 × 225 × 35 cells, with a resolution of 2 m and 5 nesting grids (Fig. 2). A 10% telescoping factor was applied from ground level, extending the model domain to a maximum height of 160 m. The tallest building (30m), leaves a vertical gap of 130 m between its top and the model upper boundary, ensuring sufficient space above the urban area. Three simulation cases with different meteorological inputs were analyzed, and their output results were compared (Table 1). The roughness length (z_0) was set to 1m for all cases. Case 1 used measurements only from the "Ateneo" station; Case 2 used measurements from both the "Ateneo" and "ARPA" stations; and Case 3 used meteorological data provided by the MLUCM BEP+BEM model.

Table 1. Three simulation cases using different ENVI-met meteorological inputs.

Case	ENVI-met meteorological input
1	Air temperature (°C); Relative humidity (%); Wind speed (m/s); Wind direction (°); Precipitation (mm)
2	Air temperature (°C); Relative humidity (%); Wind speed (m/s); Wind direction (°); Precipitation (mm); Downward short-wave radiation (W/m^2)

3	Direct downward short-wave radiation (W/m^2); Diffuse downward short-wave radiation (W/m^2); Downward long-wave radiation (W/m^2); Air temperature (°C); Relative humidity (%); Wind speed (m/s); Wind direction (°); Precipitation (mm)

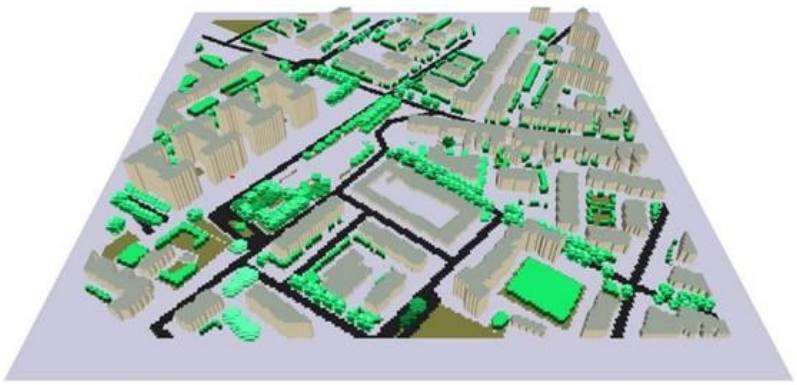

Figure 2. 3D model reconstruction in ENVI-met.

2.3. MLUCM BEP+BEM and ENVI-met model chain

The methodology involves the use of a modelling chain consisting of the recently released MLUCM BEP+BEM urban parameterization model (Pappaccogli et al., 2025) and the ENVI-met neighborhood-scale CFD model (Fig. 3). MLUCM BEP+BEM incorporates the vertical turbulent diffusion scheme of Santiago and Martilli (2010) with the Building Effect Parameterization (BEP, Martilli et al., 2002) and the Building Energy Model (BEM, Salamanca et al., 2009). It features improved turbulent length scales and eddy diffusivity coefficients that account for atmospheric stability, along with a detailed representation of urban vegetation, including green spaces and street trees. Designed for offline applications, the model maintains low computational demands, making it well-suited for independent simulations, coupling with climate projections or ERA5 reanalysis. The MLUCM BEP+BEM properly describes the vertical layout of the urban fabric considering the distribution of heat, humidity and moment sources throughout the urban canopy layer. The model also estimates energy consumption within buildings for both cooling/heating systems, providing a comprehensive perspective on the urban energy balance at neighborhood scale. ENVI-met is a CFD (Computational Fluid Dynamics) model that simulates at high spatial (0.5-10m grids) and temporal (10s) resolutions. The meteorological inputs required for the initial and boundary conditions of ENVI-met can come from observations at a nearby site or from a mesoscale meteorological model such as Weather Research and Forecasting (WRF) model (McRae et al., 2020).

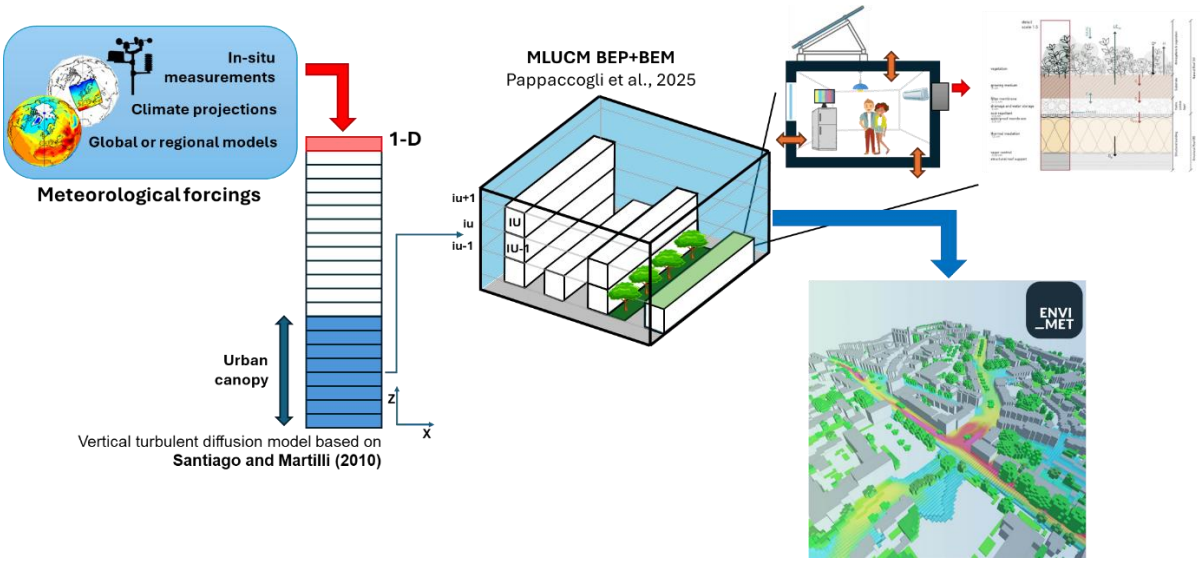

Figure 3. Modelling chain composed by: ERA5 reanalysis or climate projections data, MLUCM BEP+BEM/ENVI-met model.

3. RESULTS

3.1. Model forcings and observations

Fig. 4 shows the profiles of the meteorological forcings used as input in ENVI-met for the three simulated cases. In all cases a north-westerly wind was set for the wind direction and the absence of precipitation. The values of all input variables are every 30 minutes, as required by ENVI-met. In Fig. 4a the temperature values for case 1 and 2 are slightly lower than case 3 for most of the day except for the early morning hours (from about 06:00 LT to 10:00 LT). The comparison shows that the output values of the MLUCM BEP+BEM model (case 3) are similar to the input values coming from the data of the Ateneo station. The profiles of cases 1, 2 and 3 reach a maximum at 14:00 LT of 32.94°C and 33.63°C, respectively; cases 1 and 2 have a minimum of 25.53°C at 04:00 LT while case 3 has a minimum of 26.12°C at 05:00 LT.

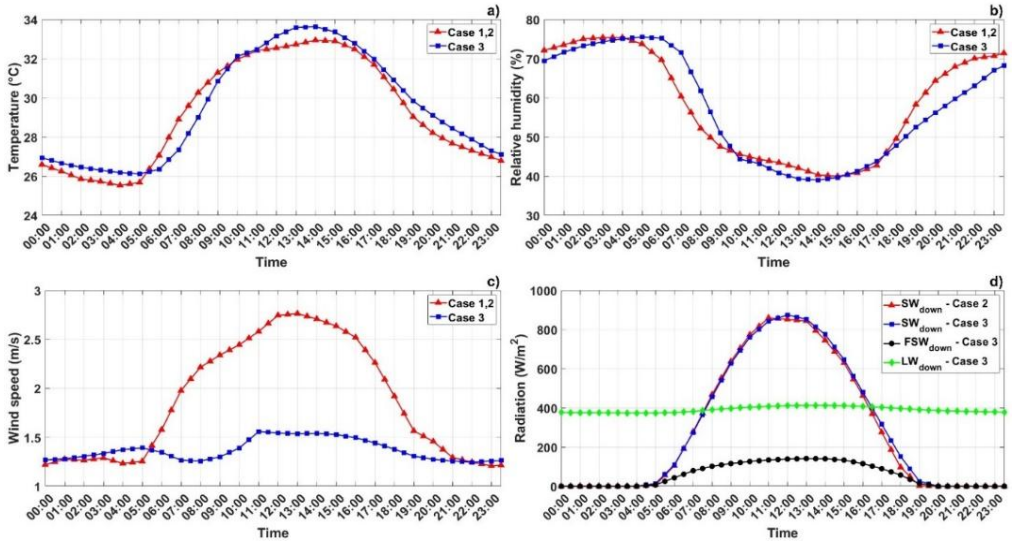

Figure 4. ENVI-met input meteorological forcing profiles based on daily pattern obtained from the selected period for the three cases every 30 minutes. a) Air temperature (°C); b) Relative humidity (%); c) Wind speed (m/s); d) Radiative components.

Relative humidity profiles (Fig. 4b) are similar during the daytime, reaching their minimum in the central hours and their maximum at night, ranging between 40% and 70%. Slight discrepancies occur in the early morning (05:00 LT – 09:00 LT) and evening (06:00 LT – 00:00 LT), corresponding to air temperature variations. Fig. 4c highlights a difference in wind intensity between 06:00 LT and 08:00 LT, particularly during midday. In cases 1 and 2, wind speed peaks at around 3 m/s, whereas in case 3, it is roughly half that value. In contrast, wind speeds between 21:00 LT and 05:00 LT are similar across all cases. These discrepancies arise from differences in data sources: cases 1 and 2 use data from the Ateneo station, representing wind intensity at roof level, while case 3, based on MLUCM BEP+BEM data, accounts for drag effects caused by buildings in the study domain, despite being taken at the same vertical level. Fig. 4d shows different radiative components used as input for cases 2 and 3. The SWdown profiles for cases 2 and 3 are very similar, with a maximum of about 860 W/m^2 at noon, whereas FSWdown reaches values of around 140 W/m^2 during the central hours, while LWdown assumes values between 376 W/m^2 and 412 W/m^2.

3.2. Analysis of modelling outputs

Fig. 5 presents a comparison between the simulation results from ENVI-met and the observed temperature and relative humidity recorded by the thermo-hygrometer. The observed temperatures are higher than three simulated cases from 00:00 LT to 09:00 LT, while they are significantly lower during the central hours (11:00 LT-17:00 LT), when the differences between simulations and observations vary on average between 1.31°C (case 1), 0.84°C (case 2) e 1.43°C (case 3). After 18:00 LT, temperature differences are minimal, with observed values falling between case 3 (highest) and cases 1 and 2 (lowest). In cases 1 and 2, these discrepancies remain small during the early nighttime hours, while in case 3, they progressively reduce and disappear by midnight.

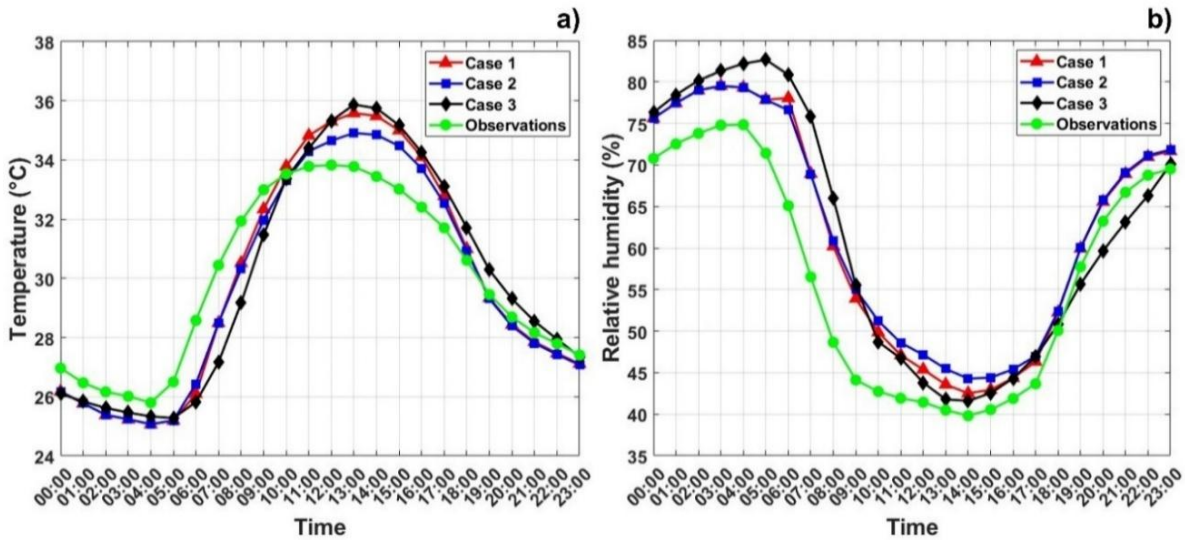

Figure 5. Air temperature (a) and relative humidity (b) profiles obtained from the three simulated cases compared with the observations.

It is worth pointing out that the rapid rise in temperatures observed during the early morning hours is probably due to the positioning of the thermo-hygrometer, which is located to the south-facing wall of the building. Similarly, temperatures decrease more rapidly due to the shading of the area surrounding the building, which is reflected in a peak temperature at 12 noon (average of 33.9°C). To quantitatively assess the model's performance, the mean error (BIAS) and root-mean-square error (RMSE) were calculated. As shown in Tab. 2, case 1 exhibits the lowest RMSE, indicating the smallest overall error. However, it also has the most negative BIAS, suggesting a greater tendency to underestimate values. In contrast, case 3 has the highest RMSE but a BIAS close to zero, meaning that despite discrepancies in daily minimum and maximum values, it accurately captures the overall daily temperature trend on average.

Table 2. RMSE and BIAS for the three cases.

	Temperature (°C)		Relative humidity (%)	
Case	RMSE	BIAS	RMSE	BIAS
1	1.23	-0.05	6.02	5.01
2	1.04	-0.24	6.38	5.53
3	1.54	0.01	7.93	5.01

In Fig. 5b the observed relative humidity (RH) values are lower than the three simulated cases from 00:00 LT to 13:00 LT, while they become similar from 13:00 LT to 23:00 LT, ranging between 40% to 75%. From 00:00 LT to 09:00 LT the observed values are lower than the three simulated cases on average of 7% (case 1 and 2) and 11% (case 3), whereas the three profiles are similar for the rest of the day. Tab. 2 reports for RH a lower RMSE value for case 1 and a higher one for case 3. The BIAS values are around 5% for all three cases, which means that the simulated results tend to overestimate the observations.

Fig. 6 illustrates the differences in air temperature simulations between case 2 and case 3 at pedestrian level (2m above ground). This analysis compares case 2, which best matches the observed measurements, with case 3 to assess the similarity of model results at 04:00 LT (Fig. 6a) and 13:00 LT (Fig. 6b), corresponding to the minimum and maximum air temperature values, respectively. At 04:00 LT, smaller differences are observed in a limited portion of the study area, ranging from -0.30 °C to over -0.16 °C, while the rest of the domain exhibits more pronounced discrepancies. In this period, case 3 generally shows higher temperatures than case 2, bringing its values closer to the observations. At 13:00 LT, smaller differences are found in the southern part of the domain (ranging from -0.88°C to -0.56°C), while more significant discrepancies appear towards the northern edge (exceeding -1.00 °C). According to the mean daily pattern, larger differences occur during this hour (13:00 LT) due to notable variations in input temperature and wind speed intensity. Notably, both during the day and at night, temperature differences are smaller in areas with taller buildings and street canyons. This suggests that the MLUCM BEP+BEM meteorological forcings are more representative of denser urban environments.

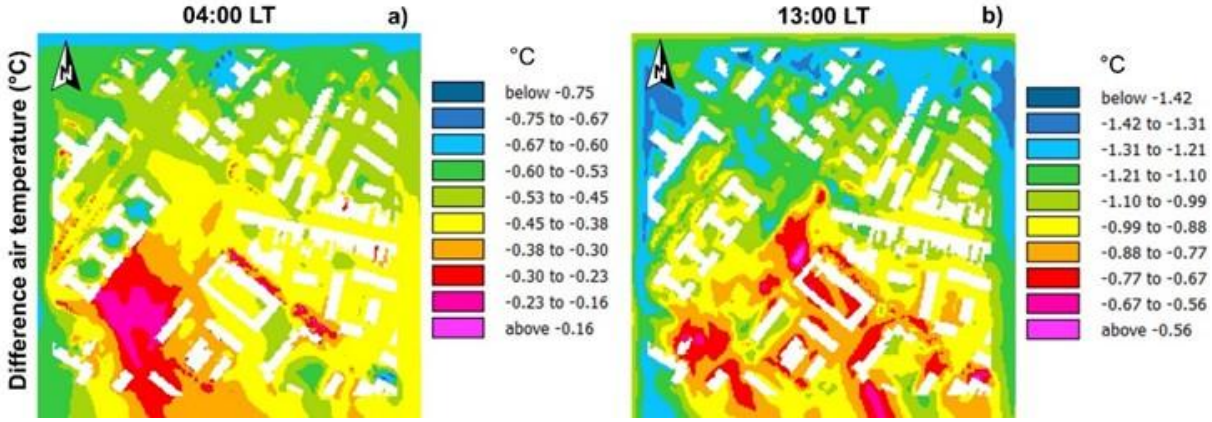

Figure 6. Difference in air temperature at 2m a.g.l. simulations between case 2 - case 3 for 04:00 LT (a) and for 13:00 LT (b).

4. CONCLUSIONS

This study emphasizes the importance of integrating different modelling approaches to improve urban microclimate simulations. By coupling the MLUCM BEP+BEM parameterization with the ENVI-met model, it assessed whether a mesoscale-based model can replace in-situ observations. The case study in Lecce demonstrated the potential of this modelling chain to capture summertime climate dynamics. Among the simulations, case 3 produced a temperature trend closest to observations. Wind speed and radiative inputs affected accuracy, with case 3 better accounting for building-induced drag in dense areas. Despite advancements, challenges remain in capturing microclimatic variability, requiring refined input data and model parameters. While the current results may not fully isolate the added value of MLUCM BEP+BEM compared to other modelling approaches, this urban parameterization enabled a more realistic representation of building energy exchanges and urban morphology. Future work will aim to better quantify its comparative benefits through targeted analyses and complementary indicators. The study provides a scalable approach for analysing extreme heat events and improving urban climate resilience.

ABSTRACT

Buildings account for a significant portion of overall energy consumption, especially in urban areas with high-density residential structures like Hong Kong. Reducing energy usage in residential buildings is a key objective in pursuing carbon neutrality. Statistics show that over 20% of household energy consumption is attributed to hot water systems, highlighting substantial opportunities for energy conservation during showering activities. Therefore, understanding occupants' showering behavior and mitigating energy consumption during showering is essential. This study employed a mixed-methods investigation that included a discrete choice experiment and collages making of ideal showering scenarios to explore the showering behaviors of occupants, particularly their comfort requirements. Twenty-one subjects, aged 19 to 70, participated in the focus group and completed the discrete choice experiment. Both qualitative and quantitative data (including transcripts of the focus group discussions) were analyzed using SPSS and QDA Miner Lite, respectively. The results indicated that participants prioritized thermal sensation, making air temperature the most influential factor in their showering setting preferences. Additionally, water flow rate and showering duration also significantly impacted their decisions. These findings provide empirical support for using visual methods in showering environment research, facilitating a deeper understanding of the diverse showering behavioral patterns related to energy consumption and comfort. Furthermore, the insights gained from this study offer evidence for designing customized bathroom environments that meet the specific needs of occupants, ultimately reducing energy consumption while maintaining thermal comfort.

Keywords: Showering behaviour, shower room environment, showering thermal comfort.

1. INTRODUCTION

Buildings account for significant global energy consumption, especially in densely populated urban areas like Hong Kong. According to statistics, buildings consume over 90% of Hong Kong's electricity, which corresponds to approximately 60% of the region's carbon emissions (Wang et al., 2018). A survey on showering behavior revealed that residents in Hong Kong shower an average of 1.4 times per day, significantly higher than in other parts of the world. The government report showed that domestic freshwater consumption constitutes 54% of the total water usage in Hong Kong (Water Supplies Department, 2014), with more than 40% of this being used for

showering (Water Supplies Department, 2020). Additionally, Wan and Yik (2004) found that electricity consumption for water heaters accounts for nearly half of the total electricity used per household. These findings highlight the considerable potential for energy savings during shower times in Hong Kong.

Occupants' behaviour, especially their interactions with building systems, is one of the crucial factors that influence the energy consumption of buildings (Ebuy et al., 2023). Previous studies demonstrated a significant correlation between occupant habits and energy consumption, highlighting the need for tailored energy efficiency measures (Ahmed et al., 2023). However, most of these studies focused on adjusting HAVC or lighting systems (Liu & Gou, 2024). Very little research has focused on the specific context of showering behaviours and their impact on energy consumption. Moreover, occupant behaviour is often unpredictable, leading to fluctuations in energy use and thermal comfort levels (Yan et al., 2023).

Understanding the patterns of occupant showering behaviours is crucial for developing effective strategies to reduce water and energy usage, thereby contributing to sustainability efforts in urban environments. Therefore, this study aims to investigate building occupants' showering behaviours to identify key patterns influencing energy consumption and water usage. By analyzing these patterns, this study seeks to provide empirical support for designing customized bathroom environments that meet the specific needs of occupants and actionable suggestions for encouraging occupants to change their showering behaviour towards a more sustainable lifestyle, ultimately reducing the overall environmental impact of residential and commercial buildings.

2. METHODS

2.1 Study design and preparation

A mixed-methods approach was employed in this study, incorporating both qualitative and quantitative data collection techniques, namely, Focus Group Discussion (FGD) and Discrete Choice Experiment (DCE). Before the FGD, a sensitization process was implemented to prepare participants for the discussion. Following the methods outlined in a previous study by Otize et al. (2022), all participants received a package 7-8 days before the FGD. This package included a hygrothermograph, a booklet, a pen, and stickers with words related to comfort in showering. Participants were asked to engage in several weekly daily activities, including self-introductions, completing a questionnaire survey about their showering preferences, describing a comfortable showering experience, etc. These preparatory activities aimed to help participants reflect on and explore the features of their showering behaviour.

2.2 Focus group discussion

The FGD was held in a multi-functional room at The Hong Kong Polytechnic University. Participants were divided into groups of 5 to 6 individuals. Two researchers facilitated the discussion: one served as the moderator while the other took notes and photographs. The focus group comprised five parts: introduction, discrete choice experiment (DCE) regarding showering preferences, sharing experiences related to comfort in showering, collage creation, and the presentation of the collages. The entire process lasted approximately one hour (see Figure 1). During the experience sharing and presentations, participants' voices were recorded. After the

introduction, participants were asked to sign a consent form, which informed them that their voices would be recorded and assured them that the data would remain confidential and used solely for this study.

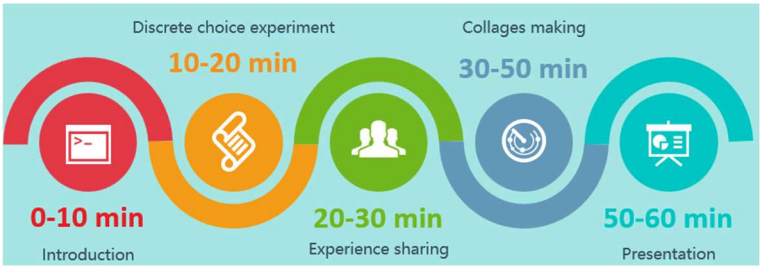

Figure 1. Focus group flow chart.

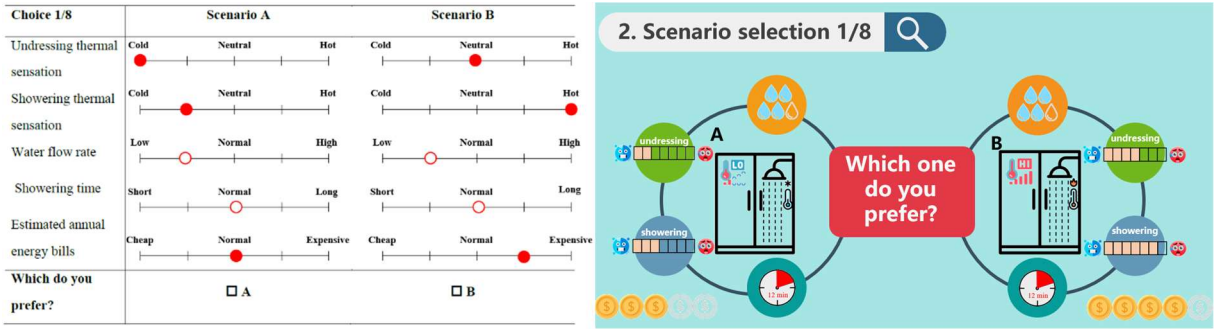
The discrete choice experiment (DCE) is similar to the questionnaire used during the sensitization phase and validates the questionnaire design. The DCE aimed to elicit participants' preferences regarding showering settings without asking them directly. This experiment selected eight showering scenario pairs based on four factors: water temperature, air temperature, water flow rate, and showering time, each having two levels. The occupants' annual energy bills and thermal sensations during the undressing and showering periods in the scenarios were calculated. To enhance participants' understanding, five factors—undressing thermal sensation, showering thermal sensation, water flow rate, showering time, and estimated annual energy bills—were utilized in both the questionnaire and the DCE (see Figure 2). Participants were then asked to select their preferred option between the paired choices.



a) Questionnaire b) Discrete Choice Experiment

Figure 2. Examples of questions used in the Questionnaire and Discrete Choice Experiment.

For the collage-making activity, participants were provided with an A3 cardboard canvas and various materials, including newspapers, magazines, colored papers with different textures, washi tapes, and paper-cutting and joining tools. The materials were consistent across all groups. Participants were instructed to use these materials to make a collage about their ideal showering environment within a 20-minute timeframe. During the collage-making process, they were not allowed to communicate. After all the participants completed the collage-making, they were invited to present their artwork in a two-minute presentation.

2.3 Data analysis

All the quantitative data, including demographics, questionnaires, and DCE, were imported into SPSS and analyzed using four steps. First, descriptive statistics of frequency and percentage were performed to understand the general information of the participants. Then, paired-sample t-tests were conducted to compare the questionnaire and the DCE results. Third, a series of chi-square tests were conducted to test the impacts of the four variables on participants' preferences regarding showering settings. Lastly, the effects of participants' characteristics on their choices were evaluated using independent t-tests and Chi-square tests. It is worth noting that considering the relatively small sample size, the significance threshold for the statistical analyses was set as 0.1 in this study.

For the audio data collected during the FGD, this study only focused on the explanations provided during the collage-making presentations (i.e., the last ten minutes of the FGD). All recordings were transcribed verbatim in Microsoft Word files and subsequently imported into the QDA Miner Lite v3.0. Each participant was treated as a separate case. Then, these data were analyzed using content analysis as proposed by Kuckartz (2019). Specifically, the main text was coded according to a coding scheme that included several categories and codes.

3. RESULTS AND DISCUSSION

3.1 Descriptive Results

Twenty-one subjects participated in this focus group study, averaging 42.2 years (SD = 18.8) old. Their information is shown in Table 1. The majority of participants were female (67%), single (76%), and reported being in good health (67%). The highest level of education achieved varied among participants: 14% had a high school diploma, 19% held a bachelor's degree, 38% had a master's degree, and 19% possessed a doctoral degree. Most participants lived with others (67%), and their household sizes varied: 33% had a living area of less than 200 square feet, 38% had a living area between 200 and 500 square feet, and 29% had a living area between 500 and 700 square feet.

Table 1. Participants' general information.

Variables	Categories	n(%)
Gender	Female	14 (67%)
	Male	7 (33%)
Health	Excellent	2 (9.5%)
	Good	6 (28.6%)
	Fair	12 (57.1%)
	Poor	1 (4.8%)
Highest education	High school	3 (14%)
	Bachelor	4 (19%)
	Master	8 (38%)
	Doctor	4 (19%)
Martial status	Single	19 (76%)
	Married/cohabiting	4 (19%)
Live alone	Yes	7(33%)
	No	14 (67%)
House area	<200 sf	7 (33%)
	200-500	8 (38%)
	500-700	6 (29%)

Showering duration	<10 min	8 (38%)
	10-15	5 (24%)
	15-20	6 (29%)
	20-25	2 (9.5%)
Age*	23-76	42.2 (18.8)
Shower times per week*	1-10	6.9 (1.8)

* Continuous variables presented in min-max, mean (S.D.).

Participants' showering behaviors also varied: 38% took showers lasting less than 10 minutes, 24% took showers lasting 10-15 minutes, 29% took showers lasting 15-20 minutes, and 9.5% took showers lasting 20-25 minutes. On average, they showered 6.9 times per week (SD = 1.8), with most reporting seven showers per week. Notably, one participant showered once a week, while two reported showering ten times per week.

3.2 Impacts on showering setting preferences

According to the comparison between the questionnaire's choice selection results and the focus group ($\chi^2 = 45.9, p < 0.001$), participants' answers to these two question sets were closely related. Among the 168 selections (21 participants* 8 questions), 128 (76.2%) were the same. This consistency suggests the reliability of the responses. During the focus group, questions were fully explained to ensure participants understood the concepts. Consequently, this study focused on the data collected during the FGD.

Table 2. Comparison between results collected during the questionnaires and focus groups.

NO.	**Questionnaire**		**Focus Group**		χ^2**(p)**
	A	B	A	B	
1	29%	71%	38%	62%	**7.29 (0.007)**
2	19%	81%	48%	52%	**5.44 (0.02)**
3	71%	29%	62%	38%	**2.91 (0.088)**
4	38%	62%	29%	71%	**7.29 (0.007)**
5	86%	14%	81%	19%	0.46 (0.489)
6	71%	29%	52%	48%	**4.30 (0.038)**
7	52%	48%	62%	38%	**8.24 (0.004)**
8	48%	52%	52%	48%	**5.84 (0.016)**

Note: the significant results (p<0.1) are marked in bold.

The collected data were used to check the relationships between participants' choices and the four tested variables. As indicated in Table 3, air temperature, water flow rate, and showering duration emerged as the key factors influencing participants' preferences. Specifically, participants favored relatively higher air temperatures, lower water flow rates, and longer showering durations. In contrast, water temperature did not significantly impact their decisions.

Table 3. Relationships between participants' choice and four tested variables.

	Tw		Ta		Water flow rate		Showering duration	
	Low (36 ℃)	High (40 ℃)	Low (24 ℃)	High (28 ℃)	Low (0.13 kg/s)	High (0.17kg/s)	Short (12 min)	Long (16 min)
Selected	50%	50%	43.5%	56.5%	55.4%	44.6%	45.2%	54.8%
χ^2(p)	0.00 (1.000)		**5.762 (0.016)**		**3.86 (0.050)**		**3.05 (0.081)**	

Note: the significant results (p<0.1) are marked in bold.

Moreover, this finding also aligns with participants' importance ranking (see Table 4). According to the collected data, participants valued showering thermal sensation the most, followed by water flow rate, showering duration, and undressing thermal sensation, while energy bill was the least important factor that might influence their decision.

Table 4. Importance ranking of the variables that might influence showering comfort and energy consumption.

	1st	2nd	3rd	4th	5th
Undressing thermal sensation	14.3	4.8	19.0	**42.9**	
Showering thermal sensation	**61.9**	23.8	4.8	9.5	
Water flow rate	14.3	**47.6**	28.6		9.5
Showering duration	4.8	9.5	**33.3**	38.1	14.3
Energy bills	4.8	14.3	14.3	9.5	**57.1**

Note: the most selected options are marked in bold.

Besides the showering setting-related variables, the impacts of participants' characteristics (as shown in Table 1) were also tested. However, none of the investigated personal information significantly impacted participants' decision-making, probably due to the small sample size.

3.3 The ideal showering environment

Based on the collages created by the participants and their explanations, a coding system was developed that consisted of seven categories: Visual, Acoustic, IAQ, Thermal, Feeling, Decoration, and Others. Each category included two to eight codes. In total, 27 codes were used in the content analysis. The frequencies of 23 codes (except for those only appeared once), as they appeared in the recordings, are presented in Figure 3.

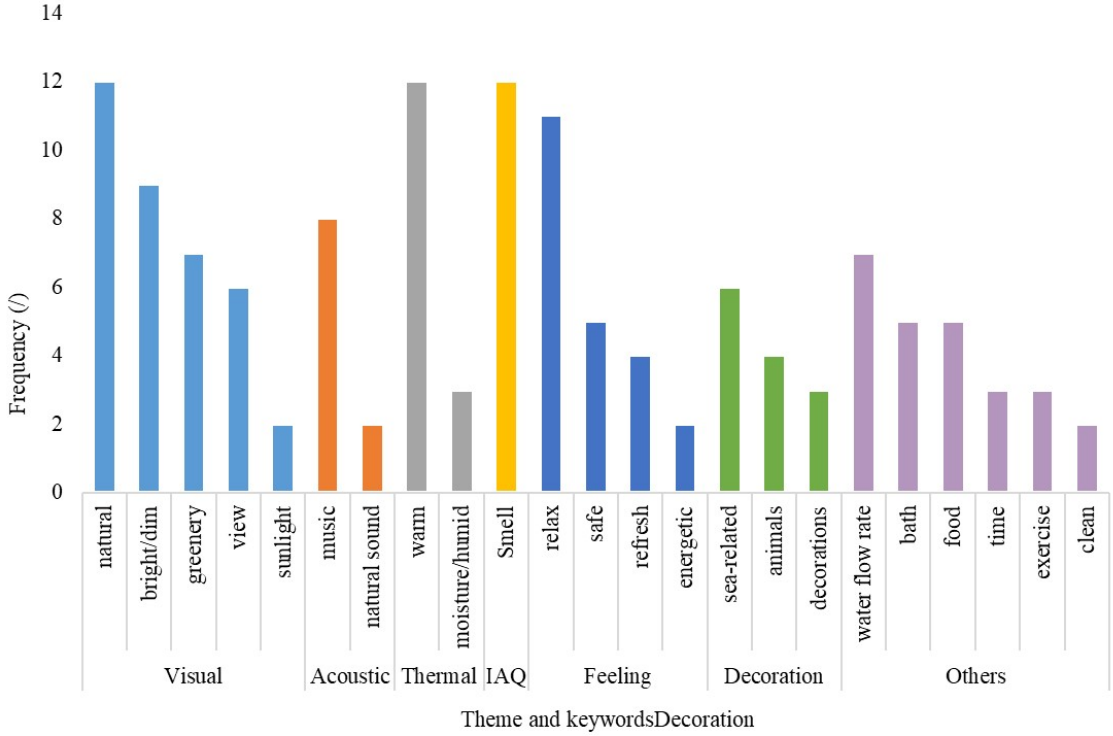


Figure 3. Frequency of the keywords appeared in the participants' focus group discussions.

As illustrated in Figure 3, the visual category was the most frequently mentioned, with 36% of participants discussing aspects related to visuals. Within this category, "natural" was the most commonly used keyword, with 12 participants expressing a preference for natural surroundings, environments, or decorations. Other frequently mentioned keywords included "smell" and "warm", with 12 participants indicating a desire for fragrance in their bathrooms, most favoring citrus or floral scents. Additionally, 12 participants specified their temperature preferences, with a majority seeking a neutral environment—neither too hot nor too cold. The term "relax" was also prevalent, as 11 participants expressed a desire for a relaxing atmosphere, with one participant using this term four times during the presentation. Beyond these commonly mentioned requirements, over 30% of participants articulated specific lighting and background music needs.

The analysis suggests that participants' awareness of energy conservation during showering is insufficient, as most did not prioritize energy bills associated with showering. The result might be attributed to the relatively low energy consumption during showering. Increased advocacy and education on energy-saving practices are recommended. Furthermore, these results indicated that air temperature was the primary factor influencing participants' preferences. However, according to a previous study, air temperature was less critical for energy consumption than water temperature and flow rates (Zhang et al., 2023). Therefore, it is suggested to maintain a relatively high air temperature while keeping water temperatures and flow rates lower to save energy and ensure comfort during showering.

Regarding the bathroom design, improvement should focus on several key elements. First, maintaining a comfortable air temperature is crucial, possibly through adjustable heating systems. Incorporating natural decor, such as greenery or nature-inspired artwork, can create a calming environment. Installing a speaker system that plays soothing music when the shower is in use adds to the relaxing atmosphere. Aromatherapy options, like built-in diffusers with popular scents such as citrus and floral, can elevate the sensory experience. Lastly, adjustable lighting allows users to customize the ambience, catering to different moods and preferences. These features collectively enhance the showering experience by making it more personalized and enjoyable.

3.4 The application of collage-making

The combination of FGD and collage-making proved to be an effective approach to identify occupants' nuance showering behaviour and preferences. Compared with traditional investigation methods, this visualization method could reveal deeper and latent insights that are important to occupants' ideal showering environment and experience. For example, natural-related decorations, as one of the most frequently mentioned keywords in participants' collages and presentations, were not prioritized by the researchers and rarely investigated in previous related studies. Additionally, this method could help designers to convey abstract ideas into practical solutions. For instance, most participants mentioned relaxed environment, which is quite abstract and hard to realize. However, at the meantime, most of them included fruits/floral scents and background music in their collages. This provided detailed and practical guidance for creating a comfort and relaxed showering environment and covered the gap between user experience and practical bathroom design.

4. CONCLUSION

Showering behavior and bathroom design affect occupants' thermal comfort and building energy consumption. Focus group studies incorporating discrete choice experiments and collage-making activities were conducted to understand these impacts and identify the optimal showering environment. Quantitative and qualitative analyses were performed using SPSS and QDA Miner Lite. The results revealed that air temperature, water flow rate, and showering duration significantly influenced participants' preferences for showering settings. Participants preferred relatively higher air temperatures, lower water flow rates, and longer showering durations, suggesting that comfort is a key determinant in their choices.

Additionally, the qualitative data highlighted that most participants desired natural decorations, soothing music, and pleasant fragrances in their bathrooms. Specifically, keywords such as "natural," "warm," and "relax" were frequently mentioned, indicating a strong inclination towards creating a calming and inviting atmosphere. These findings provide valuable insights for future bathroom design, applicable to residential settings and the hospitality industry, such as hotels or public shower houses. By integrating elements that enhance thermal comfort and aesthetic appeal, designers can create showering environments that cater to users' preferences, ultimately promoting well-being and satisfaction. Furthermore, optimizing water flow and temperature settings can significantly contribute to energy savings during showering.

SUMMARY
Wi-Fi networks can be used for human detection, but their accuracy depends on optimized router placement and configuration to minimize interference. Human sensing involves tracking spatio-temporal data, such as location, movement, or actions like gestures and falls. This study investigates different router placements in studio apartments and one-bedroom spaces with obstacles like walls. The goal is to analyze signal coverage while assessing the interference from other devices. An experimental approach is used, employing Wi-Fi routers and signal measurement devices to map signal distribution and identify areas where human presence impacts signal strength. Physical interference is measured and integrated into Python workflows to quantify disturbances affecting detection accuracy. These metrics help evaluate router placement for reliable data collection and network stability. This study shows how router placement affects signal behaviour and human detection, ensuring accurate sensing and efficient network performance in various indoor environments.

Keywords: Wi-Fi sensing, Human detection, Interference minimization.

1. INTRODUCTION

Wi-Fi-based human detection is gaining attention for smart buildings, security, and indoor environmental quality (IEQ) monitoring (Wang, Wang, and Liu 2024). Unlike cameras or motion sensors, which can be intrusive and expensive, Wi-Fi sensing offers a cost-effective, non-intrusive alternative using existing infrastructure (Ahmad, Ullah, and Choi 2024). However, router placement and configuration significantly impact detection accuracy, as signal interference, obstacles, and environmental factors can distort readings. This study examines how different router placements affect stationary human detection, aiming to enhance occupant localization and improve thermal comfort, energy efficiency, and air quality.

Most research in Wi-Fi sensing has focused on movement detection and gesture recognition, often neglecting the role of router placement in stationary human detection (Ma, Zhou, and Wang 2020). While Channel State Information (CSI) has been used for presence tracking, its connection to building science applications like HVAC optimization and IEQ enhancement remains underexplored. This study fills that gap by experimentally analyzing router placement effects in an indoor setting, showing that Wi-Fi can serve as a reliable occupancy sensing tool.

Accurate human detection enables dynamic HVAC control and ventilation optimization, reducing energy waste and ensuring healthier indoor environments. By optimizing router placement, Wi-Fi sensing can be integrated into smart buildings, making indoor spaces more efficient, adaptive, and sustainable.

2. METHODOLOGY

2.1.Experimental Setup

This study was conducted in a 3×5×2.5 m enclosed room, designed to evaluate the impact of human presence on Wi-Fi signal propagation. The experiment involved a Wi-Fi transmitter (Raspberry Pi 4) and a receiver (ASUS RT-AC86U), which were tested under two placement configurations. In the Entrance-Wall configuration, the receiver was positioned at (0, 1.5) m, near the entrance, while the transmitter was placed at (5, 1.5) m, along the opposite wall. This configuration aimed to simulate a conventional router placement scenario often found in indoor spaces (Fig 1). In contrast, the Diagonal configuration placed the transmitter at (0, 3) m and the receiver at (5, 0) m, forming a diagonal orientation across the room (Fig 1). The goal of this setup was to observe how alternative router positioning might affect signal distribution and human detection capabilities. A single individual was instructed to stand stationary for two minutes at nine predefined locations (nodes) distributed evenly throughout the room. These positions were selected to assess the impact of human presence on signal strength variations. The stationary nature of the individual allowed for the isolation of signal disturbances caused by the occupant's presence rather than movement, providing a controlled dataset for analysis.

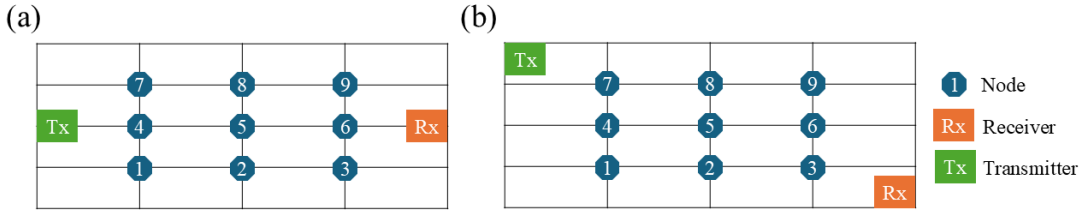

Figure 1. Room layout with nodes (a) Entrance-Wall, and (b) Diagonal configurations.

2.2.Data collection and processing

To evaluate the effects of human presence on Wi-Fi signal propagation, CSI data was continuously recorded during each test scenario. CSI measurements were collected for each of the nine stationary positions, capturing variations in signal behavior as the individual moved between predefined nodes. CSI recordings captured fine-grained fluctuations in signal strength, phase shifts, and multipath effects, which are essential for detecting human presence and its impact on wireless propagation. The primary focus of the data analysis was on identifying signal disruptions, attenuation effects, and fluctuations in CSI values across different node locations and router placements. identifying signal disruptions, attenuation effects, and fluctuations in CSI values across different node locations and router placements.

3. RESULTS

The CSI magnitude data across different node positions for the Entrance-Wall and Diagonal configurations reveal variations in signal strength, attenuation, and multipath effects, all of which influence human detection accuracy. Wi-Fi signals interaction with obstacles, reflections, and router placement, affecting localization and sensing reliability can be defined by analyzing the CSI values. The multipath effect occurs when Wi-Fi signals reflect off obstacles (e.g., walls, furniture) causing variations in CSI values that affect signal stability and human detection. Figure 2 presents the average CSI magnitudes at different nodes for both configurations, demonstrating how placement impacts signal reception. In the Entrance-Wall configuration, the highest CSI values

were recorded at Nodes 1 (1120), 2 (1050), and 7 (1078), suggesting strong signal reception due to their proximity to the transmitter or receiver. In contrast, Node 4 exhibited the lowest CSI value (280), indicating significant attenuation likely caused by physical obstructions. This reduction in signal strength results from barriers or human presence blocking the direct line-of-sight transmission. Meanwhile, Nodes 5 (490) and 6 (350) displayed moderate CSI values, suggesting partial obstruction or distance-related signal loss. The fluctuations in CSI values suggest multipath effects, where signals reflect off walls and objects, contributing to variations in signal strength. In the Diagonal configuration, the highest CSI values were recorded at Nodes 1 (1260) and 9 (1330), indicating stronger signal reception at room extremes. This could be attributed to broader coverage and constructive interference from reflected signals. However, Nodes 3 (280) and 7 (210) experienced the lowest CSI values, highlighting severe attenuation in these regions. The sharp drop at Node 7 suggests strong obstruction or destructive interference, where multipath reflections canceled out the direct signal. Moderate CSI values at Nodes 4 (854), 5 (602), and 6 (910) indicate that multipath reflections reinforced rather than attenuated the signal. Comparing both configurations, the Diagonal setup provided stronger coverage at extreme points but suffered from major signal loss at Nodes 3 and 7. The Entrance-Wall setup exhibited more stable high CSI values but experienced a drop at Node 4, suggesting obstructions weakened the signal. The greater variability in the Diagonal configuration suggests that multipath effects were more pronounced, leading to unpredictable CSI fluctuations. CSI drops at specific nodes indicate human presence or obstacles affecting signal transmission, making Wi-Fi a useful tool for occupancy detection. Router placement impacts detection accuracy, with the Entrance-Wall setup offering more stable CSI values but being sensitive to localized obstructions, while the Diagonal setup provides broader coverage but requires optimization to reduce signal loss.

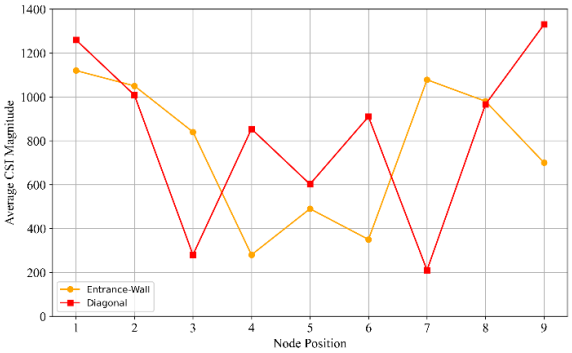

Figure 2. Average CSI magnitude at different nodes in Entrance-Wall and Diagonal configurations.

Table 1 provides an analysis of phase shift variations across different node positions in Diagonal configuration, highlighting deviations caused by the presence of an occupant. The baseline phase represents normal signal conditions in an unoccupied room. The raw phase data captures fluctuations in phase values due to environmental factors and the human presence at Node 4. A large deviation is observed at Node 4, confirming the occupant's presence. Moderate deviations at Node 7 suggest that the occupant’s presence also affects nearby positions due to multipath effects. All other nodes exhibit small or minimal deviations, indicating that they are likely unoccupied. The classification of a 0.1 difference as minimal, small, or moderate depends on the magnitude of the baseline phase value—when the baseline is large (e.g., ±2.5), a 0.1 change is minor, but when the baseline is small (e.g., 0.3), the same change is proportionally larger. Thus, "minimal

deviation" is used when the change is insignificant compared to the baseline, "small deviation" when slightly more noticeable, and "moderate deviation" when the change is significant relative to a small baseline.

Table1. Interpretation of phase shift variation at different nodes

Node	Baseline Phase (rad)	Raw Phase Data (rad)	Interpretation
1	-2.5	-2.4	Small deviation, likely unoccupied
2	1.2	1.1	Minimal deviation, likely unoccupied
3	-2.8	-2.7	Small deviation, likely unoccupied
4	-1	0.8	Large deviation, occupant present
5	-0.7	-0.6	Small deviation, likely unoccupied
6	2	2.1	Minimal deviation, likely unoccupied
7	0.3	0.2	Moderate deviation, occupant nearby
8	0.5	0.4	Minimal deviation, likely unoccupied
9	1.8	1.7	Small deviation, likely unoccupied

4. CONCLUSIONS

This study demonstrated the impact of Wi-Fi router placement on human detection accuracy using Channel State Information (CSI). The results highlight how different placement configurations influence signal reception, attenuation, and multipath effects, ultimately affecting occupancy detection reliability. The entrance-wall configuration provided more stable CSI values, making it suitable for detecting stationary occupants in predefined areas. However, it was more sensitive to localized obstructions, as seen in the attenuation at Node 4. On the other hand, the diagonal configuration offered broader coverage, achieving higher CSI values at room extremes (Nodes 1 and 9), but suffered from greater variability and signal loss at certain locations, particularly at Nodes 3 and 7. The study also explored phase shift variations to enhance human presence detection. The analysis showed that large deviations in phase data, particularly at Node 4, confirmed occupant presence, while moderate deviations at Node 7 suggested the influence of multipath effects on nearby positions. These findings validate the feasibility of using Wi-Fi-based phase shift analysis for non-intrusive and cost-effective occupancy detection in indoor environments. Overall, the results emphasize the critical role of router placement in optimizing Wi-Fi sensing applications for smart buildings. While entrance-wall placement is preferable for stable and localized occupancy detection, diagonal placement may be beneficial for larger area coverage but requires optimization to mitigate signal loss.

SUMMARY
Occupancy plays an essential role in influencing the energy consumption and operation of heating, ventilation, and air conditioning (HVAC) systems. Traditional HVAC typically operate on fixed schedules without considering occupancy. Advanced occupant-centric control (OCC) adopted occupancy status in regulating HVAC operations. RGB images combined with computer vision (CV) techniques are widely used for occupancy detection, however, the detailed facial and body features they capture raise significant privacy concerns. Low-resolution thermal images offer a non-invasive solution that mitigates privacy issues. The study developed an occupancy detection model utilizing low-resolution thermal images and CV techniques, where transfer learning was applied to fine-tune the You Only Look Once version 5 (YOLOv5) model. The developed model ultimately achieved satisfactory performance, with $precision$, $recall$, $mAP50$, and $mAP50-95$ values approaching 1.000. The contributions of this model lie not only in mitigating privacy concerns but also in reducing computing resource demands.

Keywords: occupant-centric building control, HVAC system, computer vision, face detection

1. INTRODUCTION

The building sector is responsible for 34% of global energy consumption (United Nations Environment Programme, 2024). Heating, ventilation, and air conditioning (HVAC) systems are the most energy-intensive systems in buildings, accounting for 38% of building energy consumption (González-Torres et al., 2022). Existing HVAC systems usually operate on fixed schedules, easily causing over-conditioning (Wu et al., 2024). Occupant-centric control (OCC) has emerged as an advanced strategy to address this issue by utilizing actual occupant information to control HVAC operations. Among various occupant-related factors, occupancy plays an essential role in determining the on/off status of HVAC systems. Studies have shown that integrating occupancy into HVAC operations can achieve an energy-saving ratio between 19% and 44% (Pang et al., 2020), demonstrating the significant benefits of leveraging occupancy for HVAC control.

Incorporating occupancy into HVAC operations begins with occupancy detection, which forms the essential foundation. Existing studies primarily rely on passive infrared, radio frequency signal technology, cameras, environmental sensors, Wi-Fi, and Bluetooth for occupancy detection (Ding et al., 2022). Passive infrared, radio frequency signal technology, and environmental sensors are relatively easy to deploy (Ding et al., 2022). However, passive infrared is unable to detect static people and multi-occupant scenarios, and has a limited detection range (Choi et al., 2021; Ding et al., 2022). Radio frequency signal technology is highly sensitive to indoor electromagnetic conditions (Ding et al., 2022), while environmental sensors (e.g., CO_2 sensors) often experience

delay issues when detecting occupancy (Choi et al., 2021). Wi-Fi and Bluetooth are efficient and convenient, however, their connection points do not always match the actual number of occupants (Ding et al., 2022). Cameras offer high accuracy in detecting occupancy and can immediately track changes in occupants (Choi et al., 2021; Ding et al., 2022), in particular, computer vision (CV) techniques are commonly applied to images for occupancy detection (Choi et al., 2021).

Many existing CV-based occupancy detection models employ Red, Green, and Blue (RGB) images for detecting occupancy. Tien et al. (2020b) applied a convolutional neural network to images to detect occupancy activity, achieving an average detection accuracy of 80.62%. Similarly, Choi et al. (2021) integrated a CV-based occupancy-centric counting method into the HVAC and lighting systems in two offices, achieving a 10.2% energy reduction. Overall, CV-based occupancy detection models commonly achieve high accuracy while contributing to building energy savings. However, most of these studies rely on high-resolution RGB images, which raise significant privacy concerns since the detailed facial and body features of occupants are captured (Choi et al., 2021). In addition, the high-resolution nature of RGB images requires high computing power and memory capacity (O'Mahony et al., 2020). To address this challenge, it is crucial to conserve computing resources when developing a CV-based occupancy detection model. Here, low-resolution thermal images provide an effective option since they not only mitigate privacy concerns but also reduce processing demands.

In summary, existing occupancy detection models reveal two main research gaps. First, most occupancy detection approaches based on passive infrared, radio frequency signal technology, environmental sensors, Wi-Fi, and Bluetooth, encounter significant limitations in practical applications. Second, the use of RGB images for occupancy detection raises privacy concerns and requires high computing resources. To address these gaps, this study aims to develop an occupancy detection model leveraging low-resolution thermal images and CV techniques. The novelty lies in its non-invasive nature and ability to mitigate privacy concerns, making it more psychologically acceptable to occupants. Furthermore, it reduces the requirement for computing resources, enhancing its practicality for real-world building environments.

2. METHODOLOGY

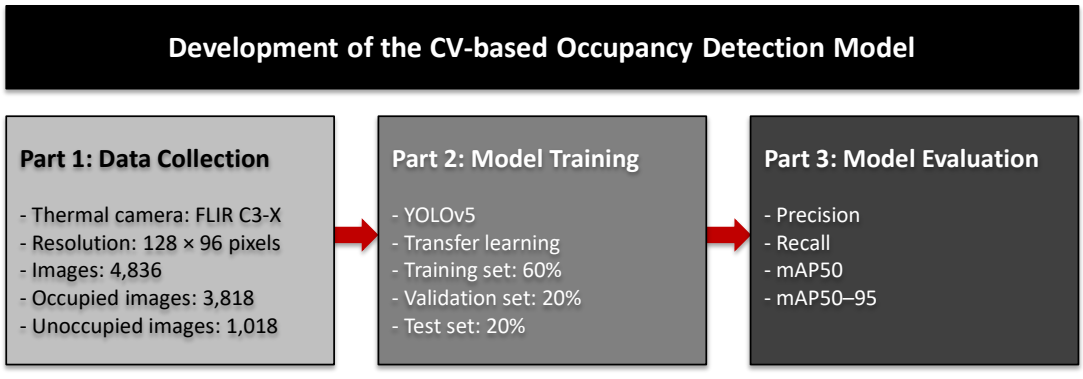

Figure 1. The methodological framework for developing the CV-based occupancy detection model.

Figure 1 illustrates the methodological framework for developing the CV-based occupancy detection model, consisting of three main parts: (1) data collection, which involves gathering sufficient low-resolution thermal images under occupied and unoccupied scenarios; (2) model

training, where transfer learning is applied to fine-tune the You Only Look Once version 5 (YOLOv5) model using the collected thermal images; and (3) model evaluation, which assesses the reliability of the developed model based on four metrics.

2.1. Data collection

Occupant thermal images were collected in a single-person office at The Hong Kong Polytechnic University on 8 August 2024. To simulate a realistic working environment, a single occupant performed typical computer-based tasks following their natural working habits, without any prescribed activity schedule or arrangement. Thermal images were captured using a FLIR C3-X compact thermal camera, featuring a low-resolution of 128 × 96 pixels ("FLIR C3-X Compact Thermal Camera with Cloud Connectivity and Wi-Fi | Teledyne FLIR," 2024). The camera was mounted on the upper bezel of the computer monitor and connected to the computer via USB. To ensure sufficient data collection, thermal images were automatically captured at 10-second intervals using radiometric streaming through the FLIR Desktop Atlas SDK. By the end of the day, a total of 4,836 thermal images were collected, comprising 3,818 images with the occupant present and 1,018 without, resulting in an occupied-to-unoccupied ratio of 3.75.

2.2 Model training

The study initially employed the YOLOv5 model to detect occupant faces since it demonstrates efficient and robust performance in this field (Jeoung et al., 2023). However, the publicly available YOLOv5 model produced unsatisfactory detection results when applied to the low-resolution thermal images collected in this study. This result may be attributed to the YOLOv5 model being pretrained on the Common Objects in Context (COCO) dataset (Choi et al., 2021), which offers limited exposure to low-resolution thermal images. Consequently, the pretrained YOLOv5 model likely struggled to capture the distinctive features of occupant faces in low-resolution thermal images, resulting in its suboptimal detection performance.

To improve the detection accuracy of the YOLOv5 model on low-resolution thermal images, an end-to-end transfer learning approach was employed. In this approach, the original YOLOv5 weights were fine-tuned using a curated dataset of low-resolution thermal images. Unlike traditional transfer learning methods that freeze early layers to retain generic feature representations, this approach involved fine-tuning the entire model. The layers of YOLOv5 were retrained on the curated dataset of low-resolution thermal images. This end-to-end retraining ensured that the model adapted comprehensively to the specific characteristics of thermal images, such as reduced resolution, lack of color information, and distinct thermal patterns.

LabelImg, a graphical image annotation tool, was utilized to label face bounding boxes in the thermal images ("HumanSignal/labelImg," 2024). The annotations were saved in YOLO-compatible .txt files, capturing the coordinates of the labeled bounding boxes ("HumanSignal/labelImg," 2024). All thermal images containing occupants were labeled, while annotation files for unoccupied images were left blank. After completing the annotation process, the thermal images and their corresponding annotation files were randomly split into a training subset (60%), a validation subset (20%), and a test subset (20%) for model training. Table 1 presents the sample sizes for each subset, with the occupied-to-unoccupied ratio in each subset matching the overall dataset ratio of 3.75.

Table 1. Sample sizes for the training, validation, and test subsets.

Subset	Thermal images		Annotation labels		Occupied-to-unoccupied ratio
	Occupied	Unoccupied	Occupied	Unoccupied	
Training	2290	610	2290	610	
Validation	764	204	764	204	3.75
Test	764	204	764	204	

2.3 Model evaluation

To evaluate the reliability of the trained model, the test subset was employed to assess detection performance under unseen scenarios. In this evaluation, it is essential to set an appropriate confidence threshold, as detection accuracy is highly sensitive to this parameter (Choi et al., 2022). Specifically, only objects with confidence scores exceeding the threshold are detected, while those below it are ignored (Choi et al., 2022). Thus, a low confidence threshold raises the likelihood of falsely detecting non-occupant objects, while a high confidence threshold increases the risk of missing true occupants (Choi et al., 2022). Following prior studies (Sohn et al., 2020; Xiao et al., 2021), this study adopted a confidence threshold of 0.9 to ensure robust detection performance. In addition, four criteria were used to assess the model performance, including $precision$, $recall$, $mAP50$, and $mAP50-95$. $Precision$ and $recall$, derived from $true\ positive\ (TP)$, $false\ positive\ (FP)$, and $false\ negative\ (FN)$, are defined by equations (1) and (2) ("formula of Box(P R mAP50 mAP50-95) Issue #9221," 2024). $mAP50$ and $mAP50-95$ are based on $average\ precision\ (AP)$ calculated at specific Intersection over Union (IoU) thresholds ("formula of Box(P R mAP50 mAP50-95) Issue #9221," 2024). $mAP50$ calculates the AP at an IoU threshold of 50%, while $mAP50-95$ provides a stricter assessment by averaging the AP across IoU thresholds ranging from 50% to 95% in 5% increments ("formula of Box(P R mAP50 mAP50-95) Issue #9221," 2024). Higher values across these four criteria indicate better model performance ("What is Box(P R mAP50 mAP50-95)?," 2024).

$$Precision = \frac{TP}{TP + FP} \tag{1}$$

$$Recall = \frac{TP}{TP + FN} \tag{2}$$

3. RESULTS AND DISCUSSION

3.1. Description of thermal images

As indicated in section 2.1, a total of 4,836 thermal images were collected. Figure 2 presents representative thermal images under occupied and unoccupied scenarios. Specifically, Figure 2(a) depicts the most typical unoccupied condition, while Figure 2(b)-(j) illustrate various occupied scenarios. Among these, Figure 2(b) shows the most typical occupied condition, featuring a frontal face view. Figure 2(c)-(d) display partial face visibility, Figure 2(e)-(g) show the face obscured by a hand or bottle, and Figure 2(h)-(j) present side-face views with varying head orientations. Notably, the diversity of head orientations, occupant gestures, and the limited visibility of occupant faces in these thermal images poses significant challenges for developing an effective occupancy detection model, as further discussed in section 3.3.

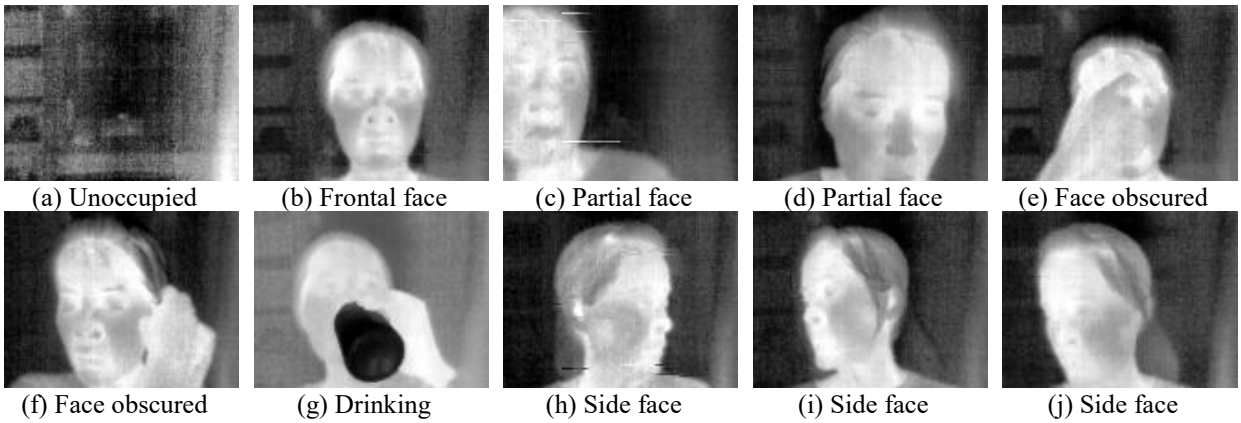

Figure 2. Representative thermal images featuring occupied and unoccupied scenarios.

3.2. Evaluation of model performance

Figure 3 illustrates the training curves of $precision$, $recall$, $mAP50$, and $mAP50-95$ of the model on the validation subset across 250 epochs. $Precision$ quickly converged to nearly 1.000, while $recall$ gradually stabilized around 1.000 despite minor fluctuations. Similarly, $mAP50$ rapidly stabilized near 0.995, and $mAP50-95$ progressively converged to approximately 0.980, demonstrating the robust detection capabilities of the model across varying IoU thresholds. As described in section 2.3, the study evaluated the model performance on the test subset. Table 2 summarizes the results of the four evaluation criteria on the test subset. Overall, the model performed excellently on the test subset, achieving a $precision$ of 1.000, $recall$ of 0.984, $mAP50$ of 0.991, and $mAP50-95$ of 0.975. These consistently high scores indicate the strong accuracy and generalizability of the developed occupancy detection model under unseen scenarios.

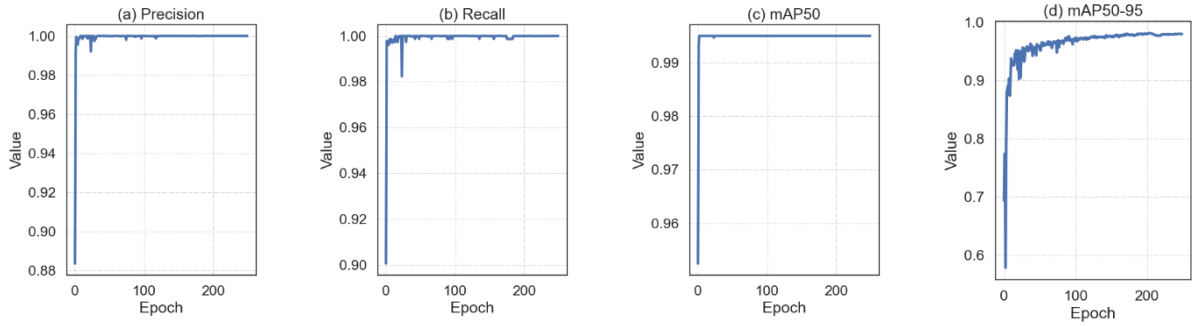

Figure 3. Training curves of $precision$, $recall$, $mAP50$, and $mAP50-95$ of the model on the validation subset across 250 epochs.

Table 2. Results of four evaluation criteria on the test subset.

	$Precision$	$Recall$	$mAP50$	$mAP50-95$
On the test subset	1.000	0.984	0.991	0.975

To ensure the reliability of the developed occupancy detection model, the study compared its performance with other similar CV-based detection models reported in previous studies. $Precision$ and $recall$ were selected as the key comparison criteria since they are widely used to evaluate model performance in this field. Table 3 summarizes the comparison results of $precision$ and $recall$ of the developed model and other similar CV-based detection models

from previous studies. The prior models examined in Table 3 primarily focus on detecting occupant activities (such as sitting, standing, and walking), the on/off status of the personal computer monitor, the open/closed status of windows, and worker tracking in off-site construction. The $precision$ of these CV-based models ranges from 0.864 to 0.987, while their $recall$ ranges from 0.828 to 0.967. By comparison, the occupancy detection model developed in this study achieved a $precision$ of 1.000 and a $recall$ of 0.984, exceeding the highest values reported among the examined models. These findings highlight the superior performance and reliability of the developed model in detecting occupancy.

Table 3. The comparison results of $precision$ and $recall$ of the occupancy detection model developed in this study and other similar CV-based detection models in previous studies.

	Detection target	*Precision*	*Recall*
This study	**Occupancy**	**1.000**	**0.984**
(Tien et al., 2020a)	Occupant activity	0.932	0.930
	Personal computer monitor _ on	0.914	0.860
(Tien et al., 2022)	Occupant activity _ sitting	0.925	0.891
	Occupant activity _ standing	0.906	0.828
	Occupant activity _ walking	0.864	0.927
	Window open	0.962	0.909
(Xiao et al., 2022)	Worker tracking in off-site construction	0.987	0.967

3.3. Analysis of occupancy detection

Figure 4 presents the actual and detected occupancy curves on the test subset. The model successfully detects the majority of occupancy states, with only a few exceptions. Specifically, out of 968 thermal images in the test subset, only 12 occupied images were not detected. Figure 5 presents the detection results for representative thermal images, corresponding to the scenarios shown in Figure 2. As seen in Figure 5(b)-(f) and Figure 5(j), the model correctly detects occupancy even under challenging conditions such as partial face visibility, side-face views, and faces obscured by a hand. In contrast, Figure 5(g)-(i) show three occupied scenarios that the model failed to detect. In these cases, although the room was indeed occupied, the model incorrectly identified it as unoccupied. This misclassification is likely due to the limited visibility of the occupant face, as specific head orientations (e.g., side-face views) and occupant gestures (e.g., drinking) do not provide sufficient visual information for the model to capture, leading to incorrect identification. These observations suggest that head orientations, occupant gestures, and face visibility play a significant role in influencing the model detection performance.

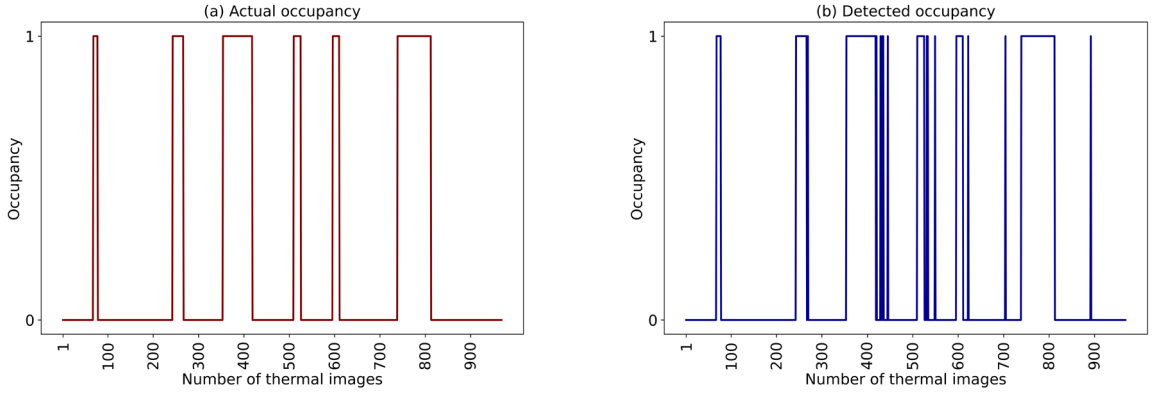

Figure 4. Actual and detected occupancy curves on the test subset.

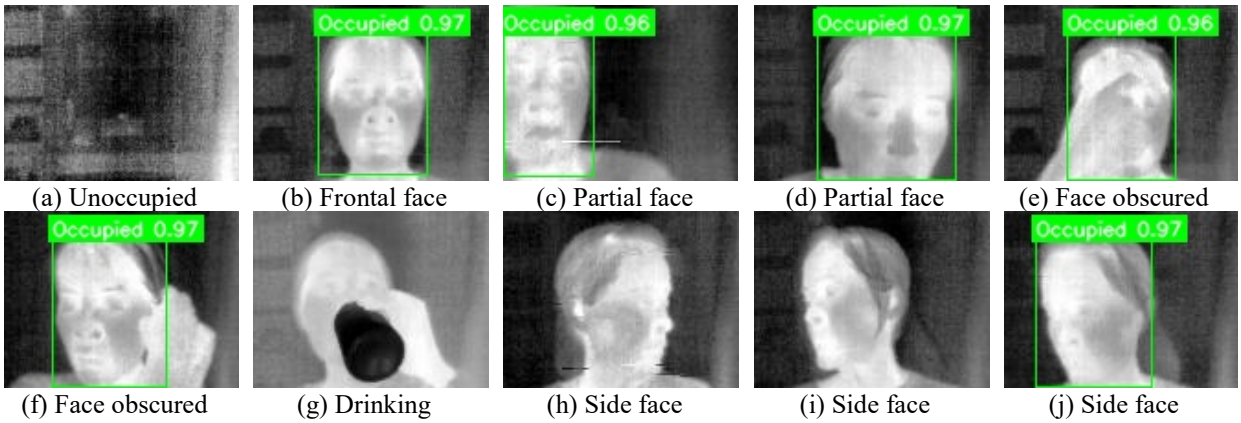

(a) Unoccupied (b) Frontal face (c) Partial face (d) Partial face (e) Face obscured

(f) Face obscured (g) Drinking (h) Side face (i) Side face (j) Side face

Figure 5. Detection results of representative thermal images corresponding to Figure 2.

4. CONCLUSION

Occupancy plays an essential role in influencing the energy consumption and operational status of HVAC systems. OCC system has become increasingly recognized in HVAC management since it utilizes actual occupant information to optimize system operation. Reliable occupancy detection is a fundamental requirement for developing an effective OCC system, as it directly determines the on/off status of HVAC equipment. However, most existing CV-based detection models rely on RGB images, which can raise privacy concerns and require high computing resources. To address these challenges, the study developed an occupancy detection model based on low-resolution thermal images combined with CV techniques. A total of 4,836 thermal images were collected for model development, ultimately achieving $precision$, $recall$, $mAP50$, and $mAP50-95$ values close to 1.000 on the test subset. Furthermore, the detection results reveal that head orientations, occupant gestures, and face visibility significantly affect the model performance.

The developed occupancy detection model demonstrates exceptional accuracy, making it highly suitable for integration into OCC systems to determine the on/off status of HVAC systems and potentially achieve energy savings. Additionally, its non-invasive design effectively addresses privacy concerns, enhancing psychological acceptability among building occupants. The use of low-resolution thermal images also reduces the demands on computing resources, thereby improving the practicality and applicability of the model in real-world building environments. The study acknowledges a limitation that most thermal images collected in this study predominantly capture frontal face views, which may not fully represent diverse real-world scenarios. Model accuracy tends to decrease when processing thermal images with varied head orientations, occupant gestures, or limited face visibility. However, these conditions are commonly encountered in practice. To address this, future research should focus on enhancing the model robustness when detecting thermal images with incomplete or minimally visible occupant faces, heads, bodies, and diverse orientations and gestures, thereby further improving its reliability and adaptability across a wide range of real-world applications.

ABSTRACT
Extreme heat events, the most lethal weather condition in the United States, are increasing and pose significant risks to vulnerable populations such as elderly and low-income residents. Vulnerability is exacerbated in homes lacking adequate cooling systems. In the Capitol East neighbourhood in Des Moines, Iowa 50-60% of homes lack central air conditioning. Indoor temperature in buildings without active cooling vary significantly during the summer heat, however, gathering real-time temperature data is challenging due to dynamic factors within and around a building. Developing machine learning-based model predictions could enhance and personalize heat emergency management by predicting real-time indoor temperatures. This system could mitigate dangers associated with excessive heat for residents of homes without AC across the U.S. To ensure the accuracy of the machine learning (ML) model, training and validation are needed. This paper presents the first step towards a predictive indoor dry bulb temperature model based on data collected from buildings in the study area during the summer of 2023 using the Energy Plus-based plugin Climate Studio. To assess the influence of building variables, windows to wall ratios of 5% and 10% were simulated and compared with measured data. for some homes, simulated temperatures were higher than measured for both 10% and 5% WWR. Conversely, in buildings with lower simulated temperatures than measured for both WWR levels, 5% WWR showed lower temperatures than 10%.

Keywords: Indoor Temperature Prediction, Thermal simulation, Extreme Heat Emergency Management

INTRODUCTION

Extreme heat is the deadliest type of weather in the United States (US) and disproportionately affects vulnerable populations (Donegan 2019). Called the ‘silent killer’ by health experts (TNC 2019, Voelkel et al. 2018) due to its gradual and invisible nature, extreme heat is especially dangerous for the elderly (Hajat et al. 2007) and low-income residents who are less likely to have centralized or adequate home cooling. The Fourth US National Climate Assessment predicts that extreme heat events will increase markedly with significant threat to human health (Angel et al. 2018). The frequency of high humidity/dew point days, which cause a 10–30% increase in daily human mortality by the fifth day at > 90°F are also predicted to increase (Kalkstein 2014). Lack of central air-conditioning (US EIA 2015) and the impact of urban heat island (UHI) effects caused by urban density and lack of tree canopy can create dangerous indoor living conditions. This impact is exacerbated in residences of low-income neighborhoods (Hoffman 2020).

To address the dangers of excessive heat, many public health authorities use a Heat Health Warning System (HHWS) to raise public awareness. However, HHWS alerts are based on dynamics of large air mass weather conditions that lack spatial and temporal specificity (Sheridan 2018). While HHWS predictions are based on outdoor conditions, most heat stress illnesses are occurring indoors and differ significantly based on context (Kuras et al. 2017).

This study is part of *CommHeat*, funded by the US National Science Foundation's Smart and Connected Communities program (2023-2025 # 2226880). *CommHeat* develops a community-focused microclimate-informed indoor heat emergency alert system that will enhance and personalize community heat-related emergency management capacity. The framework combines data collection from residents and community partners in a low-income neighborhood of a US Midwestern city. Ultimately the project will develop scientific machine learning (SciML) approaches to reliably predict heat flux and human response to support vulnerable community residents and stakeholders during extreme heat events in identifying which homes and residents might be at risk of overheating.

Indoor temperature directly affects occupants' thermal comfort; however, gathering real-time temperature data during an extreme event is challenging due to privacy concerns. Developing a machine learning-based system based on dynamic factors within a building's indoor environment could enhance and personalize heat-related emergency management by predicting real-time indoor temperatures. This system could mitigate dangers associated with excessive heat for residents of homes without AC across the U.S. A major challenge in developing a ML model based on field-collected temperature data is that the collected data does not yet account for changes in climate patterns, as they are trained and tested using data from a current period. The Earth is becoming warmer compared to the past (Wang et al. 2023), and this trend is expected to continue. As a result, temperature data collected during the summer of 2023 may not be sufficient to predict future indoor temperatures during summer and seasons may shift. Simulating indoor temperatures in buildings presents a promising solution, as it allows for the generation of temperature data for any desired future period. By using simulated indoor temperature data, an ML model can be trained to reflect future conditions more accurately. However, a key challenge in this approach lies in the accuracy of the simulations, which can be affected by various input parameters. Among these, the window-to-wall ratio is a critical factor influencing indoor temperature. Thus, to ensure the accuracy of the ML model, training and validation are needed. Window to Wall Ratios have been identified as a major factor to assess building cooling loads (Li et al. 2021). The aim of this study is to assess relationship between window-to-wall ratios of 5% and 10% and the indoor dry-bulb temperature variation inside the buildings. This analysis will help adjust the simulated temperature to match field-collected data, ensuring validation for developing the machine learning algorithm.

2. METHODOLOGY

This study presents the first step to develop predictive indoor dry bulb temperature model based on data collected from eight houses and one apartment unit in an inner city neighbourhood of a midwestern city in the US with the Köppen Climate Classification subtype of hot summer continental climate (Des Moines, Iowa Köppen Climate Classification, 2024). The data was collected during the summer of 2023. The methodology for this study is separated into three phases: thermal simulation of houses, comparison of simulated data with in-field collected data, and identification of parameters to align simulated data with collected data (Figure 1).

2.1 Phase 1 (Thermal simulation of houses)

In the initial phase of this study, the EnergyPlus Weather EPW file containing TMY3 data was downloaded from (EnergyPlus, 2025). The dry bulb temperature, relative humidity, wind speed, and wind direction values in the TMY3 file were updated with measurements recorded during the summer (from July 24, 2023, to September 13, 2023) at one-hour intervals. The data was collected

using a ClimaVue 50 weather station by Campbell Scientific in close vicinity of the houses. This modified EPW file was then utilized for thermal simulations in ClimateStudio. Climate Studio, a specialized plugin for the Rhinoceros 3D platform using EnergyPlus and Radiance as modelling engine (Solemma, 2025) was employed for building energy and lighting simulations.

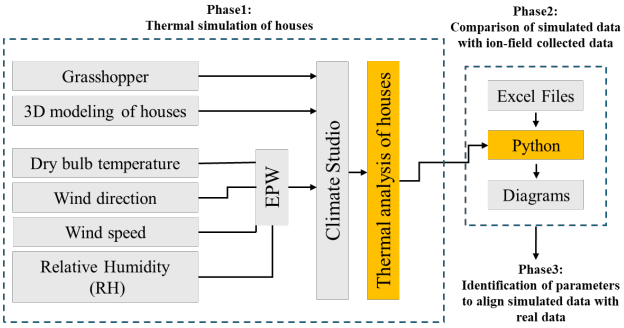

Figure 1. Flowchart of the study illustrating its three phases: (1) thermal simulation of houses, (2) Comparison of simulated data with in-field collected data, and (3) Identification of parameters to align simulated data with real data.

For the thermal simulation, five of the houses were first modelled and simulated within the Rhino environment. In the absence of precise dimensional data for the buildings, a parametric 3D model was created using the Grasshopper plugin (Simply Rhino, 2025) environment based on publicly available geospatial data. Grasshopper is a Rhino based plugin for visual programming and parametric design tool. In this script, the window-to-wall ratio and the dimensions of the buildings are controlled with adjusting sliders. All individual 3D models of the buildings were created using a Grasshopper script as illustrated in Figure 2. Another script (Figure 3) was used to calculate the window-to-wall ratio.

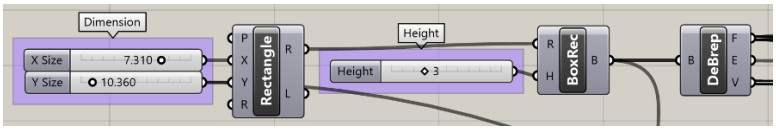

Figure 2. The script used for 3D modelling in Grasshopper

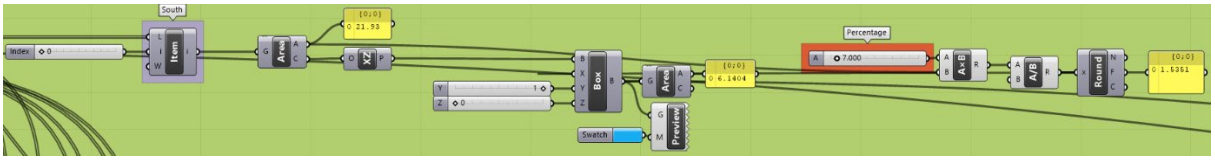

Figure 3. The script used for the window modelling

Table1. The properties of the materials used in the thermal simulations of the buildings

Buildings features	U-value W/ $(\boldsymbol{m^2.k})$	Thermal capacitance kJ/k/$\boldsymbol{m^2}$
Roof	0.23	95.64
Exterior facade	0.06	80.77
Slab	0.29	394.98
Ground slab	1.53	1833.56

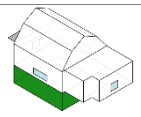
Then, the estimated dimensions of each of the buildings was extracted from the GIS (Geographic Information System) files of Polk County Iowa. Each 3D model was used for the thermal simulation. Then, Climate Studio was used to simulate the temperature inside the houses. The material used for the simulation was adjusted to residential building template material (Table1) prepared for the inner city neighborhood in a previous project which used the Urban Modelling Interface (MIT Sustainable Design Lab, 2025.).

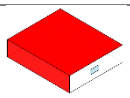
2.2 Phase 2 (comparison of simulated data with in-field collected data)

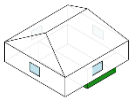
In the second phase indoor temperature of houses was recorded using Onset Hobo sensors during the warm months, from July 24, 2023, to September 13, 2023. These sensors were installed near the windows to measure the indoor temperature every ten minutes. The temperature hourly data obtained from the simulation was then compared with the data collected from the sensors.

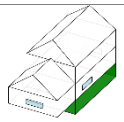
Then, the simulated indoor temperatures were compared with the data collected from sensors installed inside the buildings to determine the alignment between the simulation results and the field-measured temperature data for the nine houses. All buildings are named alphabetically for easy comparison with each other and to keep locations anonymous as was promised to the residents (Table 2). Since multiple factors influence the simulation of indoor temperatures, such as internal loads, occupancy schedules, infiltration rates, and window-to-wall ratios, discrepancies were observed between the simulated results and the field data. Among these factors, the window-to-wall ratio was identified as having a significant impact on indoor temperatures.

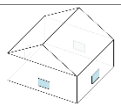
Table 2. The building's geometric features used for the simulation

Houses used for the simulation				
House A	Unit B	House C	House D	House E
				










2.3 Phase 3 (identification of parameters to align simulated data with real data)

The final phase of the study focuses on identifying a pattern that could convert thermal data extracted from the simulations of five houses located in the inner-city neighborhood into measured data. To achieve this, two different window-to-wall ratios of 10% and 5% were selected for each direction in the thermal simulation of each house (Figure 3), with the goal of finding a correlation to modify the pattern of the houses' internal temperature. To determine the correlation, the simulated data was subtracted from the measured data, and the resulting differences were analyzed for both WWR 10% and 5% scenarios. Additionally, for each scenario, the number of instances where the temperature difference was less than 1°C was calculated and evaluated.

3. RESULTS

The simulated temperatures were measured during three periods of time. July 24 to July 31, August 1 to August 31, and September 1 to September 13.

3.1. The comparison of the July data

According to the simulation results with a 5% window-to-wall ratio in July for Unit B and House D, 75% and 56% of the time, the predicted interior dry bulb temperature was lower than the

measured temperature from the sensors installed inside the building. Among the times when the simulated temperature was lower than the measured temperature for Unit B, 23% of the time, the difference of simulated data and sensors extracted data was less than 1°C (Figure 4).
However, for the 10% window-to-wall ratio, 56% of the simulated temperature data was lower than the data obtained from the sensors. Of this, 30% had a temperature difference of less than 1°C (Figure 4).

In contrast, for Unit B, 55% of the time, the dry bulb temperature data collected during July was higher than the simulated temperature with a 5% window-to-wall ratio. Among these instances, 22% of the time, the difference was less than 1°C. The pattern observed with the 10% window-to-wall ratio followed a similar trend in temperature fluctuations but with different percentages of change. 51% of the time, the simulated data was lower than the real data, with 22% of this data showing a difference of less than 1°C. The simulated temperatures for House A and House C were generally higher than the collected data in July when considering the WWR of 5% and 10%. This increase was more pronounced for the 10% WWR in both cases. Among the instances where the simulated temperature exceeded the real temperature for the 10% WWR, building C showed a temperature difference of less than 1°C in 26% of the cases, whereas House A showed this result only 3% of the time. All the simulated data was higher than the real collected data for the House E both with 10% and 5% WWR (Figure 4).

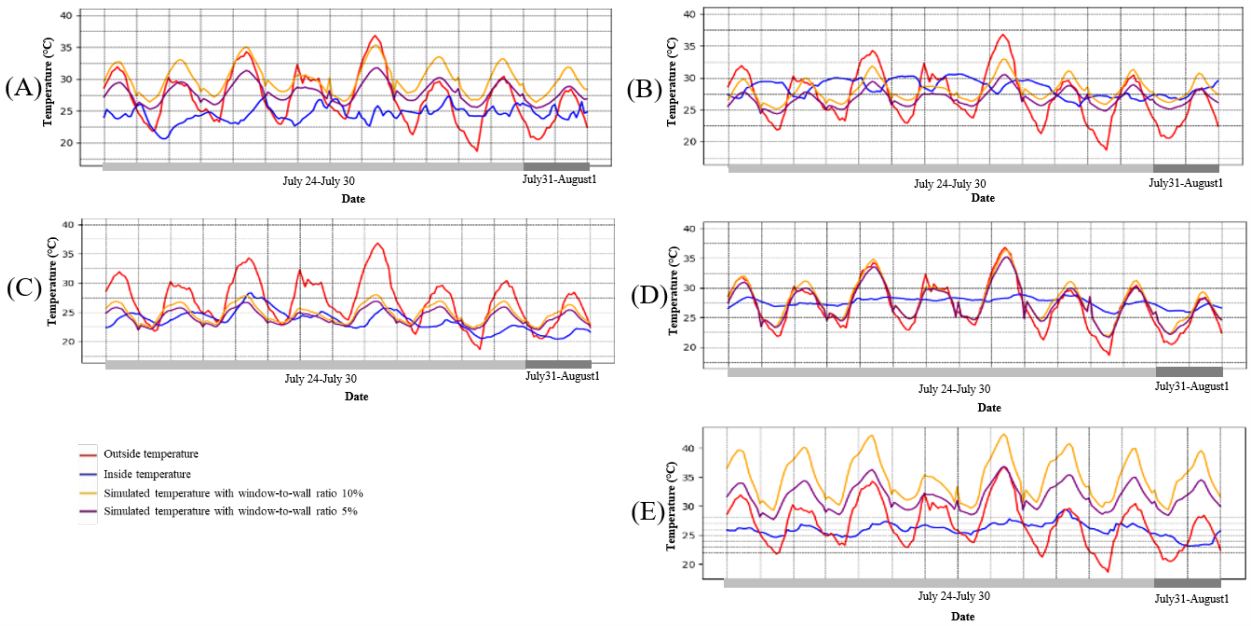


Figure 4. Thermal simulation results from July 24 to July 31:
A: House A, B: Unit B, C: House C, D: House D, E: House E

3.2. The comparison of the August data

However, the results from August showed that the temperature measured by sensors inside three out of the five houses (A, C, and E) was lower than the simulated data for most of the time. In contrast, the temperatures in the B and D Houses displayed a different pattern, with both 5% and 10% window-to-wall ratios (WWR). A similar pattern was observed in the three buildings, House A, C and E. In these buildings, the simulated temperatures with both 5% and 10% WWR were generally higher than the real data collected most of the time (Figure 5).

For House C, the simulated temperature was 58% times higher than the real with a 5% WWR, and it increased to 68% with a 10% WWR. The temperature difference between the simulated and real temperatures was within 1°C for 68% of the time, with 5% WWR in building C (Figure 5). However, when the WWR increased to 10%, this percentage dropped to 18%. Building A exhibited a higher temperature difference, with a simulated increase of 86% for a similar WWR. 15% of the time, the simulated temperature was within 1°C of the actual temperature. Additionally, 14% of the time, the simulated temperature was lower than the real temperature, and 48% of the time, the temperature difference was less than 1°C. The simulated temperature results for building E with a 5% WWR were higher than the real data 97% of the time. Of these instances, 78% showed a temperature difference of less than 1°C between the real and simulated temperatures. For the 10% WWR, all the simulated data were higher than the real data, and none of the temperature differences were less than 1°C. House D and B followed a similar pattern. In these buildings, the simulated temperature was higher than the real temperature when considering a 10% WWR; however, for the 5% WWR, the real data was higher than the simulated temperature (Figure 5).

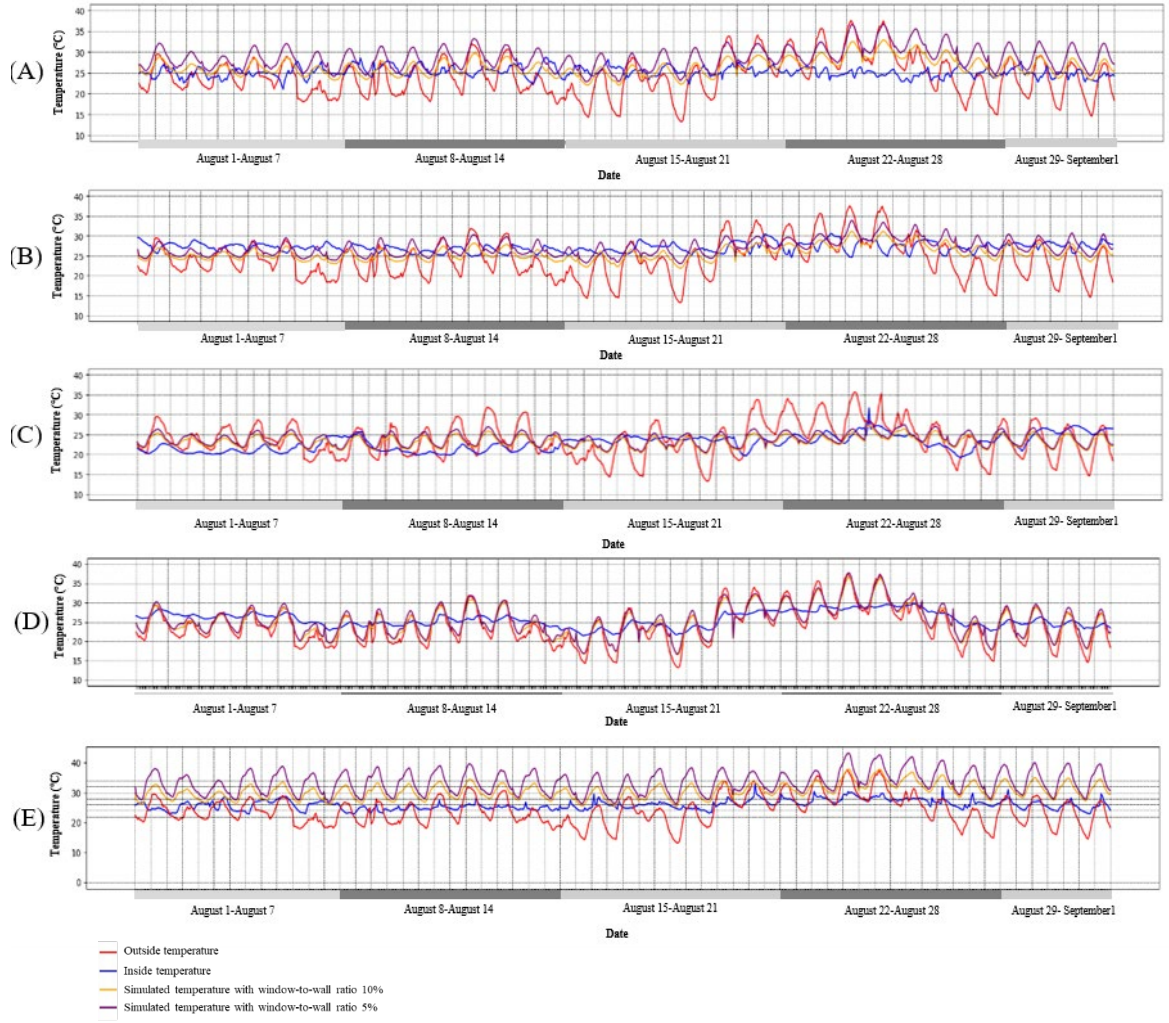

Figure 5. Thermal simulation results from August1 to August 31:
A: House A, B: Unit B, C: House C, D: House D, E: House E

3.3. The comparison for the September data

According to the simulation data from September for Houses B, C, and D, the simulated temperatures were generally lower than the measured temperatures for both 5% and 10% WWR (Figure 6). However, for all these buildings with a 5% WWR, the simulated temperatures were higher than the measured temperatures most of the time. For House C, the simulated temperature was lower than the real temperature in 39% of times, and in 40% of those instances, the difference was less than 1°C when considering both the 5% and 10% WWR. Similarly, building D showed that 23% of the time, the difference between the simulated and measured temperatures was less than 1°C (Figure 6).

In House A, the simulated temperature was higher than the measured temperature 51% of the time for a 5% WWR and 71% of the time for a 10% WWR. In most of these instances (60%), the difference between the simulated and real temperatures was less than 1°C. However, for building E with a 5% WWR, the simulated temperature was lower than the measured temperature 68% of the time. In contrast, for the 10% WWR, the simulated temperature was higher than the real temperature 93% of the time (Figure 6).

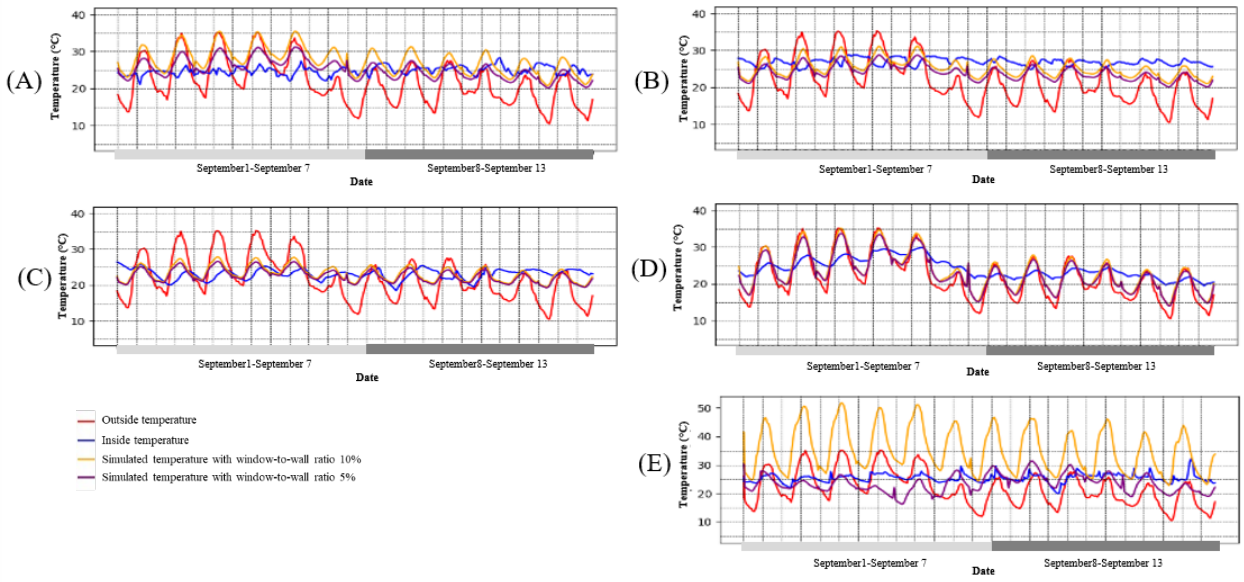

Figure 6. Thermal simulation results from September1 to September 13:
A: House A, B: Unit B, C: House C, D: House D, E: House E

DISCUSSION AND CONCLUSION

The analysis of the thermal data from simulations and real measurements of the five buildings in this inner-city neighborhood over three months revealed significant insights into the relationship between window-to-wall ratios (WWR) and internal temperature patterns. According to the results achieved from the simulation, the window-to-wall (WWR) ratio had different effects on the buildings' interior temperatures, and this effect followed a distinct pattern for each month. The results from the three months showed that in some buildings, the simulated temperature was higher than the measured temperature for both 10% and 5% WWR; in these buildings, the 10% WWR resulted in a higher simulated temperature than the 5%. In buildings where the simulated

temperature was lower than the real temperature for both 10% and 5% WWR, the 5% WWR showed a lower simulated temperature compared to the 10% WWR. Thus, while considered a major factor, the WWR cannot be the only factor to determine indoor temperature. Thus, other external factors will also need to be assessed in the next steps to develop the SciML model. Therefore, the next step in this project will be to include further factors, such as interior equipment and lighting loads, as well as external vegetation and trees, still need to be studied for their impact on indoor temperature in future work.

SUMMARY

This study evaluates the interaction effects between heating practices, such as adjusting indoor setpoint temperatures, and the calculated energy-saving potential highlighting opportunities to rethink the scale and effectiveness of retrofit strategies. Advanced energy simulations were conducted for a typical terraced house, using three different setpoint temperatures during the heating season to assess their impact on the energy performance of three retrofit scenarios: singular measures, moderate interventions, and deep retrofits. Results show that reducing setpoint temperatures alone decreased energy demand up to 45%. Additionally, the performance of deep energy retrofits was significantly diminished under lower setpoint temperatures. This finding suggests that for households with low indoor temperature settings the benefits of deep retrofits may be outweighed by their implementation costs. These results highlight the importance of considering occupant heating habits when designing retrofit strategies to optimize energy savings and improve decision-making processes.

Keywords: Heating practices, Building modelling, Energy retrofitting

1. INTRODUCTION

Deep energy retrofits have become a widely adopted strategy to enhance building performance in response to the climate crisis. While energy renovation projects in Europe progress, concerns persist about achieving climate goals within the necessary timeframe and at a reasonable cost (Eyre et al., 2023; Filippidou et al., 2018). Retrofits primarily focus on technological optimizations, such as insulation upgrades, ventilation improvements, and installation of new heating systems. However, these measures often fail to deliver the anticipated energy savings, resulting in an "energy performance gap" (Giandomenico et al., 2022).

Occupant behavior is a critical contributor to this gap, since it is hard to predict but also significantly influences a building's energy performance (Gram-Hanssen & Georg, 2018). As building envelopes and energy systems are optimized, the impact of occupant behaviour becomes even more critical (Hu et al., 2023). Yet, renovation projects rarely account for the diversity of occupant practices. Instead, they typically rely on assumptions of standardized occupancy patterns based on average energy use and heating habits (Marshall et al., 2016; Van Moeseke et al., 2024). This "one-size-fits-all" approach neglects the dynamic interplay between retrofit measures and occupant behavior, limiting the effectiveness of energy renovations (Levesque et al., 2019).

Occupant heating habits, such as the use of adjusted setpoint temperatures, can significantly impact overall energy use in buildings (Du et al., 2019; Recart et al., 2025). Studies have demonstrated

that small changes to indoor temperatures can yield significant energy savings without compromising comfort (Hoyt et al., 2015). Nevertheless, reducing indoor temperatures as a strategy to lower energy demand is often overlooked. A common argument against this approach is the concern that indoor temperatures below 18-20°C may lead to unhealthy and uncomfortable conditions (Ortiz et al., 2017). However, emerging research has challenged this assumption, demonstrating that thermal comfort can be achieved across a broader range of temperatures (Chappells, 2010; van Marken Lichtenbelt et al., 2017). For instance, Schellen et al. (2010) showed that both young adults and elderly individuals can tolerate thermal variations between 17°C and 25°C across seasons. Similarly, Van Moeseke et al. (2024) found that systematically lowering setpoint temperatures from 19°C to 15°C, combined with the use of personal insulation and heating strategies resulted in significant long-term adaptation and achieved average energy savings of 50%.

By incorporating occupant heating practices into the energy retrofit decision-making process, there is an opportunity to rethink the scale and effectiveness of energy retrofitting projects. This study investigates the potential for reducing energy demand and associated costs by integrating heating practices that extend beyond traditional comfort assumptions. In this context, we examine the potential for energy demand reduction and the associated economic implications of three different levels of energy retrofit implementation, each considering different indoor temperature scenarios.

2. METHODS

In this study, we conducted building simulations to evaluate how considering a broader range of heating habits influences the performance of energy retrofit measures. The case study focused on a standard Dutch terraced house, which constitutes approximately 40% of the residential building stock (Ministerie van Binnenlandse Zaken en Koninkrijksrelaties (BZK), 2022). For the Dutch terraced house, the exterior wall assemblies were defined as double brick walls, the floors as concrete slabs, and the roof as a pitched structure with moderate insulation. The building consists of three floors, two of which are conditioned: the ground floor and the first floor, while the second floor remains free-floating. The house is mid-row, featuring adiabatic partitions on both sides, with its main façade oriented south (See Figure 1).

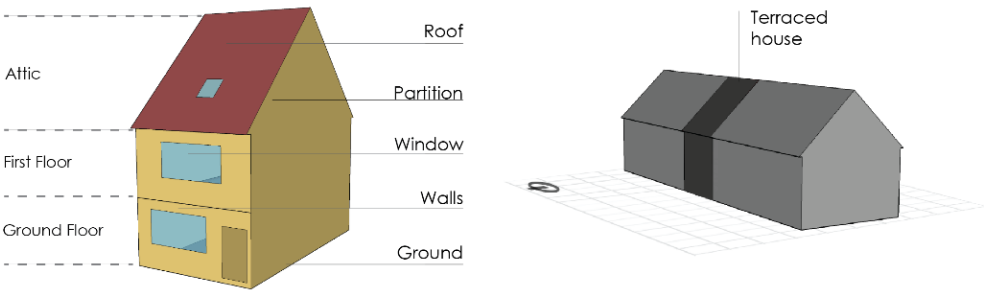

Figure 1: Terraced house - Left: schematic perspective illustrating its ground floor, first floor, and attic. Right: Schematic representation showing its spatial position.

2.1. Occupant's heating practices and general assumptions

To estimate the influence of occupant's heating practices on building energy performance, we intentionally included a broad range of occupant's heating habits, some of which deviate from traditional comfort norms. Our focus was on the adjusting setpoint and setback temperature during heating season, defined as October 1st to May 31st. We assumed full occupancy, with the ground floor used for daily activities and the first floor designated for sleeping As a benchmark, we use a setpoint of 20°C (standard) during occupied hours with a setback of 16°C for unoccupied hours. To represent a wider range of heating habits, we included two additional setpoint schemes: 18°C (SP18) and 15°C (SP15) during occupied hours, with corresponding setbacks of 14°C and 11°C for unoccupied hours as illustrated in Figure 2.

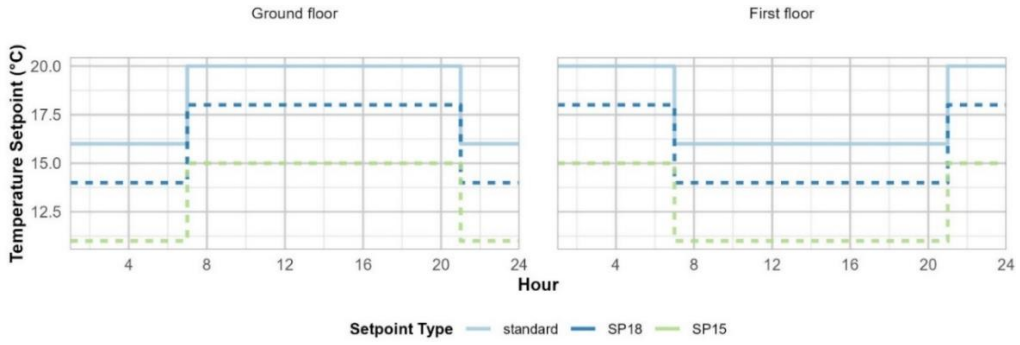

Figure 2: Daily setpoint temperatures The continuous line represents the reference setpoint, while the dashed lines indicate the temperature reduction.

2.2. Energy retrofit measures

To evaluate the impact of energy retrofitting, we introduced a series of measures aimed at improving the home's thermal performance, including single, moderate, and deep retrofits, as illustrated in Table 1: single retrofits (SR), which focus on specific thermal improvements such as walls, roofs, and windows; moderate retrofits (MR), which involve broader upgrades targeting multiple components of the building envelope; and deep retrofits (DR), which comprise comprehensive measures that significantly disrupt daily life. In total, we tested eight different strategies, each combined with various heating practices to assess their effectiveness.

Table 1: Existing conditions and energy retrofit measures for the three intervention levels

Intervention level	**No renovation**	**Single Retrofit (SR)**			**Moderate Retrofit (MR)**			**Deep Retrofit (DR)**	
Renovation measure	**Existing condition**	**SR1**	**SR2**	**SR3**	**MR1**	**MR2**	**MR3**	**DR1**	**DR2**
Walls (m^2 K/W)	0.690	2.237		-	2.237	2.237	2.237	6.250	6.250
Roof (m^2 K/W)	1.718	-	-	-	5.650	5.650	5.650	8.264	8.264
Windows (W/m^2K)	5.894	-	2.665	-	-	2.665	2.665	0.687	0.687
Partition (m^2K/W)	0.610	-	-	-	-	-	-	-	-
Ground Floor (m^2K/W)	0.758	-	-	-	-	-	-	-	-
Infiltration (ach)	0.7	-	-	0.1	-	-	0.3	-	0.1
Mechanical ventilation with heat recovery	-	-	-	-	-	-	-	80% efficiency	80% efficiency

2.3. Building simulation

The simulation model was developed using DesignBuilder v7, integrated with EnergyPlus 9.4, to represent the case study and quantify heating energy demand. We use weather data from De Bilt, the Netherlands, that provided hourly inputs for temperature, humidity, and solar radiation, all synchronized with the simulation's 10-minute time step (NEN, 2018).

2.4. Key performance indicators (KPIs)

The KPIs for evaluating energy efficiency correspond to annual space heating demand (kWh/year), expressed as percentage reduction (%). Additionally, to estimate the operational costs for each retrofit package, we applied a fixed gas price to the energy demands simulated in the study. Initial investment costs were sourced from the Kostenkentallen database, which offers detailed pricing information for various retrofit measures, including building envelope upgrades, ventilation systems, and heating systems (RVO, 2024). We calculated the simple payback periods by considering both operational cost savings and initial investments for all proposed packages, and the net present value (NPV) over a 30-year period, assuming a 5% discount rate.

3. RESULTS

3.1. Energy demand reductions

The assessment approach used in this study resulted in the development of eight renovation packages based on three different setpoint temperature profiles: Standard, SP18, and SP15. The findings shown in Figure 3, reveal that adjusting setpoint temperatures significantly impacts heating load reduction. Specifically, adopting the SP15 setpoint profile can reduce heating loads by up to 45%, while the SP18 scheme achieves a 20% reduction compared to the reference case.

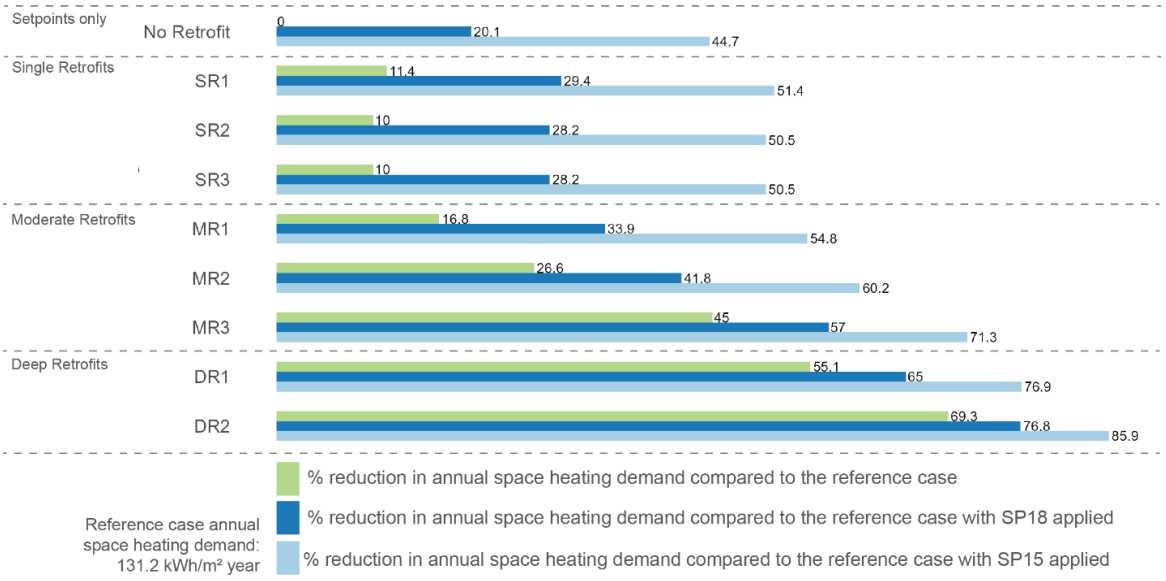

Figure 3: Energy demands reduction for retrofit packages across different setpoint temperature scenarios

The results showed that the reduction in energy demand achieved with SP18 is comparable to the outcomes of moderate retrofit packages MR1 and MR2, which yielded reductions of 17% and 27%, respectively. For single retrofits, such as cavity insulation (SR1), window upgrades (SR2), and infiltration reduction (SR3), energy savings were slightly more, ranging between 28% and 29%.

Deep energy retrofits, which include envelope improvements and mechanical ventilation with heat recovery, showed significant energy reductions, with DR1 and DR2 achieving reductions of 65% and 69%, respectively. Notably, the SP15 setpoint scheme showed the largest energy savings across all retrofit categories, even when applied to less intensive retrofit measures. For instance, single retrofit measures under the SP15 scheme achieved savings of approximately 50%, outperforming some moderate and deep retrofits using either the Standard or SP18 profiles.

3.2. Economic assessment

The payback analysis highlights a preference for implementing moderate or single retrofit measures compared to deep energy retrofits (see Figure 4). Single retrofits, such as SR1, SR2, and SR3, require lower initial investments and demonstrate shorter payback periods along with more favorable NPV. In contrast, as investment levels increase with packages like MR3, DR1, and DR2, payback periods are longer, and NPV decline, showing lower returns for higher-cost retrofits. Notably, the SP15 setpoint scheme achieved significant energy demand reductions and resulted in higher NPV across all retrofit categories. In contrasts, the SP18 profile yielded better NPV than the Standard setpoint profile, particularly for single and moderate retrofits. Despite their substantial energy-saving potential, deep retrofits may not be financially viable due to their high costs and long payback periods.

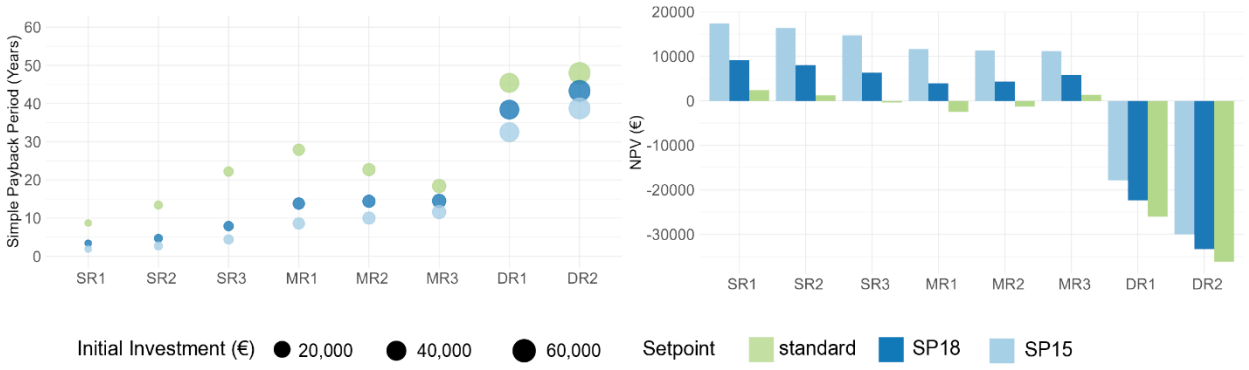

Figure 4: Left: simply payback period. Right: Net Present Value (NPV) for all retrofit packages.

4. CONCLUSIONS

This study aimed to quantify the impact of three different levels of energy retrofit implementation (single, moderate, and deep) while considering distinct heating practices to evaluate their potential for reducing energy demand and associated economic implications. By incorporating a broader range of heating habits into the retrofit decision-making process, the study highlights the opportunity to reassess the scale and design of retrofit measures. Tailoring retrofit projects to

account for heating practices can lead to solutions that are both energy-efficient and economically viable while considering the efficient use of materials and labor.
The results showed that single and moderate retrofits were the most cost-effective strategies, offering shorter payback periods and favourable NPV. These findings suggest that modest investments can achieve energy savings comparable to more extensive retrofits when combined with lower setpoints, making them practical options for budget-conscious households.

In contrast, deep retrofits, despite their significant energy-saving potential, were not financially viable due to high upfront costs and extended payback periods. This emphasizes the importance of balancing energy savings with economic feasibility. This extent of this study was limited to heating season. Additionally, we did not include thermal comfort analysis since the main focus was to explore possibilities beyond standard comfort parameters, as existing models are mainly calibrated for office settings rather than domestic buildings. Future research should build on this approach by exploring tensions between lowering setpoints, energy justice and comfort practices, and incorporating CO2 emissions of retrofit measures into the comparison.

SUMMARY
Reinforced concrete (RC) buildings in Taiwan usually use tile as a construction finish material. The wet construction of an RC building envelope wall system consists of cement mortar, adhesive, and tiles. The layers are about 3 cm in size and could protect the RC. However, large and small earthquakes can cause varying degrees of damage to buildings. When earthquakes damage the exterior wall system, its ability to protect the building is reduced.
In this study, we set the thrust force as a seismic force to two RC specimens and controlled the story drift ratio from 0% to 0.750%. The purpose of the study is to define the condition of the exterior wall system of the RC building after an earthquake. Low and high specimen wall sizes are 180×150cm and 70×240cm. A comprehensive analysis of crack characteristics and tile adhesive strength was conducted through the failure process of the wall systems.

Keywords: envelope wall system, wet construction, earthquake damage, adhesive strength

1. INTRODUCTION

An integrated building is constructed with a structural framework enveloped by an outer shell. The building envelope system protects the building structure from external environmental impacts, thereby ensuring the building's durability. Taiwan, located on the Pacific Ring of Fire, frequently experiences tectonic movements that cause earthquakes. Large and small earthquakes can cause varying degrees of damage to buildings, with seismic zones experiencing more damage. When the building envelope system is damaged, its ability to protect the building is reduced. While previous earthquake damage assessments have primarily focused on building structures, our research emphasizes the importance of building envelope systems in addressing durability issues.

Taiwan has high temperatures and humidity, and the exterior walls of reinforced concrete (RC) buildings often use tiles as building envelope materials. The building envelope used in the wet construction process typically involves several steps, including the structural framework, cement mortar layer, waterproofing layer, and adhesive layer, depending on the requirements of the construction companies. This study conducts cyclic thrust experiments on walls to observe the location of shear cracks during the displacement process and the width of the maximum and residual cracks. The research aims to identify the key factors influencing the pull-off strength of building envelope material.

2. EXPERIMENTAL PROGRAM

The tile installation consists of the following steps: structural layer, cement mortar layer, and adhesive layer. (Figure 1) The tile size is 4.5 × 9.5 cm. Two specimens have dimensions of 180 × 150 cm (code name: 1815) and 70 × 240 cm (code name: 0724). The tile pull-off areas of specimen 1815 are divided into five zones along the diagonal, including left, right, upper, lower, and diagonal sections. Each zone contains nine pull-off test positions, totaling 48 pull-off test positions across the entire wall. (Figure 2) Taking the left zone as an example, it is divided into three sections from bottom to top: sections 1, 2, and 3, each having three pull-off test positions. During the first cycle of 0.000% drift ratio, the pull-off test is conducted in section 1; at 0.375%, the test is conducted in section 2; and at 0.750%, the test is conducted in section 3.

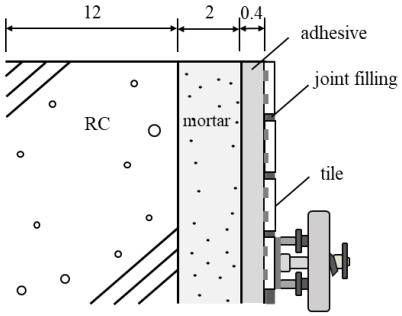

Figure 1. Diagram of the wall section and pull-off testing machine (Unit: cm)

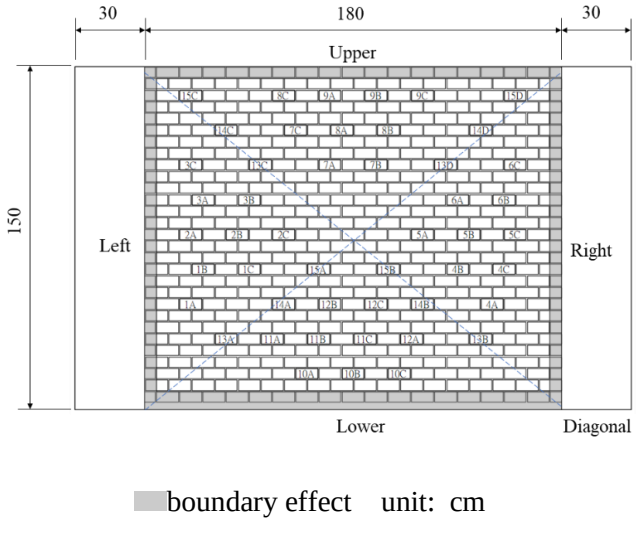

Figure 2. Specimen 1814 plan

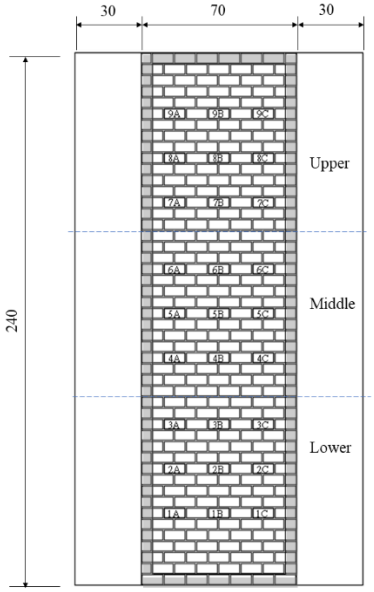

Figure 3. Specimen 0724 plan

The tile pull-off areas of specimen 0724 are divided into three zones, including upper, middle, and lower sections. Each zone contains nine pull-off test positions, totaling 27 pull-off test positions across the entire wall. (Figure 3) Taking the lower zone as an example, it is divided into three sections from bottom to top: sections 1, 2, and 3, each having three pull-off test positions. During the first cycle of 0.000% drift ratio, the pull-off test is conducted in sections 1- 1A,1B, and 1C; at 0.375%, the test is conducted in sections 2- 2A,2B, and 2C; and at 0.750%, the test is conducted in sections 3- 3A,3B, and 3C.

This study involves a cyclic thrust experiment, where the specimen undergoes repeated lateral thrust. The rift ratio (%) is calculated using the displacement (cm) parameter, as shown in Equation (1). In this equation, Δh represents the displacement between the original center of the specimen and the displaced position after thrust, and H denotes the height of the specimen.

$$(\text{Drift Ratio}) = \frac{\Delta_h}{\mathrm{H}} \quad (1)$$

Zone 1, 4, 7, 10, and 13 of 1815 are designated the control group before the main loading. During the first cycle at a drift ratio of 0.375% (displacement of 0.675 cm), pull-off tests are conducted in zones 2, 5, 8, 11, and 14. During the first cycle at a drift ratio of 0.750% (displacement of 1.350 cm), pull-off tests are conducted in zones 3, 6, 9, 12, and 15. (Table 1)

Table 1. Experimental setup

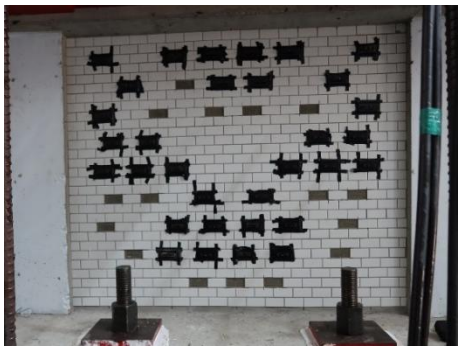
Specimen	Aspect Ratio (cm)	Drift ratio (%) of cyclic thrust experiments	Drift ratio (%) for pull-off testing	Pull-off test zones
1815	180 ×150	From 0.000% to 0.750%	0%	1(Left)、4(R)、7(U)、10(Lower)、13(D)
			0.375%	2(Left)、5(R)、8(U)、11(Lower)、14(D)
			0.750%	3(Left)、6(R)、9(U)、12(Lower)、15(D)
0724	70 ×240	From 0.000% to 0.750%	0%	1(Lower)、4(M)、7(U)
			0.375%	2(Lower)、5(M)、8(U)
			0.750%	3(Lower)、6(M)、9(U)

3. TEST RESULTS

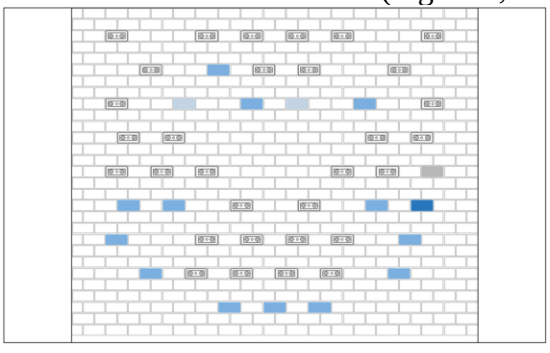
3.1. Pull-off strength and crack width of specimen 1815

Before conducting the thrust experiment, 16 data for pull-off strength were obtained from different zones. The highest strength was 5.97 kN in 4C, while the lowest was 2.20 kN in 13C. At a drift ratio of 0.125% with a displacement of 0.225 cm, the first cycle produced flexural cracks of 0.20 mm and shear cracks of 0.40 mm. When returning to zero in the first cycle, the flexural crack width was 0.03 mm, and the shear crack width was 0.10 mm. (Figure 4, Table 2)

At a drift ratio of 0.375% with a displacement of 0.675 cm, the first cycle produced flexural cracks of 0.20 mm and shear cracks of 1.30 mm. When returning to zero in the first cycle and thrust of 1612.23 kN, the flexural crack width was 0.10 mm, and the shear crack width was 0.50 mm. Three tiles had already fallen off during the pull-off test, resulting in 13 data. The maximum pull-off strength was 5.20 kN in 11B, while the minimum was 0.81 kN in 11A.(Figure 5, Table 2)



(a) Specimen photo



(b) Damage record

Figure 4. 1815-1 Drift ratio 0.000%

At a drift ratio of 0.750% with a displacement of 1.350 cm, the first cycle produced flexural cracks of 0.60 mm and shear cracks of 3.00 mm. When returning to zero in the first cycle and thrust of 2029.17 kN, the flexural crack width was 0.20 mm, and the shear crack width was 1.25 mm. Eight tiles had already fallen off during the pull-off test, resulting in 8 data. The maximum pull-off strength was 4.75 kN in 9B; the minimum was 0.34 kN in 12A. During the third cycle, the wall was destroyed, and the failure strength was 1362.4 kN. (Figure 6, Table 2)

3.2. Pull-off strength and crack width of specimen 0724

Before conducting the thrust experiment, 9 data points for pull-off strength were obtained from different zones. The highest strength was 9.77 kN in 1A, while the lowest was 4.72 kN in 7B. At a drift ratio of 0.125% with a displacement of 0.3375 cm, the first cycle produced flexural cracks of 0.10 mm and shear cracks of 0.05 mm. When returning to zero in the first cycle, the flexural crack width was 0.015 mm, and the shear crack width was 0.01 mm.(Figure 7-8, Table 3)

At a drift ratio of 0.375% with a displacement of 1.0125 cm, the first cycle produced flexural cracks of 0.15 mm and shear cracks of 0.30 mm. When returning to zero in the first cycle and thrust of 594.41 kN, the flexural crack width was 0.03 mm, and the shear crack width was 0.06 mm. The maximum pull-off strength was 6.79 kN in 8B, while the minimum was 0.74 kN in 2B. (Figure 7-8, Table 3)

At a drift ratio of 0.750% with a displacement of 2.025 cm, the first cycle produced flexural cracks of 0.35 mm and shear cracks of 0.35 mm. When returning to zero in the first cycle and thrust of 778.35 kN, the flexural crack width was 0.04 mm, and the shear crack width was 0.06 mm. The maximum pull-off strength was 6.41 kN in 9A; the minimum was 0.52 kN in 6C. (Figure 7-8, Table 3)

Table 4 presents the average pull-off strengths of walls 1815 and 0724. For wall, 1815:The average strengths of the left zone at drift ratios 0.000%, 0.375%, and 0.750% are 4.90 kN, 1.69 kN, and 1.54 kN. The right zones are 4.30 kN, 1.54 kN, and 1.45 kN. The upper zones are 3.39 kN, 1.69 kN, and 4.75 kN. The lower zones are 4.80 kN, 2.55 kN, and 0.48 kN. The diagonal zones are 3.42 kN, 1.35 kN, and 1.80 kN. The average strengths across all regions are 4.16 kN, 1.76 kN, and 2.00 kN. At 0.375%, the highest pull-off strength, 5.20 kN, occurred at location 11B, where no surrounding cracks were observed. The strength at a drift ratio of 0.375% was reduced by 2.36 times compared to 0.000%. At 0.750%, the reduction was less pronounced. This was due to locations 9B and 15D maintaining high strengths of 4.75 kN and 4.12 kN despite unidirectional cracks caused by shear forces.

For wall 0724:The average strengths of the upper zone at drift ratios 0.000%, 0.375%, and 0.750% are 4.72 kN, 5.60 kN, and 5.52 kN. The middle zones are 5.89 kN, 2.88 kN, and 1.77 kN. The lower zones are 8.70 kN, 2.72 kN, and 2.88 kN. The average strengths across all regions are 6.44 kN, 3.74 kN, and 3.39 kN. At a drift ratio of 0.375%, the highest pull-off strength, 6.79 kN, occurred in the upper zone at location 8B, with no surrounding cracks observed. The strength at 0.375% was reduced by 1.72 times compared to 0.000%. At a drift ratio of 0.750%, the reduction factor was 1.90 compared to 0.000%. The highest pull-off strength at 0.750% was 6.41 kN in the upper zone at location 9A.

4. CONCLUSION

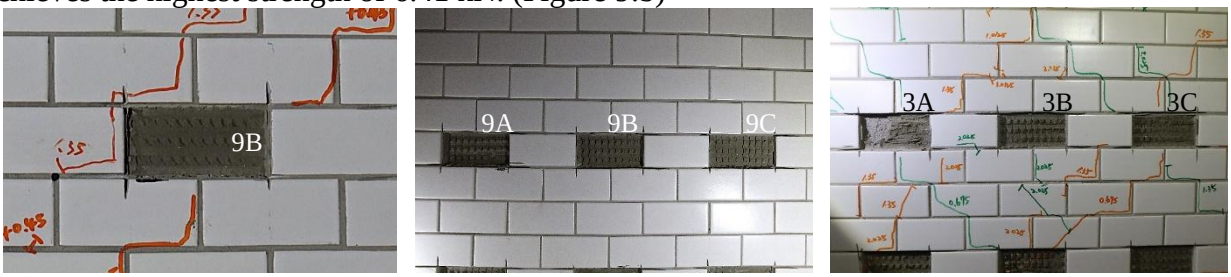
This study conducted Cyclic Thrust Experiments on walls with different drift ratios to observe the shear crack locations, the widths of the maximum and residual cracks, and the displacement process. The influence of cracks caused by seismic loading on pull-off strength was analyzed. The key conclusions are as follows:

4.1. Crack Characteristics

Most of the cracks formed along the grout of the tiles. As the thrust increases, the width and the number of cracks increase. In wall 1815, drift ratios of 0.125%, 0.375%, and 0.750%, the residual shear cracks increased from 0.10 mm, 0.50 mm to 1.25 mm, while the maximum cracks were 0.45 mm, 1.20 mm, and 3.50 mm. In wall 0724, drift ratios of 0.125%, 0.375%, and 0.750%, the residual shear cracks increased from 0.01 mm, 0.06 mm to 0.06 mm, while the maximum cracks were 0.05 mm, 0.30 mm, and 0.35 mm. The residual cracks in the shear direction of the two walls differ by a factor of 10.

Cracks that pass through behind the tiles will affect pull-off strength. For example, a drift ratio of 0.375% in wall 1815,11B, which had no cracks, showed the highest strength at 5.20 kN. 11A, with forward and reverse shear cracks passing through, had the lowest strength at 0.34 kN.

At location 2B of wall 0724, both forward and reverse directional cracks intersect, resulting in the lowest strength of 0.74 kN. In contrast, at location 8B, no cracks are present, and the highest strength of 6.79 kN is recorded. At a drift ratio of 0.750%, the overall strength generally decreases. For wall 1815, location 9B has the highest strength of 4.75 kN, with only unidirectional cracks appearing along the grooves (Figure 9.a). For wall 0724, location 9A, with no intersecting cracks, achieves the highest strength of 6.41 kN. (Figure 9.b)



(a) 1815:9B (b) 0724:9A 9B 9C 0724:3A 3B 3C

Figure 9. Drift Ratio 0.750% Cycle1 Maximum pulling force position

4.2. The pull-off strength differences between shear short walls and flexure tall walls

Cyclic Thrust Experiments caused X-shaped shear diagonal cracks on the 1815 short wall. At a drift ratio of 0.375%, the strength decreased by 2.36 compared to 0.000%. At 0.375%, 4 tile specimens had already fallen off the wall surface; by 0.750%, 8 tile specimens had fallen off.

Cyclic lateral loading caused flexural cracks on the 0724 tall wall, concentrated at the bottom of the specimen. At a drift ratio of 0.375%, the strength decreased by 1.72 compared to 0.000%. During the pull-off test at a drift ratio of 0.750%, the upper zone (e.g., 9A, 9B, 9C) exhibited the highest pull-off strength, with no cracks (Figure 9.b). In contrast, the lower zone (e.g., 3A, 3B, 3C) showed significant intersecting bidirectional cracks (Figure 9.c).

At a drift ratio of 0.375%, the strength of the short wall decreased significantly compared to the tall wall. Both walls showed noticeable strength reduction at 0.375%, but no further reduction occurred at 0.750%.

According to the National Standards of the Republic of China, the adhesion strength is 2.565 kN. For wall 0724, only the strength in Zone 6 at 0.750% fell below the standard value, while all other average strengths exceeded the standard. In contrast, the average strength of wall 1815 at 0.375% was 1.45 times lower than the standard value. During the experiment, the surface tiles on the tall wall retained their adhesive strength and did not fall off, resulting in an overall higher average pull-off strength than the short wall.

SUMMARY
The building sector faces challenges in balancing occupant comfort and resource efficiency. Indoor environmental quality (IEQ) systems often regulate entire spaces, including unoccupied areas, leading to resource waste and unguaranteed comfort. This has spurred the development of personalized environmental control systems (PECS), which adjust IEQ conditions to individual occupants' needs, enhancing comfort while potentially reducing energy use through effective design and operation. PECS have been studied using simulation and experimental methods, with their performance reported using diverse methods metrics. In this study, the results from a literature review conducted in the framework of IEA EBC's Annex 87 (Subtask D) on PECS will be presented. The objective of the review is to give an overview of different PECS performance simulation evaluation methods (building simulations, computational fluid dynamics), approaches and KPIs used to assess thermal comfort & IAQ.
Keywords: personalized ventilation, CFD simulations, experiments, key performance indicators

1. REVIEW METHODOLOGY AND OVERVIEW OF STUDIES

This review was carried out following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement. An extensive literature search was conducted, targeting publications from 1990 to 2023. Databases searched include namely Web of Science, ScienceDirect, PubMed and Scopus. Keywords were grouped into three levels: (i) general context ("built environment", "indoor environment", "occupant", "human", "user", "system", "HVAC"), (ii) PECS-specific terms ("personal", "personalized", "individual", "micro", "local", "centric", "portable"), and (iii) evaluation methods ("simulations", "computational fluid dynamics", "chamber studies", "lab studies", "field studies", "experiment"). An extensive number of potential publications was obtained, out of which studies unrelated to PECS or typically encountered indoor environmental conditions were excluded yielding a total of 302 papers. From the final pool of selected papers, the studies were classified depending on the adopted PECS evaluation method(s): a) Building simulations (BS), b) Computational fluid dynamics (CFD) studies, c) chamber or lab studies (CS) and c) field studies (FS) and relevant methodological elements were extracted. CS was the most common method (174 studies) used in the literature, followed by CFD (81 studies), BS (30 studies) and finally FS (17 studies). In this work, BS and CFD studies will be highlighted. PECSs were further classified into thermal management PECS regulating only the body's heat loss mechanisms "thermal PECS". When additionally regulating IAQ, they were referred to as "thermal+IAQ PECS". Moreover, the mobility of the PECS was defined and used in the classification. Building attached PECS refers to devices that are integrated within the building envelope. Semi-detached refers to PECS that have more degrees of freedom in certain planes and can be attached to the furniture. Detached PECS refer to PECS that are portable and independent from the building. Other refers to vehicles or aircrafts.

Figure 1 illustrates the chronological progression of simulation studies on PECS. Since 2010, there has been a notable rise in studies using Building Simulation (BS) and Computational Fluid Dynamics (CFD). Notably, no IAQ-only PECS were assessed using BS, likely due to the typical assumption of uniform zonal conditions, which limits BS's ability to evaluate air quality. Detached

thermal PECS became a common focus in BS studies from 2017, with a peak in 2022. CFD, offering detailed insights into temperature and airflow in microenvironments, was used more frequently than BS. Throughout the years, building-attached or semi-detached PECS addressing both thermal and IAQ control were consistently studied. Most of these involved ceiling- or desk-mounted personalized ventilation systems delivering conditioned outdoor air.

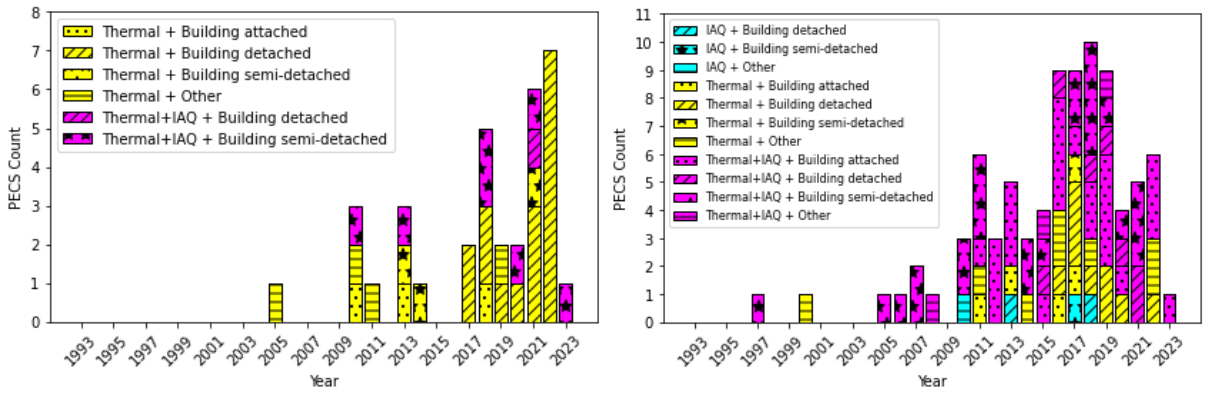

Figure 1. Illustration of the chronological evolution of PECSs' simulation studies: BS (left), CFD (right)

1.1 Building simulations

Three different approaches were identified in the literature to integrate PECSs into BS tools: direct, collaborative and custom. Direct approaches model PECSs and its operation directly into the computational domain in the building simulation tool. **Figure 2** presents the use of these methods to simulate the different types of PECS. Direct approaches were possible with tools such as IES-VE and IDA-ICE and were used for thermal chairs (Shahzad et al., 2018) (thermal, building detached PECS) and personalized ventilation (PV) (Lipczynska et al., 2021) (thermal+IAQ, building semi-detached PECS). These tools allow for some degree of spatial granularity when simulating PECS. However, their accuracy was not proven as validation studies were either not conducted or conducted without the presence of PECS. Collaborative approaches model used BS tools (Modelica, Energy plus, etc.) to model the building and its general systems and couple the PECS externally as a boundary condition. They were used mainly for building detached thermal PECS (e.g., desk fans, thermal chairs, foot heaters, heated furniture). This was done via coupling with thermoregulation models (Boudier & Hoffmann, 2022)or PECSs' performance curves (Veselý et al., 2019). Collaborative methods did not consider the interaction between the PECS and the background environment. The limitations associated with the first two methods gave rise to the final integration method – the custom method; where authors develop their own code of the building its systems and the PECS. These codes differ in their level of space discretization. The simplest ones divide the space into two interacting zones: an occupied zone with PECS and the second zone representing the rest of the space and more complex codes discretize the macroclimate and microclimate control volumes into multi-layers (Al Assaad et al., 2018; Jain & Shorey, 2015). Thus, custom codes consider the interaction between the PECS and the background environment. They were the most consistently used method across all PECS types.

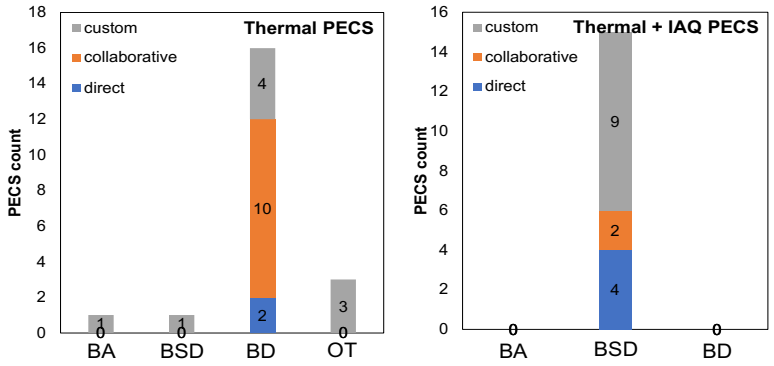

Figure 2. Different integration methods of building attached (BA), building semi-detached (BSD), building detached (BD) and other (OT) (i.e., vehicles) thermal and thermal+IAQ PECS into BS.

Figure 3 illustrates the different approaches used to assess thermal comfort using BS. 3 approaches were mainly used. The most common one was to couple the BS model with thermophysiological models (AUB (Salloum et al., 2005), Tanabe (Takahashi et al., 2021)) and sensation/comfort models (Zhang's (Zhang et al., 2010a)). The outputs were a thermal sensation and comfort votes on a 9 pt scale assessed for cases with and without PECS. This approach was used for building detached thermal PECS and semi-detached thermal+IAQ PECS in tandem with custom and collaborative methods. The second most used approach was the PMV/PPD used across all PECS types and for all three integration methods. However, its implementation was not always clarified. Finally, the third approach was via subjective experiments conducted in climatic chambers or field tests. Other approaches used include the adaptive comfort model, regression equations for thermal comfort derived from the first approach, and temperature and RH(%) levels falling within certain ranges. For IAQ, it was only assessed in two studies on PV (Al Assaad et al., 2018; Harrouz et al., 2023) using custom integration approaches as BS tools were meant for thermal/energy simulations. In these custom codes, the species' transport equations were solved and key performance indicators such as the ventilation effectiveness and CO_2 removal rates from the indoor air were calculated.

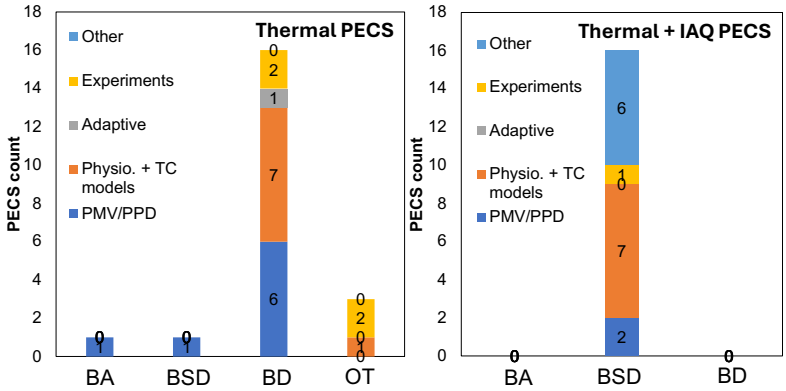

Figure 3. Comfort evaluation methods of building attached (BA), building semi-detached (BSD), building detached (BD) and other (OT) (i.e., vehicles) thermal and thermal+IAQ PECS using BS

1.2 CFD simulations

Computational fluid dynamics (CFD) serves as a powerful tool offering a detailed visual analysis of the performance of PECS in indoor built environments. Ensuring high-quality simulations requires a well-managed numerical modelling process accounting for the geometry including the

computational thermal manikin (CTM), grid generation and refinement, turbulence models, numerical schemes and boundary conditions. Implementation of realistic CTM with humanoid shapes guarantees an accurate prediction of the convective heat transfer between the body surface and ambient environment, radiant heat transfer between the body and walls and the buoyancy driven thermal plume. **Table 1** presents the adopted mesh types/metrics and CTM types in PECS CFD studies. In the PECS literature, only Reynolds-Averaged Navier-Stokes (RANS) models have been used, due to their balance between computational efficiency and accuracy. Among these, the most commonly used was the Re-Normalization Group (RNG) k–ε model (30%), followed by the realizable k–ε model (18%), the standard k–ε model (10%), the shear stress transport (SST) k–ω model (6%), the Reynolds Stress Model (RSM) (3%)—often combined with Lagrangian particle tracking—and the zero-equation model (1%). Notably, 15% of studies did not report the airflow model used, while 19% provided only partial information (e.g., referring simply to a "k–ε model"). From the 81 main studies, 62 validate with their own experimental data from climatic chamber experiments or field tests, 12 validate from published experimental data sets in the literature and 7 studies do not mention any validation.

Table 1. Adopted mesh types and mesh metrics in PECS CFD studies

Mesh type	**(%) of studies***
Hexahedral structured	14%
Tetrahedral/polyhedral unstructured	43%
Hybrid	8%
Mesh metrics	**(%) of studies**
Skewness	Only 26% report 1 or 2 of these metrics
Aspect ratio	
Orthogonality	
Grid growth rate	
Mesh sensitivity analysis	40%
CTM	**(%) of studies**
realistic	54%
simplified	21%
rectangular	15%
single segment	10%

**35% of studies do not detail their adopted mesh*

In the literature, different methods were adopted to assess the thermal comfort performance of PECS. The methods varied in complexity and were not particularly motivated by the specific PECS type. The coupling of physiological models as done in (Gao et al., 2006), (Zhang (Zhang et al., 2010b), Radtherm software including the Fiala model (Fiala et al., 2001), AUB (Al-Othmani et al., 2008; Salloum et al., 2005)) and Zhang's thermal sensation and comfort models (Zhang et al., 2010c) with CFD models were the most common method for all PECS types. The coupling was often clearly laid out in the studies with explanatory flow charts. The second approach was to use psychological rational models such as the PMV/PPD, standard effective temperature (SET) and equivalent temperature (ET) at segmental level. In the latter, the studies do not detail all the necessary inputs to calculate these quantities. Few studies on convective-based PECS additionally assess the DR, turbulence and airflow fluctuation frequencies (Conceição & Awbi, 2021). All CFD studies utilize temperature and velocity contours to further support their conclusions. To study the

IAQ performance of PECS, studies can be classified depending on their scope into 3 main categories:
C1: Studies assessing IAQ performance with respect to non-infectious exogenous or endogenous pollutants/**C2:** Studies assessing the ability of the PECS in protecting occupants from cross contamination due to exposure to infectious aerosols & **C3:** Studies that assess IAQ indirectly via air renewal metrics that evaluate the amount of clean air delivered to the occupant. Note that some studies can belong to multiple categories. **Figure 4** shows the used KPIs for IAQ assessment and occurrence frequency per category and PECS type. The intake fraction (iF) (i.e., ratio of mass inhaled over mass emitted) was the most used KPI across all study scopes followed by the normalized concentration. The ventilation effectiveness was the second most used KPI for C1.

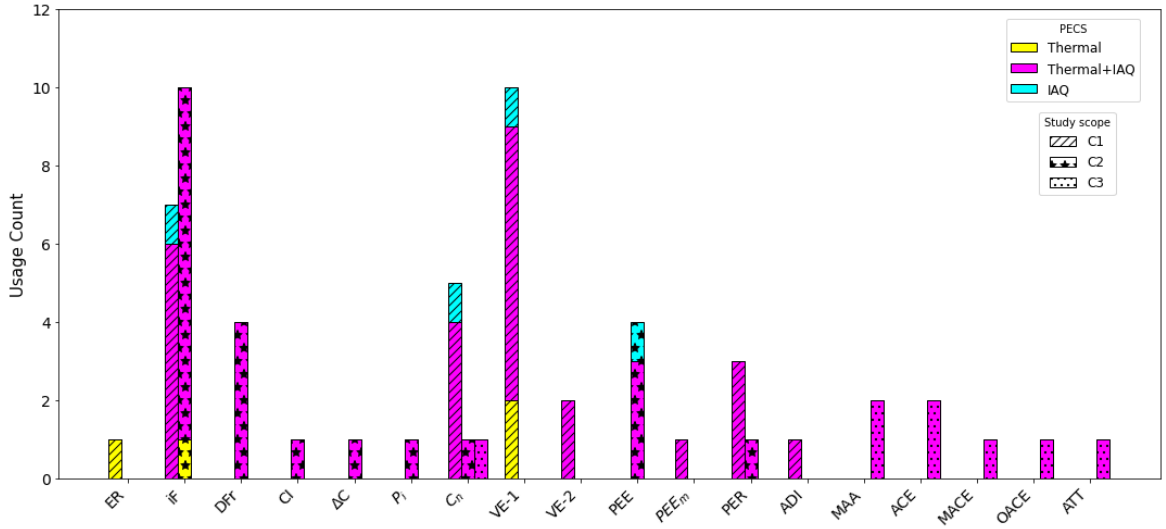

Figure 4. Usage count of KPIs used in CFD studies per PECS type and study scope (C1, C2, C3)

3. CONCLUSION

Building energy simulation tools offer significant advantages in modelling and optimizing PECSs, particularly given the limited market availability of such systems. However, several limitations remain, particularly concerning model accuracy and the lack of validation, as opposed to CFD analysis. On the other hand, CFD requires careful selection of simulation time steps, mesh refinement, and convergence criteria, all of which ensure numerical stability and reliability. In terms of methods and KPIs, various methods exist with no specific selection criteria. Currently, in the literature, there are no standardized ways in which PECSs' performance could be assessed and reported. Future work should focus on formulating such guidelines and recommendations for both researchers and practionners.

ACKNOWLEDGEMENTS

This study is performed within the framework of the International Energy Agency - Energy in Buildings and Communities Program (IEA-EBC) Annex 87 "Energy and Indoor Environmental Quality Performance of Personalized Environmental Control Systems". This work has been supported by the FWO junior postdoctoral fellowship number 1272224N for the project "Performance of resilient personalized environmental control systems (r-PECS) in non-residential buildings".

SUMMARY
Personalized Environmental Control Systems (PECS) provide individualized thermal comfort by conditioning a person's immediate surroundings rather than the entire space, offering a shift toward occupant-centered building operation. While the existing classification of PECS concerning thermal comfort focused on design aspects and heat transfer methods, this study, part of the IEA EBC Annex 87 international project, introduces a novel framework categorizing PECS by their mobility and thermal functionality. The classification includes *building attached, building semi-detached*, *building detac*hed, *wearables*, and *others*, with building-detached devices being the most common and versatile in providing a better thermal environment compared to the conventional approach. These devices typically heat extremities and cool the back and neck, while the head requires both for optimal comfort. Combining different PECS types can effectively enhance comfort across a wide range of background temperatures. Therefore, this new classification offers a deeper understanding of personalized device designs that enhance personal thermal comfort.

Keywords: thermal environment, personalized environmental comfort systems, PECS, heating and cooling, mobility.

1. INTRODUCTION

Personalized Environmental Control Systems (PECS) offer the benefit of adjusting the immediate environment around an individual based on their preferences rather than conditioning an entire room (Shinoda et al., 2024). This marks a shift in building operations, emphasizing personalized, occupant-centered comfort instead of conditioning spaces that may often be unoccupied. Over the past decades, extensive research has been conducted on PECS aimed at enhancing thermal comfort. Understanding which devices can effectively provide comfort to individuals is crucial. Several studies, including those by Veselý & Zeller (2014), Rawal et al. (2022), Song et al. (2022), and Luo et al. (2022), have systematically reviewed various personalized devices, evaluating their comfort and energy performance. However, previous classifications of thermal devices have primarily focused on design aspects (e.g., seat, foot heater, garment) and heat transfer methods (e.g., convection, radiation). This study presents findings from a systematic literature review on PECS conducted within the IEA EBC Annex 87 international project. It introduces a novel classification framework that categorizes PECS based on their *mobility* and *thermal functionality*, providing deeper insights into the types of personalized devices that can enhance thermal comfort and their applicable environmental conditions.

2. METHODOLOGY

A systematic literature review on thermal and indoor air quality-related PECS was conducted as part of IEA EBC Annex 87, using Scopus, Taylor & Francis, PubMed, Google Scholar, and Web of Science, with a focus on peer-reviewed publications in English. After several screening stages,

342 original publications related to thermal comfort and indoor air quality (IAQ) were identified, with 166 specifically examining the thermal aspects of PECS involving human participants. Among 203 test conditions from these papers, 115 reported improved thermal environments compared to conventional heating and cooling. Per convention developed within IEA EBC Annex 87, the PECS devices were categorized into 5 types: (i) *building detached* (attached to the building and immobile), (ii) *building semi-detached* (mobile but requires connection to the building by ducts or pipes), (iii) *building detached* (mobile and can be positioned freely in a room), (iv) *wearables* (attached to the human body), and (iv) *others* (related to other applications beyond buildings). Additionally, their thermal functionality was categorized into three types: heating only, cooling only, and both heating and cooling. This study focuses on devices that improve thermal environments, emphasizing their *mobility*, *thermal functionality*, applicable *background conditions* (air temperature), and targeted *body parts*.

3. RESULTS AND DISCUSSION

An overview of PECS devices that enhance thermal environments compared to traditional heating and cooling methods is shown in Figures 1–4. Figure 1 shows the distribution of PECS types, while Figure 2 presents their distribution across different background air temperatures, highlighting thermal functionality and type. Figure 3 focuses on specific design details, and Figure 4 outlines the cases where the combination of PECS were deployed.

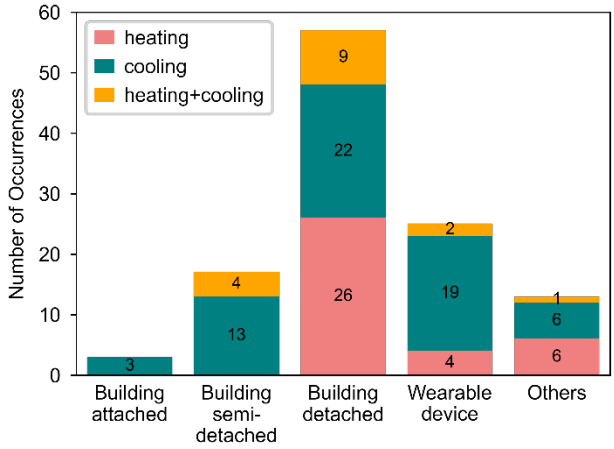

Figure 1. Overview of PECS devices providing better thermal environment per category of device type

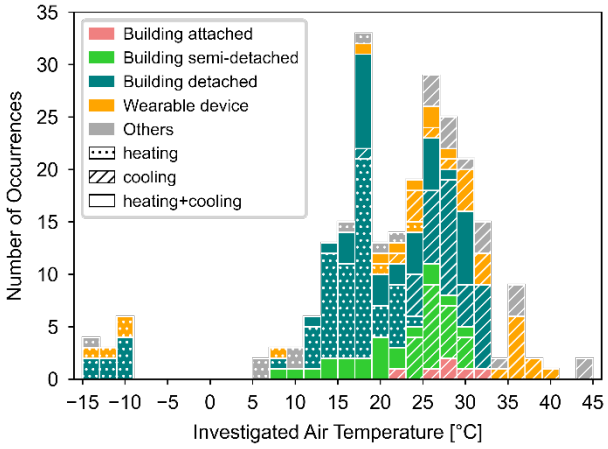

Figure 2. Range of background air temperatures tested for different types of PECS

Building detached devices occur as beneficial ones most often (50%), followed by *wearables* (22%) and *building semi-detached* ones (15%). *Building attached* devices, such as ceiling fans and air nozzles, are among the least represented, accounting for only 3% of the total. Similarly, devices categorized as *others* (e.g., car seats) make up 11%. In contrast, as shown in Figure 3, there is significantly greater diversity in the designs of *building detached* devices, highlighting a broader range of options within this category of PECS. Among specific categories, chair-based solutions (*building detached* devices) are the most frequently used for providing a better thermal environment. Interestingly, the combination of different types of PECS is the most common and effective approach for achieving an improved thermal environment, often surpassing the performance of individual PECS types. These are combinations of devices, as shown in Figure 4,

that target both core body parts and extremities, such as a heated chair and a foot warmer, a heated desk and a floor mat, or a fan and cooling desk panel.

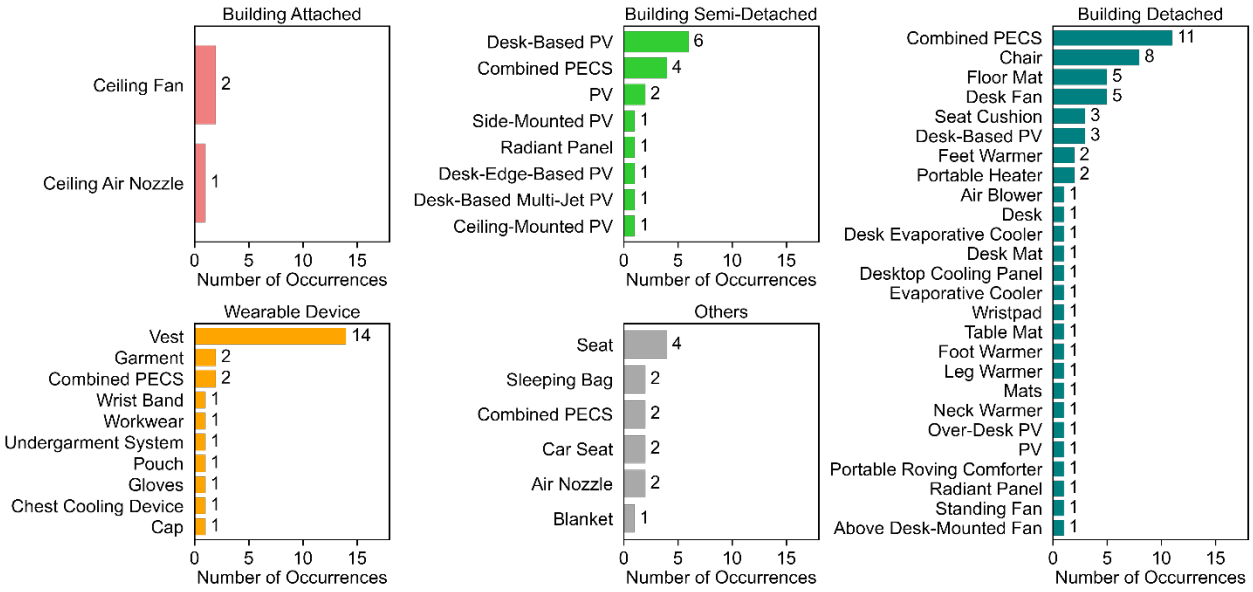

Figure 3. Frequency of studied PECS devices that provide improved comfort (PV – personalized ventilation)

The analysis of the functionality of PECS and their operational background air temperature range shown in Figure 2 further reveal the following:

- **Cooling application:** The operational range of PECS for cooling spans from as low as 18°C to as high as 45°C, with most usage occurring within the 25-33°C range. At air temperatures exceeding 33°C, wearable devices such as cooling garments and vests are predominantly utilized for outdoor work environments. Within the 21-33°C range, more typical for indoor application, building attached devices for cooling are less common compared to the building detached and semi-detached PECS.
- **Heating application**: The use of the heating function of PECS can be split into two distinct ranges: (i) sub-zero air temperatures (-15…-10°C) representing outdoor conditions and (ii) air temperatures that are typical indoors (5-30°C). Mobile devices and wearables are commonly used for outdoor applications, while building-detached PECS are more often employed indoors, particularly in the 17-19°C range.
- **Heating and cooling application**: While many PECS are designed for specific thermal applications (either heating or cooling), a few types can serve both functions. These include mainly chairs and convective systems such as air blowers.

The list of body parts shown in Figure 5 reveals that the extremities (e.g., as feet, hands, arms, thighs, and legs) were the most frequently studied body parts for local thermal sensation in heating scenarios, while the back and neck were primarily examined in cooling scenarios. This trend aligns with the understanding that cold discomfort in the extremities significantly impacts overall comfort, while cooling core body areas is essential for preventing overheating and regulating core body temperature (Gagge et al., 1967). Interestingly, the head was studied almost equally in both heating and cooling scenarios, emphasizing its important role in maintaining thermal comfort.

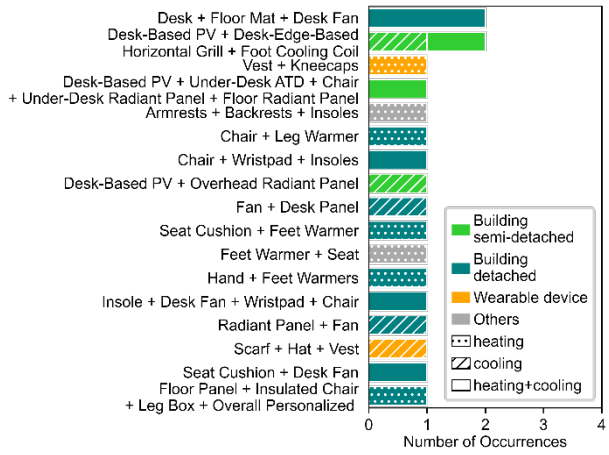

Figure 4. Overview of the combination of PECS providing better thermal environment

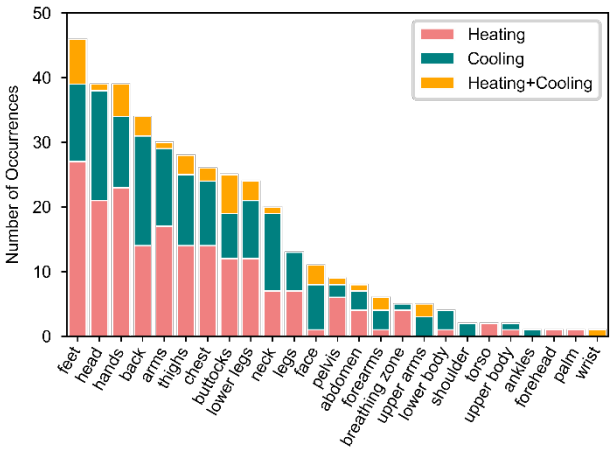

Figure 5. Body parts examined using PECS for local thermal sensation in heating and cooling cases

4. CONCLUSION

This work introduces a new classification of PECS (Personal Environmental Control Systems) based on their mobility relative to buildings, categorizing them as *building-detached*, *semi-detached*, *mobile detached*, *wearables*, and *others*. Building-detached devices are the most common and diverse, addressing different body parts in various settings - typically heating extremities and cooling the back and neck, while the head requires both for comfort. Combining PECS types, like heated chairs with foot warmers, effectively improves thermal comfort across a wide range of background temperatures. Some PECS can function to provide both cooling and heating, but often using different mechanisms (e.g., conductive heating and convective cooling in chairs, etc.). Further research into more quantitative analysis on the level of thermal comfort improvement in the proposed classification is ongoing, aiming to better understand the effectiveness of different types of PECS designs.

ACKNOWLEDGEMENTS

We thank all contributors to IEA EBC Annex 87 who participated in the systematic literature review within Thermal and IAQ domains and took part in different phases of the review process.

SUMMARY
Personalized Environmental Control Systems (PECSs) manage individuals' surroundings with limited energy use. This study evaluates user acceptance and perceived comfort of a thermal (360 W fan heater) and visual (12 W task lamp) PECS in two living-lab office environments in central Italy, both permanently equipped to monitor environmental parameters at room level and at each workstation. Twenty-four occupants participated in the study. The experimental design comprised three scenarios: a reference without PECS, a PECSs scenario with participants controlling their surroundings exclusively via PECSs, and a mixed scenario where both PECSs and background systems were available to final users. The campaign last 4 working weeks with participants providing their environmental sensation, satisfaction, and preferences by answering an online questionnaire administered twice-a-day for a total of 447 datapoints. Overall, the scenario combining the usage of PECS and background systems was the most appreciated configuration, especially considering the thermal environment.

Keywords:Personalized Environmental Control System, PECS operation, PECS control, Office environment.

1. INTRODUCTION

Occupants' environmental dissatisfaction is common in shared spaces due to standard system design and regulation aimed to accomplish the response of the average person, neglecting individual preferences and diversity (Parkinson, et al. 2023). Moreover, building systems addressing the environmental management at room-level can contribute to energy waste: to lit or condition the thermal environment of an entire room often leads to excessive energy consumption, especially when only a portion of the space is in use. Personalized Environmental Control Systems (PECS) offer a promising solution to both challenges by improving individual comfort while reducing energy consumption (Godithi, et al. 2019). The localized PECS approach enhances occupant satisfaction by catering to personal preferences while minimizing energy use since PECS generally operate with limited power to address specific areas rather than big volumes.
Heating PECS include air sleeves, heating seats, foot heaters, local radiative heating devices, among others. A review paper screened 77 projects, and it was found a very high energy saving potential, even if real-case applications resulted in a high variability of the results (Rawal, et al.

2020). Personalized lighting is also relevant since visual tasks can vary significantly in the same working/living environment. The combination of general with local lighting solutions may increase users productivity and ensure energy savings. Energy savings up to 40% were found in a study where local lighting was combined with lower general illuminance levels in (Logadòttir, et al. 2014). Visual PECS can be desktop-based luminaries, as well as ad-hoc and locally operated dynamic lighting systems.
Despite the concept and the first device date back to more than 40 years ago (Madsen e Saxhof 1977), PECS are not yet extensively applied in practice and there is limited evidence of their application in real case studies accounting for users' feedback. This study, developed in the framework of IEA EBC Annex 87 project on Energy and Indoor Environmental Quality Performance of Personalised Environmental Control Systems (IEA-EBC 2021), aims to fill this gap by observing the adoption of both thermal and lighting PECS in two office living-labs environments.

2. MATERIALS AND METHODS

The aim of this research is to evaluate the potential of thermal and lighting PECS in enhancing occupants' environmental perception in real office settings and to gather user feedback on PECS functionality. This will help assess the overall acceptability of introducing PECS in contexts where room-based regulation systems are predominantly used. To this aim, the same experimental protocol was implemented in two office living-labs in central Italy over a four-week period in winter 2025. The protocol included an environmental monitoring setup for continuous data collection at both room and workstation levels. Additionally, it involved an environmental perception survey, to be completed twice a day by participants, and a PECS operational feedback survey, to be completed once at the end of the study. This paper focuses solely on the survey results, while the analysis of environmental data will be presented in future works.

2.2 Living Labs

This section describes the two living-labs involved in the research providing a general overview of their characteristics as well as a presentation of the occupants' sample in terms of size and experimental scenarios distribution.

2.2.1. EAPL^{2}AB (LL1)

The EAPL^{2}AB comprises 10 offices on the first floor of the two-story Interuniversity Research Centre on Pollution and Environment "Mauro Felli" (CIRIAF) building in Perugia, central Italy. The city is in *Cfa* (humid subtropical) climate according to the Köppen-Geiger international climate classification. Details about building structure and thermal properties of the opaque and transparent components of the envelope can be checked in (Pisello, et al. 2016). All the LL1 offices present similar dimensions (4x4x2.9 m) and are equipped with the same HVAC and lighting system. HVAC is centralized but each room has its thermostat so that occupants can adjust the setpoint $\pm$3 °C from the target temperature. The lighting system includes four lighting fixtures (57 × 57 cm) made by four fluorescent tube light each. The environmental conditions are continuously monitored thanks to a Wireless Sensors Network infrastructure described in detail in (Pisello, et al. 2016). Three out of 10 LL1 offices were involved in this study, all North-East facing, with 2 or 3 occupants each. Overall, 7 occupants took part to the study and they were subsequently exposed to three scenarios: the reference configuration with only background systems (LL1_Room) lasting 1 week, the PECS configuration with lighting and thermal management limited to the adoption of

the introduced PECSs (LL1_PECS) lasting 2 weeks, and the mixed scenario with both PECSs and background systems available to final users (LL1_Mixed), lasting 1 week.

2.2.2. ENEA Living Lab (LL2)

The ENEA Living Lab (LL2) is on the second floor of an office building located in the Casaccia Research Centre in the northern outskirts of Rome, *Csa* (Mediterranean) climate, according to the Koppen classification. The living-lab consists of 11 rooms: 7 west oriented and 4 facing east. The rooms are 3.90m wide, 4.34m deep and 3.2m high. The LL2 has one floor above and one below at the same temperature, thus the thermal exchange with the outdoor environment takes place only through the facades. Each office is equipped with room air conditioning unit, providing space heating and cooling energy services interdependently at room level. LL2 is equipped with a smart energy management system able to control and monitor several functions of the building. A detailed description of the LL2 features can be found in (Zinzi e Chiesa 2023). 17 occupants were involved in this study, 7 assigned to private offices and the remaining in shared spaces with at least one colleague. Due to organizational constraints, it was not possible to limit the control of occupants to the room background system, therefore, in LL2 only two scenarios were tested: the reference configuration with only background systems (LL2_Room) and the mixed scenario with both PECSs and background systems available to final users (LL2_Mixed). Among participants, 3 experienced the LL2_Room and 9 the LL2_Mixed configurations for the entire duration of the campaign. The remaining 5 participants experienced both.

2.3 PECS

The PECS for lighting consist of desk led lamps, whose position, generally above the PC monitor, is set by the single user according to their preferences. The product choice was a compromise between cost and characteristics of the lamp. A relevant feature is the possibility of modulating the power in 11 levels with 12W as maximum electric power absorption; in addition, the light colour has five modes between 3000K and 6000K.

The PECS for heating is a fan heather, chosen as a good compromise between cost and performance. The device dimensions are: 150mm width, 100mm depth and 175mm height; this size makes it easy to be placed and moved on the desk depending on the user's need. The electric power absorption is 360 W constant and, unfortunately, it is not possible to modulate the power; conversely, it is possible to move the air outlet grid to properly direct the flow.

2.4 Surveys

2.4.1. Environmental perception survey

The implemented questionnaire adapts the ASHRAE procedures defined in (ASHRAE 2013) to collect right-here-right-now responses of the occupants in both thermal and visual domains. Questions are limited to sensation (5 points), satisfaction (5 points), and preference (3 points) to reduce participants' fatigue and keep their engagement high by avoiding an excessive number of questions and time to compile. The perception survey had to be filled via web twice a day: in the morning and the afternoon.

2.4.2. PECS operative feedback survey

The PECS operative feedback survey was distributed to participants that experienced the PECS scenario just once, at the end of the campaign. Questions were structured in order to focus on how people interact with PECS taking advantage of the adjustable settings and limited target areas, as

reported in Table 1.
Finally, any potential PECS limitation was further explored giving the chance to provide an open-ended list of faced challenges while using PECS.

Table 1. PECS operative feedback survey structure

PECS type	Question	Answer options
Lighting	Do you change the lamp orientation to enhance your comfort?	Never Sometimes Often Always
	Do you use the function to adjust the light intensity?	
	Do you use the function to adjust the light colour temperature?	
	Do you keep both the table lamp and ambient lights on?	
	Do you find the lamp control buttons easy to use?	Not at all Slightly easy to use Moderately easy to use Absolutely yes
Thermal	Do you change the fan's position during the day to ensure maximum comfort?	Never Sometimes Often Always
	Do you use the knob to adjust the airflow speed?	
	Do you ever keep both the fan and the air conditioner on, with the set-point higher than the one configured?	
	Do you find the heating fan easy to use?	Not at all Slightly easy to use Moderately easy to use Absolutely yes

3. RESULTS

3.1 Environmental perception

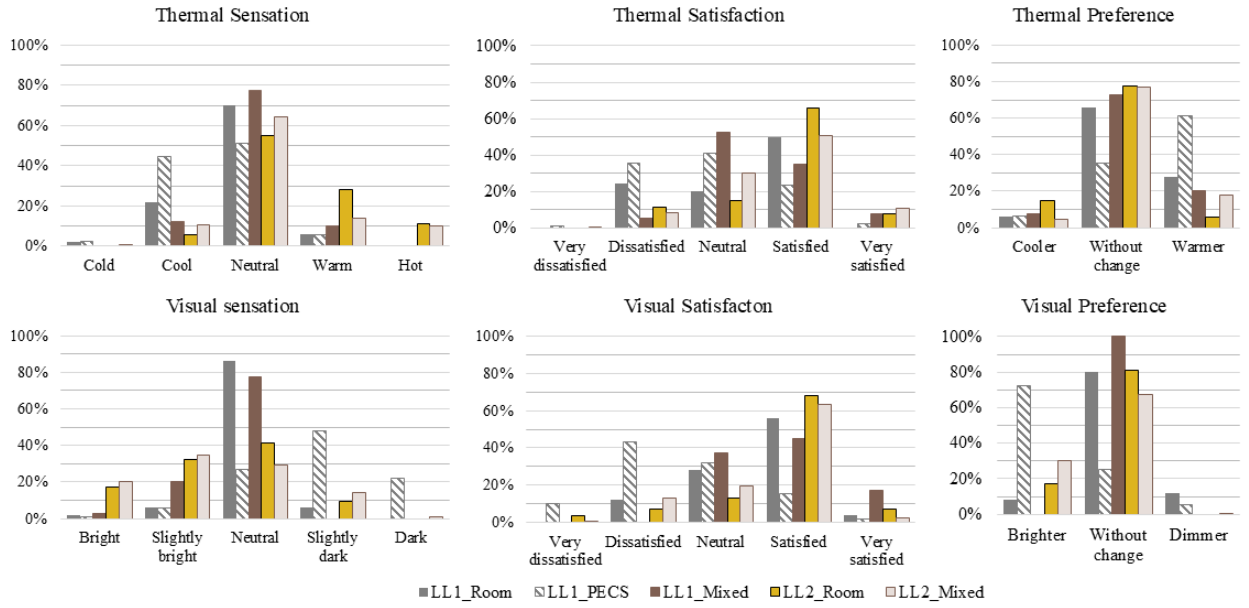

Figure 1. Environmental perception responses across scenarios and living-labs

Results are summarized in Figure 1. Focusing on responses pertaining to the thermal domain, the Mixed scenario received the highest percentage of perceived neutral thermal sensation for both LL1 (78%) and LL2 (64%). This scenario also had the highest share of "Very satisfied" votes for the thermal environment. However, on average, the Room configuration (without PECS) achieved

the highest satisfaction score in LL2, i.e. 0.70 against 0.63 of LL2_Mixed. The PECS-only scenario, evaluated only in LL1, received the lowest ratings, i.e., average thermal sensation and satisfaction of -0.42 and –0.10, respectively, with 61% of participants seeking for warmer conditions. Notably, 6% of collected environmental feedback in LL2 preferred a cooler environment, 39% of reported thermal sensation votes for the LL2_Room scenario described warm-to-hot thermal sensations, compared to 24% of the LL2_Mixed configuration.
Concerning the visual domain, the Room scenario showed the highest frequency of neutral sensation votes in both LL1 (86%) and LL2 (42%). Nevertheless, the Mixed scenario received the highest satisfaction score in LL1 (0.80) while the PECS-only scenario, experienced in LL1, received the most negative feedback in terms of visual perception, including the only average sensation leaning toward the darker side of the visual sensation scale (+0.82).

3.2 PECS operative feedback

Here only feedback from participants involved in PECS and Mixed scenarios are analysed without distinctions between LL1 and LL2 samples. The desk lamp's light intensity was the most frequently adjusted setting among the tested PECS, with 15% of participants reporting they adjusted it "Always" and another 10% doing so "Often." For the thermal PECS, the airflow speed of the fan heater was the most commonly modified setting. In contrast, the positions of both the desk lamp and the portable fan heater were rarely adjusted. Specifically, 40% of users reported "Never" changing the desk lamp's position, while 53% said the same for the portable fan heater. Overall, feedback on ease of use showed that both PECS were considered moderately to absolutely easy to use by all participants. Only 5% of the sample found the thermal PECS "Slightly easy to use." Under Mixed scenario, 80% of participants never switched on simultaneously both PECS and background systems a percentage that decrease down to 50% considering the lighting system.

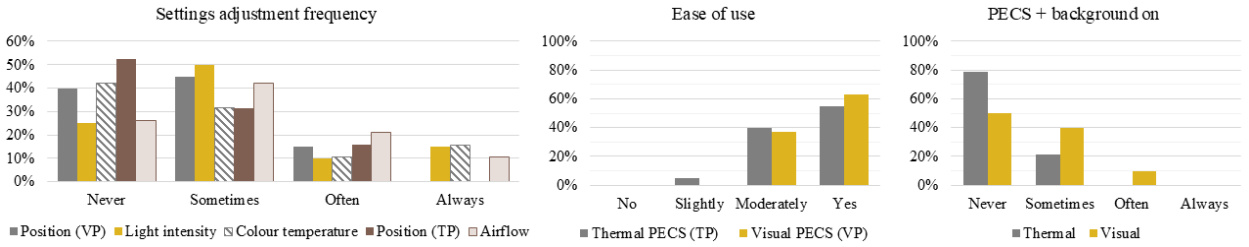

Figure 2. PECS users feedback on settings adjustment frequency and ease of use.

In the following, the main challenges and limitations of the adopted PECS are presented, as reported by LL1 participants immediately after experiencing the PECS-only scenario.
Regarding the desk lamp, 5 out of 7 participants mentioned the discomfort of working in a dark environment. Three of them further explained that although the desk lamp adequately illuminated the working area, the intense contrast with the dark surroundings results in uncomfortable conditions. One participant noted that even the combination of daylight and the desk lamp was insufficient to create a comfortable environment. Another issue highlighted by 2 participants concerned the sensitivity of the control buttons: one found them too much sensitive, while the other felt they were not sensitive enough. Additional challenges mentioned by individual participants included an excessive number of light colour temperature options (quote: *…a lot, I can't find the right one*) and the light position, which was too close to the eyes.
Feedback on the fan heater revealed that 3 participants reported no issues. However, 2 participants

expressed dissatisfaction with the PECS operation settings, citing limited functionalities and automatic, unexpected shutdowns. Additionally, 2 out of 7 users found the thermal environment inadequate, describing it as too cold, especially in the morning (…*when entering the room and the system is off, it takes too much time to reach the desired thermal conditions*). One of these users also noted that directing the heat flux towards the head was extremely uncomfortable.

4. CONCLUSIONS

Thermal and visual PECS were distributed in two office living-labs. Occupants feedback about their thermal perception and PECS operative settings were collected for four-weeks in winter, 2025. Throughout the experiment, three scenarios were investigated: without PECS, a PECS-only scenario, and a mixed-scenario characterized by the availability of PECS in addition to background system control. Findings highlight that the mixed scenario was the most appreciated one by participants while relying just upon PECS is not enough to achieve comfortable conditions. Therefore, to meet the dual goal of occupants' environmental satisfaction and building energy savings, to develop smart control is crucial to not compromise sustainability. Relevant settings to be adjusted at personal level to meet requirements that may change over time can be the intensity of light for the desk lamp and the airflow speed for convection-based PECS heater.

Outcomes are going to be further analysed combining collected perceptual votes with observed environmental conditions to identify optimal ranges of PECS use as stand-alone or supportive system to the common room-based regulation. Moreover, energy consumptions observed for the three scenarios are going to be compared to clarify PECS energy saving potentials.

SUMMARY
Dose-response data from laboratory animals are commonly extrapolated to assess human health risks associated with inhalation exposure to contaminants. However, the availability of *in vivo* data is limited because of animal protection and ethical considerations. Although monkey-based experiments represent a suitable alternative to human exposure studies, the characteristics of particle transport and deposition in monkey airways remain poorly understood. Furthermore, the external shape of the nasal cavity in the upper airway differs between humans and monkeys, which may result in differences in particle aspiration efficiency. The objective of this study was to predict the efficiencies of particle deposition and aspiration in the airways of monkeys during inhalation using computational fluid-particle dynamics. We developed a numerical airway model that reproduces the detailed geometry from the nasal cavity to the 33rd generation bronchial tubes.

Keywords: Computational fluid-particle dynamics, Monkey airway model, Particle deposition, Aspiration efficiency.

1. INTRODUCTION

The behavior of inhaled substances within the respiratory system, including the nasal cavity, airways, bronchi, and lungs, is essential for the development of inhaled pharmaceuticals such as anti-coronavirus therapeutics and drugs for managing bronchial asthma. Additionally, the atmosphere contains a wide variety of substances, ranging from gaseous compounds, such as volatile organic compounds (VOCs), to aerosol particles, such as pollen, which can be transported and absorbed into the body through respiration. Inhalation toxicity studies involving humans have ethical limitations, necessitating alternative approaches. These approaches often involve extrapolating the results from animal experiments to humans or performing experiments using artificial respiratory models. Among animal models, nonhuman primates, particularly rhesus macaques, are highly effective surrogates because of their high physiological similarity to humans. In this study, computational fluid-particle dynamics (CFPD) was employed to develop numerical monkey airway models capable of predicting particle deposition and aspiration efficiency during respiration. A highly detailed numerical airway model was constructed by replicating bronchial structures up to the 33rd generation. Furthermore, we investigated the impact of various factors, including breathing volume, particle size distribution, and airway geometry, on particle deposition within the respiratory tract.

2. MATERIALS AND METHODS

The geometric model of the rhesus macaque respiratory tract was constructed based on a study by

Corley et al., who utilized computed tomography (CT) imaging of the upper airway, spanning from the nasal cavity to the larynx, and magnetic resonance imaging (MRI) of the trachea and lungs. These images were derived from a silicone cast of a 6-month-old male rhesus macaque weighing 1.3 kg, as shown in Fig. 1. To accurately capture the transport behavior of particles from the indoor environment to the respiratory system, this study incorporated a spherical breathing zone integrated with the face features. To construct a computationally suitable airway model for CFD analysis, ANSYS/SpaceClaim software was used for segmentation and geometric repair. Furthermore, the mass flow rate to each lung lobe was preliminarily determined using a model with 48 million cells (Fig. 1b), in which a pressure outlet boundary condition was applied at the airway edge (Fig. 1a: gray zone). ANSYS Fluent was used for fluid and particle dynamics simulations. The Reynolds-averaged Navier-Stokes (RANS) equations were solved to predict airflow patterns under steady-state and transient breathing conditions. A second-order upwind discretization was applied to all governing equations in conjunction with the semi-implicit pressure-linked equation (SIMPLE) algorithm for numerical stability and accuracy. Particle simulations were applied one-way coupling Lagrangian discrete-phase model. To ensure a wide-ranging prediction of particle deposition across microscale sizes, eleven representative particle sizes were selected, ranging from 1 to 80 μm. Moreover, particle density was set to 1,000 kg/m^3. The breathing cycle was constructed based on the experimental results of Karel et al., with a ventilation volume (tidal volume) of 13.13 mL. The computational results for the macaque model were compared with those of a human model (Kuga et al. 2024) to validate the feasibility of the simulation.

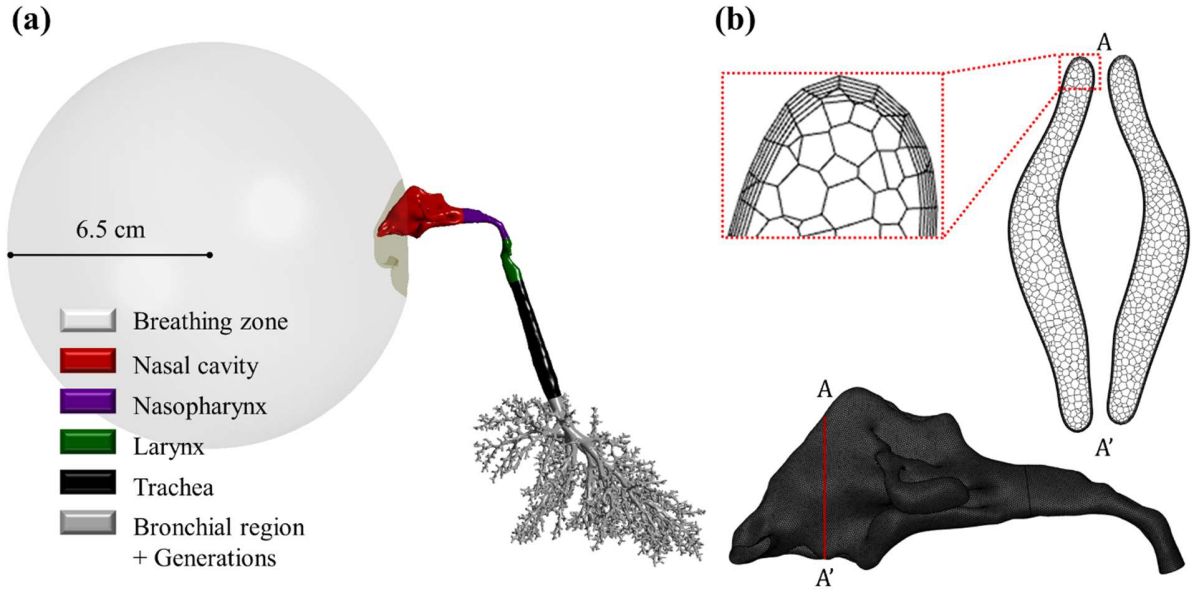

Figure 1. Overview of the constructed computed tomography-based models of the (a) rhesus macaque airway geometry and (b) computational mesh of the monkey nasal passage.

3. RESULTS AND DISCUSSIONS

3.1. Comparison of particle aspiration efficiency between monkey and human

The aspiration efficiency is defined as the ratio of the concentration of inhaled particles to the

concentration of particles in the ambient environment. Fig. 2 presents the various aspiration efficiency datasets plotted against different particle sizes. The particle aspiration efficiency of the monkey exhibited high values for the 1–20 μm particle size range, showing good agreement with the human model. On the other hand, a sharp decline was observed in the 40–50 μm particle size range for the monkey. This was likely because the simulation was conducted under isothermal conditions, which neglected the thermal plume around the body and might reduce the particle aspiration efficiency in the micrometers that are significantly affected by gravitational settling. In summary, the simulation results of the smaller particles demonstrated sufficient agreement with the human model, whereas larger particle sizes, which were significantly influenced by gravitational sedimentation, presented opportunities for further investigation.

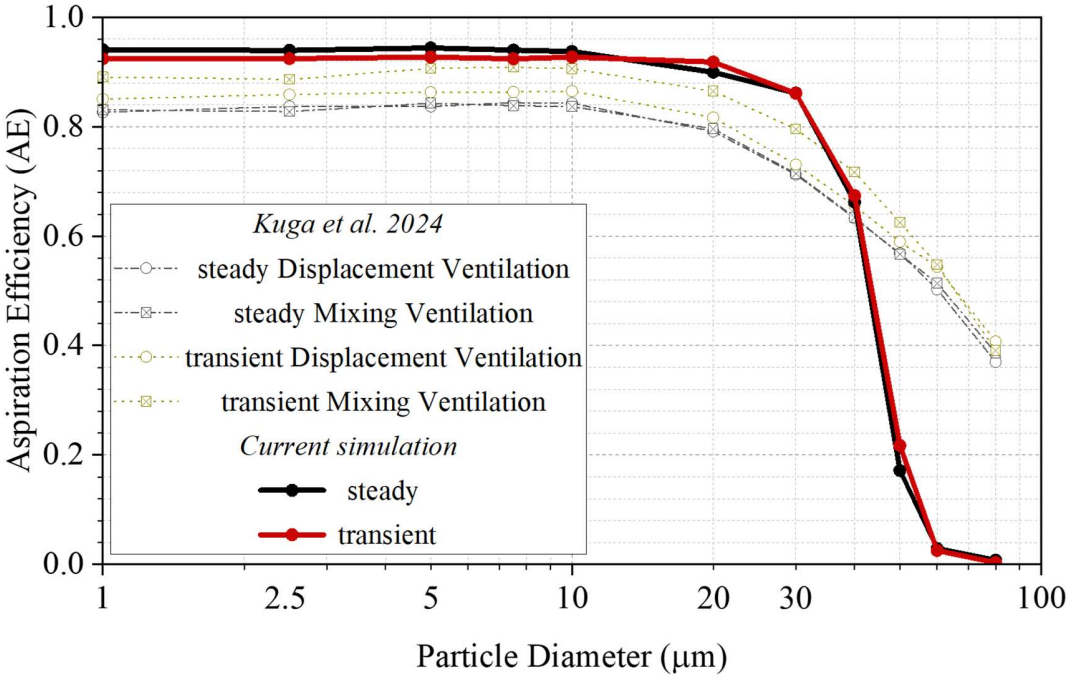

Figure 2. Comparison of aspiration efficiency as a function of particle size between the present study in the monkey model and previous simulations in the human model by Kuga et al.

3.2. Particle deposition efficiency in the monkey respiratory tract

Fig. 3 illustrates the visualization of the deposited particle distribution within the airways of the monkey model under steady inhalation (Fig. 3a) and transient breathing conditions (Fig. 3b). The figure also shows the percentage of particles deposited in each region relative to the total number of particles inhaled through the nostrils. A comparison of the three particle sizes confirmed that 5 μm particles showed the highest deposition rate across all regions. Additionally, analysis of different breathing conditions showed that unsteady breathing, including exhalation, resulted in a higher deposition rate in the upper airway. This suggests that in more realistic scenarios, the upper airway regions, particularly the nasal cavity and pharyngeal areas, are more susceptible to the effects of microparticles, which requires further investigation. A similar trend was observed in a previous study in humans, further supporting the high similarity between the nasal structures of rhesus macaques and humans. Furthermore, the detailed model of the lower airways used in this study enabled the observation of microparticle deposition, which was previously difficult to detect.

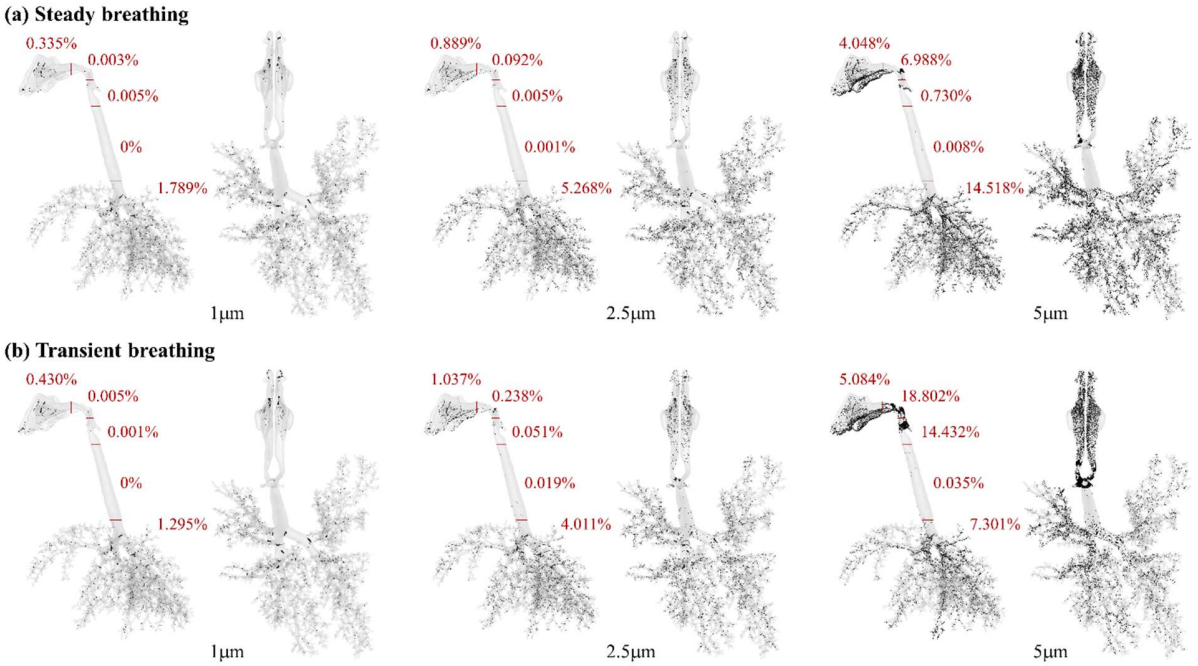

Figure 3. Deposition distribution of different inhaled particle sizes during (a) steady breathing and (b) at the end of transient breathing cycles, viewed from an isometric and superior perspective.

4. CONCLUSIONS

In the present study, detailed monkey airway models were used to simulate particle inhalation under steady and transient breathing conditions. The results obtained using the developed airway models agreed well with human data for the microparticles analyzed in this study. Furthermore, the models were effective tools for predicting particle deposition patterns, particularly for fine particles, which are traditionally challenging to analyze. The observed similarities in the deposition efficiency with human models, coupled with the unique characteristics of the monkey model, provide valuable insights into the roles of anatomical variations in respiratory mechanics and particle behavior. These insights are not only critical for advancing the understanding of respiratory diseases but also show potential for improving therapeutic strategies, such as targeted drug delivery systems.

High-accuracy and real-time prediction of non-isothermal indoor environment via neural networks with a novel activation function

Xuesong Hu [1], Ruibin Li [1], Tianle Chen [1], Naiping Gao [1,*]

[1]*Tongji University, Shanghai, China, gaonaiping@tongji.edu.cn*

ABSTRACT
Neural networks, combined with computational fluid dynamics, are among the most widely employed approaches for optimizing indoor temperature and velocity distributions. The selection of activation functions in a neural network significantly influences prediction accuracy. This study introduces a novel activation function, Leaky-Sigmoid, featuring tunable parameters (α, β), to enhance the prediction accuracy of neural networks in indoor environments. The results show that the neural networks based on Leaky-Sigmoid can predict airflow and temperature within 2 milliseconds, with an average relative error of only 2%. Moreover, the proposed networks employing Leaky-Sigmoid outperform existing models in reducing prediction errors for temperature by 19.47% and 9.10% in B3 and B5, and for velocity by 11.74% and 5.43% in B3 and C2. Lastly, the derivatives of the activation functions play a crucial role in determining the prediction accuracy. In conclusion, the Leaky-Sigmoid activation function offers substantial improvements in prediction in indoor environments.

Keywords: Neural networks, Computational fluid dynamics, Indoor environment, Activation function

1. INTRODUCTION

Artificial intelligence (AI), as a key driver of social development, has made significant advancements in fields such as autonomous driving (Grigorescu et al., 2020), image recognition (Krizhevsky et al., 2017), and various other areas. In the context of the built environment, the rapid prediction of physical parameters, the solution of partial differential equations (PDEs) (Li et al., 2021), and the acceleration of computational fluid dynamics (CFD) techniques (Obiols-Sales et al., 2020) have emerged as increasingly prominent research topics. Compared to traditional CFD methods, AI, particularly neural networks, offers a distinct advantage in terms of computational speed and efficiency. Some studies focus on the internal structure of neural networks to explore their contributions to CFD calculations. For instance, Zhou et al. (2021) examine the impact of various data preprocessing methods on prediction accuracy and conclude that data preprocessing plays a crucial role in ensuring the accuracy of indoor flow field predictions. They also find that different preprocessing approaches produce similar performance in forecasting indoor airflow. Additionally, the activation functions used between the layers of a neural network are essential components of the network's architecture. However, the mechanisms by which these activation functions affect prediction results in the field of built environment remain unclear.

Activation functions are nonlinear functions designed to enhance the network's fitting ability to capture complex patterns within neural networks. The most commonly used activation functions include Sigmoid (Cybenko, 1988), ReLU (Glorot et al., 2011), and Leaky-ReLU (Maas et al., 2013), among others. While these functions are widely applied across various tasks, their inherent

limitations cannot be ignored. For instance, the Sigmoid activation function was prone to the vanishing gradient problem (Bengio et al., 1994), which occurs during the backpropagation process and hinders effective learning in deep networks. To address this issue, the ReLU activation function (Bengio et al., 1994) was introduced, offering a simple and computationally efficient solution. However, ReLU's tendency to produce 'dead neurons'—caused by its zero output for non-positive inputs—can result in inactive neurons that fail to contribute to the training process. The Leaky-ReLU activation function partially mitigated this issue by allowing a small gradient for negative inputs. Nevertheless, its prediction accuracy is sometimes lower than that of the standard ReLU. Therefore, these limitations highlight the need for improved activation functions that enhance accuracy, stability, and generalization capabilities.

In this paper, a novel activation function, Leaky-Sigmoid, is proposed to enhance the nonlinear characteristics of ReLU-based functions while mitigating the gradient vanishing issue inherent in the Sigmoid function. To evaluate its effectiveness, we compare conventional activation functions (ReLU, Leaky-ReLU, and Sigmoid) with the proposed Leaky-Sigmoid in terms of prediction accuracy and efficiency, utilizing the same input data and network architecture for consistency. Numerical experiments show that a network configuration utilizing the Leaky-Sigmoid activate functions achieves superior prediction results under specific conditions.

2. METHODS

2.1. Settings for the Physics Model

With regard to the case settings, a three-dimensional room is considered here, as illustrated in Fig. 1 (a), with dimensions of 6.00 m, 2.44 m, and 2.44 m in the x-, y-, and z- directions. The supply air temperature is varied from 20 ℃ to 35 ℃, with an interval of 5 ℃. The supply air velocity is varied from 4.00 m/s to 6.25 m/s, with an interval of 0.75 m/s. The heat generation is set from 100 W, 200 W, and 300 W. Other boundaries are set to insulated walls. Consequently, a total of 48 cases are contained in the training database. Meanwhile, 2 cases that are never contained in the training database are set for the testing database, such as (27 ℃, 4.30 m/s, 173 W) and (32 ℃, 5.10 m/s, 230 W). All cases are assumed to be in a steady condition. The CFD simulations are run using the Fluent 2022R1 on a Windows server with a 12th Gen Inter(R) Core(TM) i9-12900K CPU.

All the prediction processes are divided into two steps. The first step is named the ‘K-fold training step’, and the second step is named the ‘true testing step’. In the first step, the 6-fold cross-validation is used for the stability of the training process. Above 48 cases in the training database, 40 cases are used for training datasets, named ‘K-train’, and another 8 cases are used for validation datasets, named ‘K-valid’. In the second step, all of the 48 cases are used for the training dataset, named ‘train’, and the 2 cases in the testing database are used for the testing dataset, named ‘test’.

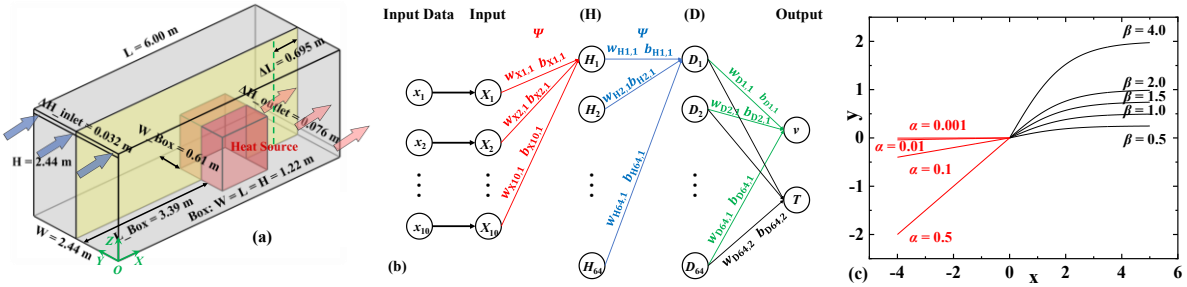

Figure. 1 The detailed information on the geometry and the neural network. (a) Geometrical model of mixing ventilation in a non-isothermal room. The cross-section examined in this study is the yellow darkened zone in the figure (y = 1.22 m). The selected monitoring line is indicated by the green dashed line (x = 5.305 m). (b) The structure of MLP in this paper. (H) is the first hidden layer and (D) is the second hidden layer, with 64 neurons in each. Ψ is the activation function for each layer. This paper is analyzed from $w_{X1,1}$ in the discussion. (c) Leaky-Sigmoid activation functions and the images of different α and β. α = 0.001, 0.01, 0.1, 0.5. β = 0.5, 1.0, 1.5, 2.0, 4.0.

2.2. Settings for Neural Networks

In this study, a neural network named multiple perceptrons (MLP) is adopted to predict the airflow and temperature distribution simultaneously. The detailed structure is shown in Fig. 1 (b), containing one input layer, two hidden layers, and one output layer. There are 64 neurons in each hidden layer. The input layer contains inlet velocity, inlet temperature, heat source's producing capacity, horizontal coordinates of the grid center, vertical coordinates of the grid center, distance of each coordinate from the inlet, distance of each coordinate from the center of the heat source, velocity coupling parameters, temperature coupling parameters, and the angle. The output parameters are velocity and temperature at each coordinate location. In the neural networks, the learning rate and the training epochs are set at 0.001 and 2500.

2.3. Settings for Activation Functions

Activation functions are necessary structures between two adjacent layers for predicting complex nonlinear features. In this study, a novel activation function called Leaky-Sigmoid is introduced. For the Leaky-Sigmoid activation functions, a variable slope (denoted as α) is introduced to the negative axis, and a scaling factor (denoted as β) is applied to the positive axis. The detailed number codes and images are shown in Table 1 and Fig. 1 (c).

$$LS(x) = \begin{cases} \alpha x, & x \le 0 \\ \beta\left(\frac{1}{1+e^{-x}} - 0.5\right), & x > 0 \end{cases} \quad (1)$$

Table 1. The detailed number codes for different combinations of α and β

3. RESULTS

3.1. Prediction Accuracy in Training and Testing Datasets

3.1.1. Evolution of model errors

In this section, the root mean square errors (RMSE) of velocity and temperature distributions are separately analyzed. Specifically, Fig. 2 (a) shows the temperature RMSE of all of the cases. In Groups A, B, and C, the T-RMSEs of training and validating results tend to decrease as β increases. This trend is more pronounced in Group C. The prediction accuracy of MLP improves with the increase of β. In terms of nonlinearity, β parameter is the scaling factor that controls the nonlinear components of the Leaky-Sigmoid activation function. This component shows a more pronounced nonlinear approximation in contrast to the linear component controlled by α. Consequently, adjusting β can enhance the ability to fit the nonlinear data in MLP. In terms of backpropagation, the computation in MLP is based on the Chain Rule. These parameters are derived through backpropagation, influenced by the multilayer neurons and activation functions, during the process of updating the weight parameters. The scaling factor β enlarges the derivative range, thereby increasing the extent of nonlinear mapping. In Group D, RMSE improves with increasing β, reaching its maximum at D3. However, the gradient vanishing issue causes computation disruption in the D5 case. This indicates that α imposes a stronger constraint on the range of RMSE than β, with β serving to fine-tune the network's performance within that range.

In Groups A, B, C, and D, most cases achieve accuracy levels comparable to those of conventional activation functions. In the test datasets, the T-RMSEs in A5, B3, and B5 are 4.05%, 7.97%, and 7.20% lower, respectively, compared to the network using the ReLU activation function. Furthermore, the v-RMSE distribution patterns of the v-train and v-K-train results shown in Fig. 2 (b) closely resemble those of the T-RMSE curves. The v-RMSEs in the test datasets are 1.97%, 5.95%, and 6.61% lower than the results obtained using Leaky-ReLU in A5, B3, and B5.

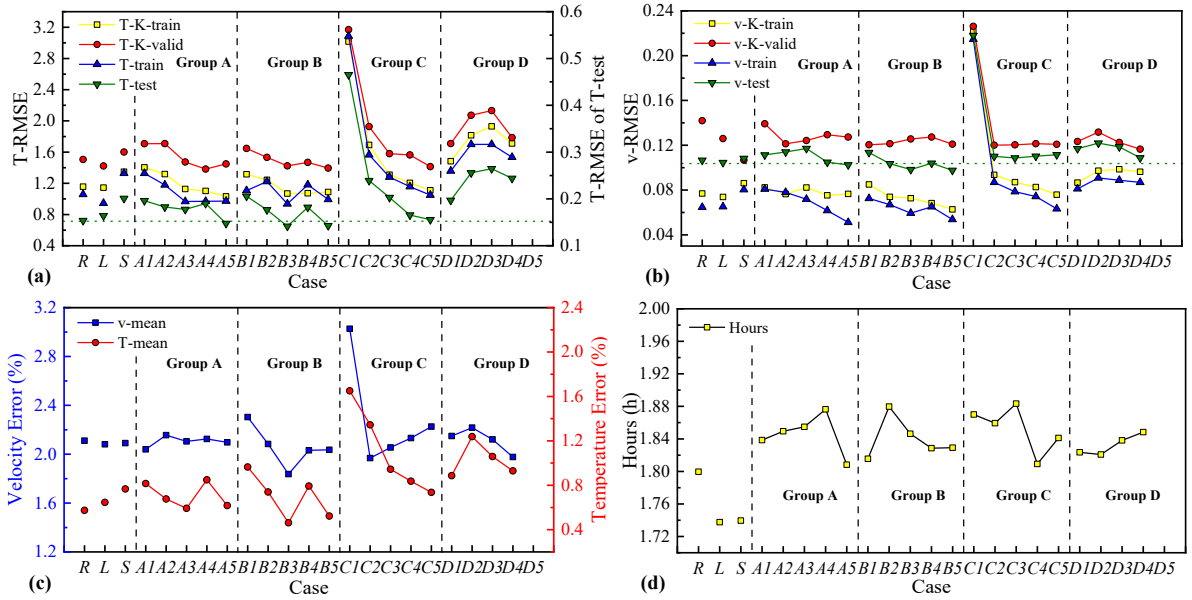

Figure. 2 Comparison of the Leaky-Sigmoid and conventional activation functions in terms of RMSE, relative errors, and training time with variables α and β. (a) RMSE of temperature. (b) RMSE of velocity. (c) Relative errors of test datasets. The yellow squares represent the v/T-K-train and the red circles for the v/T-K-valid, the blue positive triangles represent the v/T-train, and the green inverted triangles for the v/T-test in (a) and (b). (d) Training time comparison of the conventional activation functions and others with various combinations of α and β when

computing the same epochs. The equation of RMSE is $\sqrt{\frac{1}{N}\sum_{i=1}^{n}(y - y_{pred})^2}$. Where y is the CFD result, y_{pred} is the prediction result. N is the number of the coordinates.

The absolute values of RMSEs have limitations in accurately representing the true error of the test datasets, providing only a rough analysis of forecasting trends. Therefore, the relative error is employed to compare the prediction accuracy across the test datasets. The detailed prediction results are shown in Fig. 2 (c). The relative error of temperature shows lower deviations compared to those of velocity distribution, likely due to the lower complication of the data distribution.

The relative errors for temperature are generally lower than those for velocity, as the larger range of absolute values for temperature in the denominator compared to velocity. The relative errors for temperature in B3 and B5 are 19.47% and 9.10% lower, respectively, compared to the results from the ReLU activation function. For the velocity, the results of B3 and C2 are 11.74% and 5.43% lower compared to the Leaky-ReLU activation function. The detailed information is shown in Fig. 2 (c). The overall trend shows that prediction accuracy improves as β increases in each group.

3.1.2. Overall data distributions

Although there are overall analyses of the temperature and velocity results, the detailed prediction distribution remains unclear. These are crucial for analyzing the prediction characteristics of neural networks with different activation functions. As shown in Fig. 3 (a), all temperature results with different activation functions underestimate $T_{MAX\text{-}CFD}$. In Groups A, B, and C, the prediction results of temperature display more centralized trends as β increases within each group. The temperature distributions of A5, B3, B5, and C5 are most comparable to the CFD simulation.

When predicting the temperature data in the top 1%, MLPs tend to be conservative, leading to prediction values that are less dispersed compared to the CFD simulation. As β increases within each group, the range of temperature predictions more closely aligns with the CFD simulation for 1.75%–98.25% of the data, with the exception of Group D. These findings suggest that MLPs can better capture the patterns of data distributions as β increases. Additionally, MLPs are effective at predicting the velocity distributions. Furthermore, data with small gradients, such as velocity distributions, are predicted with higher accuracy, as shown in Fig. 3 (b).

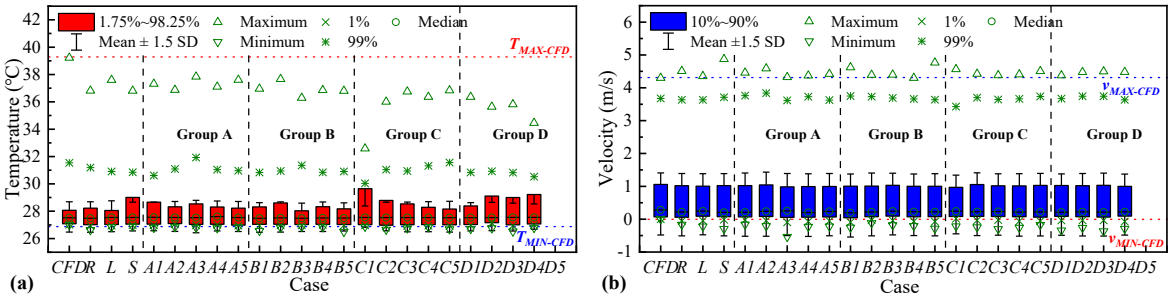

Figure. 3 The overall distribution of temperature and velocity prediction data for conventional activation functions and Leaky-Sigmoid activation functions with different α and β combinations. (a) Overall data distribution of temperature. (b) Overall data distribution of velocity. The Δ and ▽ are the maximum and the minimum values in each predicted data (velocity or temperature distribution). The * is the 1st or 99th percent of the data sequentially.

3.1.3. Local data distributions

To examine the detailed information in the key regions, some local data are extracted as shown in Fig. 4. The overall predicted temperature curves for the Leaky-Sigmoid activation functions show zigzag patterns when $\alpha \geq 0.1$ (Group C). The temperature distribution becomes progressively more unstable as α increases, displaying unexplained inflection points, especially when $\alpha \geq 0.1$. These inflection points also appear in MLPs with conventional activation functions, providing strong evidence of the absence of physical constraints in neural networks. In Groups A and B, the prediction results have a higher accuracy compared to other groups. As α increases, the MLP's prediction for the velocity range shows little variation, whereas the temperature predictions become relatively more discrete. Significant fluctuations in the temperature distribution occur only near the heat source, indicating that the activation functions may lack the sensitivity required to accurately predict data distributions in regions with high variability. Additionally, MLPs can force-fit the data and accurately capture the magnitudes of velocity and temperature, regardless of the activation function used. However, it is important to recognize that this forced-fitting approach disregards objective physical patterns and relies solely on a data-driven perspective. Enhancements could be realized by implementing more sophisticated deep learning approaches that incorporate various data pre-processing techniques.

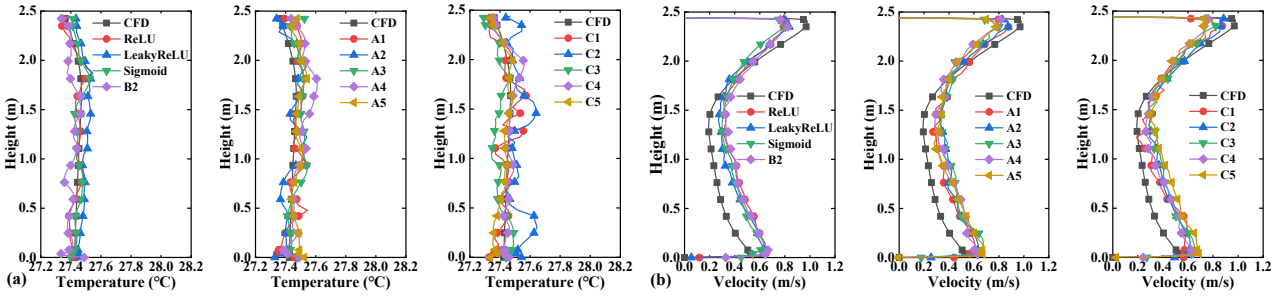

Figure. 4 Local data distribution for temperature and velocity predicted by CFD simulation, conventional activation functions, and MLPs employing Leaky-Sigmoid activation functions with various combinations of α and β at x = 5.305 m. (a) Distribution of temperature at the monitoring line. (b) Distribution of velocity at the monitoring line.

3.2. Prediction Efficiency in Training and Testing Datasets

As shown in Fig. 2 (d), within each group, the computation time is relatively shorter when β assumes a higher value. Group D is not significantly representative due to its dispersion conditions ($\alpha = 0.5, \beta = 4.0$). The average training time for the Leaky-Sigmoid activation functions is 2.4%, 6.1%, and 6.0% slower than that of the ReLU, Leaky-ReLU, and Sigmoid activation functions, respectively, when computed over the same number of epochs. The prediction time for each activation function is approximately 2 milliseconds, which is one millionth of the time required by the CFD simulations.

4. DISCUSSION

This section aims to explain the principles governing Leaky-Sigmoid activation functions through theoretical analyses, using the MLP neural network as an example, as shown in Fig. 1 (b). The formula for the total loss function is presented below. For ease of analysis, the loss ($E_{partial}$) of temperature and velocity are considered separately at each coordinate point in this derivation.

$$E_{total} = \frac{1}{N}\sum_{i=1}^{N}\left[(v_i - \tilde{v}_i)^2 + \left(T_i - \tilde{T}_i\right)^2\right] \quad (2)$$

$$E_{partial} = \left[(v - \tilde{v})^2 + \left(T - \tilde{T}\right)^2\right] \quad (3)$$

$$\frac{\partial E_{partial}}{\partial w_{X1,1}} = 2\left[(v - \tilde{v}) \cdot w_{D1,1} + \left(T - \tilde{T}\right) \cdot w_{D1,2}\right] \cdot \Psi'\left(H_1 \cdot w_{H1,1} + b_{H1,1}\right) \cdot w_{H1,1} \cdot \Psi'\left(X_1 \cdot w_{X1,1} + b_{X1,1}\right) \cdot X_1 \quad (4)$$

$$w_{X1,1}{}^{+} = w_{X1,1} - \eta \cdot \frac{\partial E_{partial}}{\partial w_{X1,1}} \quad (5)$$

In the formula, i is the index of the input data (i.e., the coordinate point index, i = 1, ..., N with N = 48 × 4733 = 227184), v_i, T_i are the real values obtained from the CFD simulation, while $\tilde{v}_i$, $\tilde{T}_i$ are the prediction values from the MLP. The physical meaning of $\frac{\partial E}{\partial w}$ is the amount of the resultant change in E when w changes, w^+ is the weight after the gradient update, and w is the weight before the gradient update. η represents the learning rate.

Eq. 5 provides the generic formula used in the above derivation to solve $w_{X1,1}$. In this network, the derivative of the Sigmoid activation function appears twice, such as $\sigma(t)\left(1 - \sigma(t)\right)$ $(t = H_1 \cdot w_{H1,1} + b_{H1,1}$, $H_1 = \sigma(\varphi))$, and $\sigma(\varphi)\left(1 - \sigma(\varphi)\right)$ $(\varphi = X_1 \cdot w_{X1,1} + b_{X1,1})$. The derivative of the Leaky-Sigmoid activation function is $\beta \cdot \sigma(t')\left(1 - \sigma(t')\right)$ $(t' = H_1' \cdot w_{H1,1} + b_{H1,1}$, $H_1' = \beta \cdot (\sigma(\varphi) - 0.5))$ and $\beta \cdot \sigma(\varphi)\left(1 - \sigma(\varphi)\right)$ $(\varphi = X_1 \cdot w_{X1,1} + b_{X1,1})$.
When $x > 0$,

$$\Psi'\left(H_1 \cdot w_{H1,1} + b_{H1,1}\right) \cdot \Psi'\left(X_1 \cdot w_{X1,1} + b_{X1,1}\right) = \beta^2 \cdot \sigma(t')\left(1 - \sigma(t')\right) \cdot \sigma(\varphi)\left(1 - \sigma(\varphi)\right) \quad (6)$$

When $x \leq 0$,

$$\Psi'\left(H_1 \cdot w_{H1,1} + b_{H1,1}\right) \cdot \Psi'\left(X_1 \cdot w_{X1,1} + b_{X1,1}\right) = \alpha^2 \quad (7)$$

When other parameters remain constant, the weights of the networks with the Leaky-Sigmoid activation functions update more quickly with larger β values, indicating a larger step size in the gradient update. As a result, each iteration of the neural network gets more information, thereby increasing the prediction accuracy. Furthermore, when x ≤ 0, the derivative of the Leaky-Sigmoid activations becomes quite low, determined by the constant α^2. Given the variance in the distribution of input data and the randomness of the initial weights, the variable including X and H_1, will alternate between positive and negative during the backpropagation process. The loss will fluctuate as the magnitude of the weight update increases or decreases with each gradient computation when α and β induce 'instantaneous switching' during the training process. This phenomenon causes the loss to fluctuate more widely as β increases, explaining the oscillations observed in some monitoring lines. Therefore, a higher β accelerates the speed of weight updates, increasing the prediction accuracy. Selecting the appropriate values necessitates thorough testing and multiple rounds of debugging. Indeed, determining the optimal value β requires careful consideration of several factors, including weight initialization, network architecture, and data distribution, among others.

5. CONCLUSIONS

In this study, the performance of the Leaky-Sigmoid activation functions is detailedly evaluated by prediction accuracy and efficiency. Additionally, this study aims to understand the basic patterns underlying Leaky-Sigmoid activation functions through theoretical analysis. The main conclusions are as follows.

1) MLP can quickly predict the temperature and velocity distributions in a mixing ventilation room. To some extent, it can serve as a substitute for CFD simulation in real-time predictions of temperature and velocity distributions within a specific range of boundary conditions, achieving a relative error of approximately 2% compared to CFD simulations. The prediction time is merely 2 milliseconds, representing just one millionth of the time required by the CFD simulations.

2) In terms of training accuracy, the Leaky-Sigmoid activation functions are better than conventional activation functions in B3 and B5. When α is low, the RMSE and relative error of the neural networks during the same epoch steadily decrease as β increases, producing a gradual improvement in training accuracy. The relative errors for temperature in B3 and B5 are 19.47% and 9.10% lower, respectively, compared to the results from the ReLU activation function.

3) The specific formula of the activation functions significantly impacts both the rate of weight updates in the neural networks and the prediction accuracy. The amplitude of the oscillations in prediction results slightly increases as β increases. Additionally, it is crucial to consider the initialization of weights, as well as the width and number of layers within neural networks. Each neural network has an appropriate set of activation functions. Fixed activation functions are merely a compromise for accuracy and convenience.

SUMMARY

Managing airflow paths in residential buildings is essential for indoor air quality (IAQ), occupant comfort, and energy efficiency. While ventilation rates and system types often get attention, airflow path configuration remains underexplored. This study uses Modelica-based simulations to assess three strategies: direct exhaust, cascading, and extended cascading systems, under varying occupancy scenarios.

In direct exhaust, each room is ventilated separately, ensuring good local air quality but at higher energy costs. Cascading systems guide air from one room to another, reducing total airflow needs while maintaining IAQ. The extended cascading system furthers this by routing air through multiple zones, achieving similar IAQ with lower airflow rates and energy use.

Results show all systems maintain acceptable CO_2 levels, but extended cascading offers the best energy performance, cutting consumption by up to 30% without sacrificing comfort. The findings highlight the value of optimizing airflow paths, especially in renovation projects.

Keywords: residential ventilation, cascading ventilation, air quality, energy efficiency

1. INTRODUCTION

The residential ventilation market has faced significant challenges due to evolving consumer demands, stricter regulations, and climate goals. The building sector contributes approximately 36% of total CO_2 emissions in the European Union, highlighting its role in sustainability efforts (Economidou et al., 2020). Improving energy efficiency in buildings has become a priority, leading to tighter regulations such as the Energy Performance of Buildings Directive (EPBD). However, renovation rates remain insufficient to meet climate targets (Filippidou et al., 2016; Sandberg et al., 2016).

Deep renovations, which enhance insulation and reduce air leakage, significantly lower energy consumption (Kurnitski et al., 2014). However, increased airtightness also reduces natural airflow, negatively impacting indoor air quality (IAQ). Effective ventilation systems are essential for

maintaining acceptable IAQ levels and mitigating health risks, including Sick Building Syndrome (SBS) and Building-Related Illness (BRI) (EPA, 1991).

Beyond health, ventilation plays a critical role in reducing airborne disease transmission, as underscored by the COVID-19 pandemic. However, many systems designed for regulatory compliance fail to ensure adequate IAQ in practice, highlighting the need for performance-based design approaches. The 2022 energy crisis further emphasized the importance of energy-efficient solutions, as rising energy costs pressured households to reduce consumption. Renovation projects face additional technical and economic challenges when integrating modern ventilation systems into existing structures.

Three primary ventilation systems exist, each with distinct benefits and limitations (Zaniboni and Albatici, 2022). Natural ventilation depends on wind and buoyancy but is weather-dependent. Mechanical exhaust ventilation improves airflow control using a fan but requires ductwork and additional energy. Mechanical balanced ventilation provides precise airflow control and heat recovery but is complex to install. The optimal system choice depends on building constraints, climate, and occupant behavior.

A key determinant of ventilation efficiency is airflow path design, which influences both energy use and IAQ. Series connections between rooms can reduce fresh air requirements and simplify ductwork but may compromise air quality in downstream spaces. Fewer exhaust points lower costs but challenge uniform air distribution. These trade-offs are particularly relevant in renovations, where flexibility and adaptability are crucial.

This paper explores airflow path optimization for energy-efficient and effective ventilation in residential buildings, with a focus on renovation challenges. By examining the relationship between airflow configurations, IAQ, and energy use, this research aims to optimize ventilation design to balance sustainability and occupant well-being.

2. METHOD

The aim of this paper is to explore multiple variants of an exhaust ventilation system by examining different airflow paths and pressure drops across components, and to compare their performance in terms of indoor air quality (IAQ) and energy consumption. Extended airflow paths can offer energy benefits due to reduced overall airflow rates but may negatively impact IAQ. To evaluate the performance of the various ventilation systems, a simulation framework is required.

2.1. Building Model

For this research, a virtual building model is created using the Modelica modelling language. This equation-based language enables the modelling of building physics and allows for transient simulations. The building model is based on the IDEAS library, developed by KU Leuven (Jorissen et al., 2018). This library includes pre-made and validated sub-models (e.g., walls, windows) that can be used to construct a zonal model representing the building. The model assumes that the air in each zone is well-mixed, meaning air quality is considered uniform throughout the zone. A similar approach is used for temperature, however, thermal stack models are implemented to account for air movement caused by temperature differences. This concept is also applied to model infiltration,

specifically by placing two cracks at different heights in the wall. The dimensions of these cracks are based on the building's airtightness. Additionally, the outdoor environment (e.g., wind speed, temperature, humidity) is defined by a weather file, which varies over time and location. This weather file is also used to calculate wind pressure on the facades.

2.2. CO_2 Concentration

Carbon dioxide (CO_2) is a widely used indicator for ventilation performance, particularly due to its strong link with human activity, a relevance highlighted during the COVID-19 pandemic. Although CO_2 itself poses minimal direct health risks at typical indoor levels (requiring >10,000 ppm for extended periods to be harmful), it often co-occurs with other bio-effluents such as odours and ammonia that affect comfort and health (Fanger et al., 1988; Zhang et al., 2017). Elevated concentrations have been associated with reduced cognitive performance and sleep quality, reinforcing its role as a practical proxy for IAQ (Satish et al., 2012; Strøm-Tejsen et al., 2016).

Because of its strong correlation with occupancy, CO_2 is particularly relevant in occupied spaces. In contrast, IAQ in unoccupied zones is more influenced by emissions from materials or ventilation systems. This study follows the NBN EN 13779 standard, targeting the IDA 3 "acceptable" category, with CO_2 levels maintained below 800 ppm.

To model realistic conditions, CO_2 production is based on occupant behavior, using a metabolic-rate-based formula that links activity to emission rates (Persily and Jonge, 2017). This enables a detailed assessment of system performance under dynamic occupancy.

2.3. Humidity

Humidity is a critical factor in IAQ, significantly influencing occupant health, comfort, and building durability. High humidity encourages mould growth, which can damage furniture, pose health risks, and diminish indoor aesthetics. Conversely, low humidity may lead to nasal, throat, and eye irritation, highlighting the importance of maintaining stable humidity levels. Humidity is typically expressed as absolute humidity (g/kg) or relative humidity (RH). While absolute humidity measures moisture content regardless of temperature, relative humidity, which is more relevant to human perception, varies with temperature.

Comfort standards for indoor environments are usually based on RH, with an optimal range of 30–70% (Wolkoff, 2018; Wolkoff et al., 2021). Values below this range can cause discomfort, such as dry eyes and sore throats, while levels above 70% RH increase the likelihood of mould growth. At near 100% RH, condensation becomes inevitable, potentially causing water damage. The humidity model used in this study, similar to the CO_2 model, is linked to occupant metabolic activity (Poirier et al., 2021).

2.4. Energy Losses

Besides IAQ, energy use is the second key performance indicator for ventilation systems. The primary energy losses are thermal, resulting from the temperature difference between indoor and outdoor air. In winter, cold outdoor air increases heating demand, while in summer, warm outdoor air raises cooling needs. The extent of these losses depends on the mass flow rate of ventilated air and the temperature differential.

Thermal comfort is characterized by the operative temperature, which combines air temperature and mean radiant temperature. Achieving universal thermal comfort is complex due to variations in individual preferences, clothing, activity levels, humidity, and draft sensitivity. Fanger's Predicted Mean Vote (PMV) model, based on activity and clothing levels, is widely used (as per ISO 7730:2005), although adaptive comfort models suggest that occupants can adapt to different temperatures. For simplicity and comparability, a fixed indoor temperature of 21°C is assumed for all zones year-round, in line with EPB approaches. To fully capture the ventilation system's impact, heating and cooling losses are computed for an idealized HVAC system in each zone.

Additionally, the energy used by the ventilation fan to overcome pressure differences is included. While fan energy is generally an order of magnitude lower than thermal losses, it is still factored into the simulations.

3. CASE STUDY

3.1. The Building

For the case study, a two-story, free-standing building representative of a typical Flemish (Belgian) house is selected. This specific building geometry and structure were developed during the GEBOU-EL2EP study (Verbeeck and Hens, 2007). In this research, the building is divided into four zones with distinct functions: the downstairs living and kitchen area, and the upstairs night zone and adjacent bathroom. The zones are fully enclosed by walls, windows, floors, and ceilings modelled using the IDEAS library, enabling realistic simulation of heat losses through the building envelope.

The building is not perfectly airtight, and leakage through the walls allows for (un)intended airflow caused by buoyancy and wind pressure. Wind pressure on each façade is calculated using coefficients from AIVC for a low-rise building surrounded by obstructions equivalent to half the building's height (Liddament, 1996). A historical weather file from central Belgium is used to drive the model.

3.2. Occupancy

To simulate realistic internal loads, four virtual occupants and their associated impacts (i.e., moisture, heat, and CO_2) are modelled. Each occupant follows an individual schedule generated by the EROB model (Event-based Residential Occupant Behaviour model) (Verbruggen, 2021). This deterministic model produces unique behavioral profiles for the entire simulation period, resulting in a realistic load profile that enables performance comparison between ventilation system configurations.

3.3. Airflow Rate

Current practice in residential ventilation design is guided by national standards specifying mandatory airflow rates. In Belgium, the NBN D-50-001 standard defines design criteria for residential ventilation systems. It calculates the required airflow based on available floor space, assigning 3.6 m^3/h per square meter in rooms where occupants are regularly present. Additionally, the standard prescribes minimum and maximum airflow rates for specific room types (e.g., kitchen, bathroom). These rates are used in this case study. For the night zone, an equivalent of three bedrooms is assumed (see Table 1). When air is cascaded from one room to another, the highest required flow

rate among the rooms is used and carried through the rooms with lower ventilation demands.

Two control strategies are applied in the simulations: a fixed airflow rate controller and a simple rule-based controller. The fixed airflow rate controller allows comparison of the airflow paths without the influence of adaptive controls. The rule-based controller adjusts fan speed, and thereby total airflow rate, based on indoor pollution loads (i.e., humidity and CO_2). It can reduce airflow to 10% of the design rate when loads are low. When a threshold is exceeded, 400 ppm above outdoor CO_2 concentration or 70% relative humidity, the airflow increases to the nominal value, and decreases again when values fall below 350 ppm or 50%, respectively.

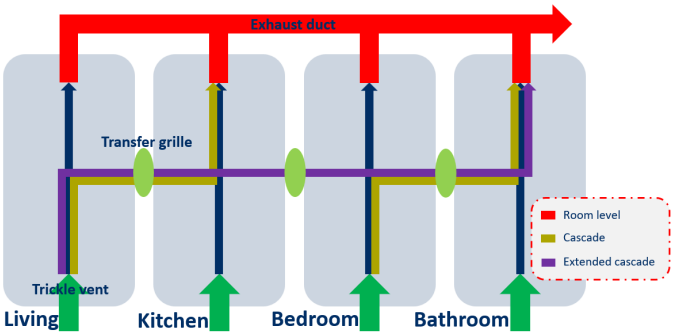

Figure 1. Illustration of the different airflow paths through the house. Red and green arrows indicate the exhaust ducts and trickle vents; the green oval represents a low-pressure-drop transfer grille.

Zone	Airflow Rate $[m^3/h]$
Living	150
Kitchen	66
Bedrooms	150
Bathroom	50

Table 1. Necessary airflow rates for each zone according to NBN D-50-001.

3.4. Ventilation System Design

Given the increased demand for renovation-oriented ventilation systems that ensure healthy IAQ regardless of outdoor conditions, this study focuses on mechanical exhaust ventilation. Three system variants are simulated:

- **Room-based ventilation system:** Each room has an independent supply and exhaust, allowing individual airflow control during the design phase.
- **Cascading ventilation system:** Fresh air is introduced into one room (typically the living room or bedroom) and cascades to another (e.g., kitchen or bathroom) for extraction, reducing total airflow without compromising IAQ.
- **Extended cascading ventilation system:** Air cascades continuously through all rooms, from a trickle vent as the supply to a single extraction point. This further reduces airflow needs, however, it does not align with regulations that require air from wet rooms (e.g., kitchen, toilet, bathroom) to be extracted directly rather than passed through to other rooms.

4. RESULTS AND DISCUSSION

The simulation results of the three ventilation systems under both fixed and adaptive control strategies are evaluated in terms of IAQ and energy consumption, fig. 2 and fig. 3 present the performance metrics for each case. To ensure clear interpretation, time spent outside the target air

quality zone is expressed in hours during which at least one zone exceeds the threshold. If multiple zones exceed the threshold simultaneously, this is multiplied accordingly. CO_2 is quantified as the duration exceeding 400 ppm above outdoor levels, while humidity is evaluated as the time spent below 30% or above 70% relative humidity—both of which indicate potential discomfort or risk.

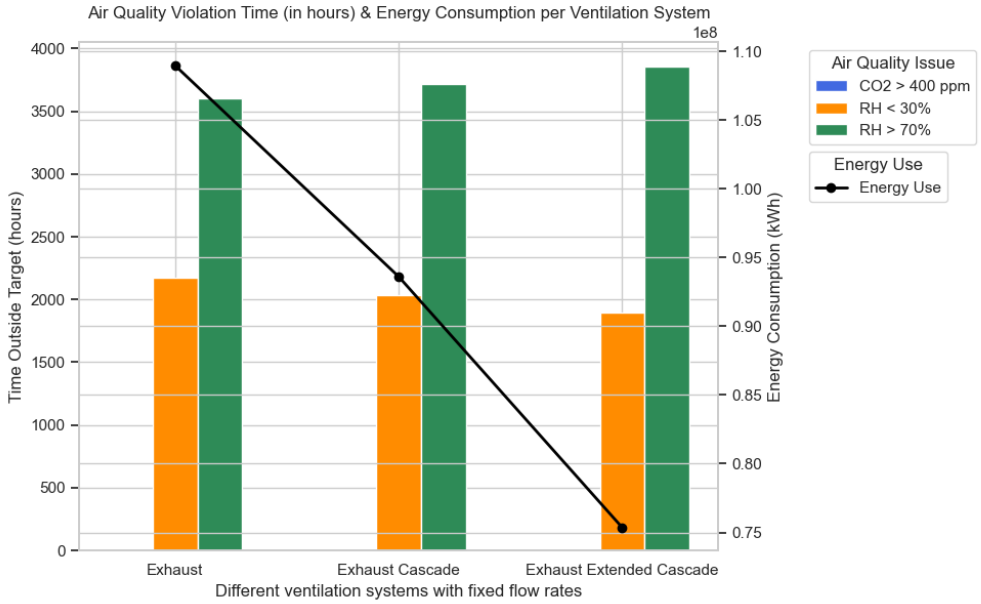

Figure 2. Summary of air quality performance and total energy use for the three ventilation systems with fixed flow rate.

A key observation is that under fixed airflow conditions, all systems maintained CO_2 concentrations within acceptable limits. However, under the rule-based control strategy, only the direct exhaust system consistently kept CO_2 below the threshold. The cascading and extended cascading systems exceeded the threshold for 54 and 485 hours, respectively. This outcome aligns with expectations, as the extended cascading system operates with the lowest airflow. Moreover, since air passes sequentially through multiple rooms, any exceedance in the first zone (e.g., the living room) is propagated downstream, compounding the total hours above threshold.

Humidity trends follow a similar pattern for both control strategies. The direct exhaust system recorded the fewest hours above 70% RH, followed by the cascading and extended cascading systems. Conversely, the extended cascading system performed best in terms of avoiding low humidity (<30%). Comparing the two control strategies, the fixed flow rate slightly outperforms the adaptive strategy for low humidity control, while high humidity exposure remains similar.

One of the major advantages of the extended cascading system is its energy efficiency, primarily due to reduced heating losses. While cooling demand increases slightly, likely due to diminished ventilative cooling in warmer periods, the total energy use is still lower. Among the flow path types, the adaptive direct exhaust configuration achieved the lowest energy use, while the extended cascading system with rule-based control used more energy than its fixed counterpart. This suggests that although adaptive control reduces airflow, it may also limit natural cooling opportunities, thereby increasing mechanical cooling demand.

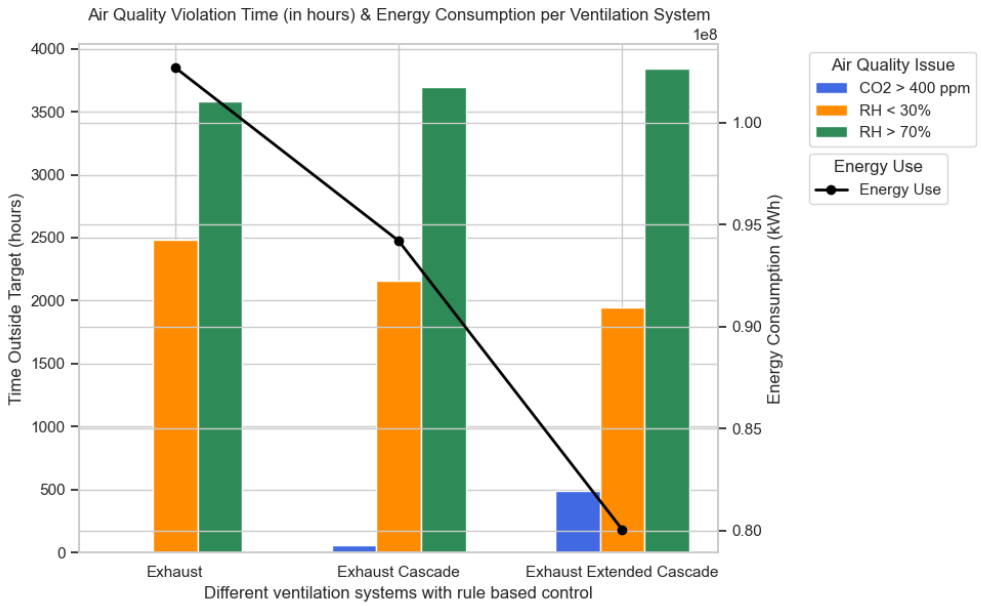

Figure 3. Summary of air quality performance and total energy use for the three ventilation systems with adaptive flow rate due to a rule based controller.

A notable limitation of this study is the absence of advanced control algorithms for both the ventilation and HVAC systems. For example, the current setup could cause simultaneous heating at night and cooling during the day. Incorporating more intelligent control strategies, such as model predictive control (MPC), that respond to occupancy and weather patterns could further reduce energy consumption and improve comfort.

5. CONCLUSION

This study evaluated three residential ventilation strategies, direct exhaust, cascading, and extended cascading systems, under both fixed and adaptive airflow control, using a simulation-based approach. All systems successfully maintained acceptable CO_2 levels under fixed flow rates, even for a two-person occupancy scenario. However, high airflow rates required to meet air quality demands led to increased energy consumption, particularly during colder periods due to heating needs. Cascading airflow through rooms emerged as a potential strategy to reduce total airflow and energy use, while still maintaining IAQ.

Humidity control proved more challenging, particularly during unoccupied periods when conditions were primarily driven by outdoor weather. While these conditions may not directly impact occupant comfort significantly, sustained high humidity poses a risk for condensation and mould growth, affecting both IAQ and building durability.

The extended cascading system demonstrated strong potential for energy savings, up to 30% compared to other systems, while maintaining competitive air quality performance. Results also indicate that airflow configuration alone is not sufficient, the interaction between control strategy and airflow path plays a critical role in balancing IAQ and energy performance.

This study focused on static airflow paths and a limited set of performance indicators. Nevertheless, the benefits of optimized airflow design are clear. Future work should explore dynamic or flexible airflow configurations that respond to occupant needs in real-time. To enable this, intelligent control systems capable of assessing IAQ and energy metrics must be integrated. Additionally, more advanced HVAC control strategies should be considered to avoid unnecessary heating or cooling and to further improve overall system efficiency.

SUMMARY
Creating healthy building environments is highly relevant in cities that face growing populations, climate change, mobility challenges, and the risk of crises such as a pandemic. Society increasingly values sustainable environments that support the functionality of buildings for their users. Adding value to the environment goes beyond sustainability for energy savings or circularity. Building engineers should be (more) aware of the impact of the built environment on building users, their performance at work, school, and home, and their health and well-being. Addressing the cross-cutting health issue in the built environment requires multidisciplinary research to find design, construction, and technology solutions for societal challenges. In line with the above context, the paper presents several examples of research studies illustrating the position of health in research executed by the Health in the Built Environment Community at the Department of Built Environment at Eindhoven University of Technology.

Keywords: Public Health, Indoor Air Quality, Human Performance, Climate Change.

1. THE RELEVANCE OF HEALTH IN THE BUILT ENVIRONMENT

Examining health in the built environment has to be preceded by understanding health. Health is not merely the absence of disease or infirmity but also includes complete physical, mental, and social well-being, as stated by the WHO constitution (WHO, 2005). In addition to this, we have to realize that health also relates to (self) managing or coping with a chronic disorder or NCD (Non-Communicable Disease). The WHO indicates that NCDs account for nearly 75% of deaths in the WHO European Region, which includes the Netherlands (WHO, 2020). Cardiovascular diseases and cancers are the leading causes of premature mortality in the region.

So we could argue that to examine health there are two tracks to follow. One is indicated as the health continuum, which comprises the route of being healthy, obtaining a disease, and having diagnostic examinations, after which there is treatment in the hospital or at home, eventually followed by rehabilitation. The other track contains self-managing or coping with one or multiple chronic disorders. NCDs usually are treated by pharmacological interventions (medication and or therapy, information, and lifestyle advice). These tracks can have an individual approach or a public health approach.

The central mission of the Dutch Ministry of Health, Welfare, and Sport (VWS) is aiming that in 2040 all Dutch citizens will live at least five years longer in good health, and the health disparities between the lowest and highest socioeconomic groups will have decreased by 30%."The mission has five objectives: Promoting Healthy Lifestyles, Improving Access to Care, Supporting People

with Chronic Diseases, Focusing on Dementia Care, Improving care and support for people with dementia and their families, and Reducing Health Inequalities (Ministerie VWS, 2023).

All objectives except the objective of improving Access to Care entail the Built Environment. The Built Environment includes elements like buildings and their services. Building façades connect Indoor Environmental Quality (IEQ) to outdoor environmental quality as well as city design, including walking and cycling paths and parks, which are crucial for promoting healthy lifestyles, enhancing quality of care, supporting mental health, and encouraging physical activity. This illustrates that the built environment could be used as a passive non-pharmacological intervention aiming at both public health as well as individual health and well-being. The application domains are broad, from home to school, work, leisure facilities, hospital, and long-term and residential care. Target groups can be all citizens, children, young people, aging adults, as well as those who take care professionally or voluntarily for someone with a care demand. Alongside understanding health, it's essential to have a deep knowledge of the target group to assess the impact of the built environment or to develop effective solutions.

There are current knowledge gaps where the needs and perceptions of target groups are often not well understood. Additionally, building environment requirements frequently overlook individuals with health problems or NCDs. Existing guidelines for the built environment do not always align well with understanding their impact on health. More research is needed to better align these guidelines with health benefits.

In the following paragraphs, a narrative of various studies tries to illustrate the above statements, considering the life course of children to older adults, including those who provide professional care when needed. Studies selected are aligned to the life course and are studies executed by the Health in the Built Environment Community at the Department of Built Environment at Eindhoven University of Technology.

2. CHILDREN AT PRESCHOOL AND YOUNG PEOPLE AT SCHOOLS

Children at preschool or daycare centers are not the easiest target group since they cannot voice their needs about the built environment. Nevertheless, highly interesting and extensive studies have been executed, focusing on the Indoor Air Quality (IAQ) in Dutch daycare centers and on the effect of the indoor environment on learning outcomes in higher education classrooms. Education is seen as a relevant prevention of health problems.

2.1. VOCs emission, ventilation, and health risks at daycare centers

This research by Zheng et al. focused on sources of indoor air contamination, such as emissions of Volatile Organic Compounds (VOCs) from materials and daycare center activities, and the effectiveness of ventilation in bedrooms to mitigate exposure to such contaminants. Analyses of VOC emissions from arts and crafts and cleaning activities representative of daycare centers demonstrated that there are clear differences between the products used (Zheng et al., 2024). Although the emission rates appear to be generally acceptable for adults, very young babies may be exposed to a health risk from such emissions. This shows the importance of considering the specific target group in the analysis.

With regard to ventilation, the study showed that in Dutch daycare centers the ventilation in the

sleeping rooms is inadequate (Zheng et al., 2023a,b). This is due to the type of beds used in such centers. They do not allow effective ventilation, which may result in unfavorable IAQ conditions for the baby or toddler, e.g., due to emissions from mattresses. The results would favor a rethinking of the design of bedrooms and beds for daycare centers. A design improvement with local ventilation was proposed (Zheng et al., 2025).

2.2. Indoor Environment Quality influencing the academic performance

The most important role for school management is to provide an optimal school climate that represents virtually every aspect of the school experience. This includes the quality of teaching and learning, school-community relationships, school organization, and the institutional and structural features of the school environment (Wang & Degol, 2016). A positive school climate is associated with students' healthy development and the retention of lecturers and can even have a predictive value for the academic performance of students (Cohen et al., 2009).

To improve the effectiveness of this climate, it is essential to create an optimal learning environment. This requires, among other things, appropriate ventilation, heating and air conditioning, ample forms of lighting, necessary acoustical control, and upkeep of maintenance (Wang & Degol, 2016). Evidence reveals that optimal indoor environmental conditions improve students' comfort, health, well-being, and performance (Brink et al., 2021). Four major factors – acoustic environment, lighting, thermal environment, and indoor air quality (IAQ) – determine the indoor environmental quality (IEQ) in school buildings (Frontczak & Wargocki, 2011). Although evidence is piling up, revealing individual contributions of IEQ factors (Brink et al., 2021), evidence which reveals the combined and interaction effects of two or more IEQ factors on students in educational settings is limited (Torresin et al., 2018).

To contribute to the understanding of combined and interaction effects, in future studies, the influence of multiple IEQ factors on students' health, well-being, and performance will be examined. The first results have come available from such studies (Brink et al. 2023), addressing the combination of acoustics, light, and air quality. By extending such research, we aim to gain more in-depth knowledge about how the indoor environment can contribute to an optimal school climate.

3. ADOLESCENTS IN THEIR WORK ENVIRONMENT

3.1. The office environment, work performance, and mental health

Multiple studies worldwide have been executed studying the effects of IEQ on office workers' work performance and mental health. Less explored are the positive health-related, also called salutogenic, aspects on office workers. One promising salutogenic aspect is sound masking in office environments to mitigate distractions and reduce mental health issues. Also, biophilic design elements in office environments positively influence psychological and cognitive responses (Bergefurt, 2023). In addition, other aspects of IEQ, such as lighting, air quality, and thermal comfort, also influence office workers' satisfaction and, consequently, their perception of health. Office workers' satisfaction with privacy, daylight, views outside, and artificial light are highly interconnected, indicating a complex mechanism influenced by multiple variables (Bergefurt et al., 2022).

Earlier research indicated that the lighting conditions experienced by office workers fluctuate throughout the day, with notable peaks in the morning and around lunchtime. Large individual differences in personal light conditions may occur depending on work schedule, traveling to work, sleep behaviour, and preferences. Office workers who worked full-time were less advantaged in their light exposure than those working part-time and spending most time away from the office (van Duijnhoven et al., 2021). Most offices are shared environments, yet office workers often wish to have control over their workspace. Greater perceived control of the indoor environment enhances comfort while impacting the incidence of sick building symptoms positively (Boerstra et al., 2013).

3.2. The care environment and job performance challenges

Healthcare professionals in hospitals and long-term care facilities encounter performance issues related to the IEQ. Hospitals can be likened to a micro city. You need to navigate from one point to another while concentrating on tasks that require either cognitive or physical effort. Remembering to execute tasks becomes even challenging during the day. Nurses may have tasks related to a certain event or related to a time or location (Patient A has to be at location B at time C). In many cases, tasks are interrupted, and remembering to proceed with the execution of the tasks is called the prospective memory. Reinten demonstrated that the PM load of nurses increased during the first 30 minutes of their shift due to distractions, which could be attributed to sound-task interference (Reinten, 2020).

In hospitals, temperature settings were perceived as slightly warm discomfort. Nurses have to wear the obligatory uniform. In hospital wards, temperatures reaching up to 25°C can cause warm discomfort. The optimal thermal sensation for nursing staff tends to be on the cooler side of the scale (Derks et al., 2018). Nurses working in operational theatres also perceive thermal comfort issues. A case study, along with perception data, revealed that within a surgical team, the anaesthesiology assistant reported significantly more complaints compared to other team members. Nurses often perceive their hands and arms as cold due to drafts, whereas surgeons generally report fewer complaints (Jacobs, et al., 2019). Another challenging environment in hospitals concerns the medication room, although nurses do not complain about the lighting. The lighting in one of the medication rooms was below 200 lux at desk level, which is inadequate for performing visual tasks (Aarts et al., 2018).

Despite the dedication and heartfelt efforts of most care staff, working in nursing homes comes with its own set of challenges. Challenges in the built environment include light conditions. Lighting conditions in nursing homes are managed by care staff, particularly in communal areas. Sinoo's studies revealed that out of seven nursing homes where illuminance levels were measured in communal areas and corridors, only one met the threshold values of 750 lx for communal areas and 200 lx for corridors. Additionally, in 90% of the measurements taken in the central or rear parts of common rooms, the limit for horizontal illuminance was not met. Horizontal illuminance at the window met the threshold in 41% of cases (Sinoo, 2016). These measurements were taken in winter (2010), indicating that care professionals need to be especially vigilant during this period to ensure residents receive adequate exposure to (day)light for both visual tasks and maintaining a healthy day/night rhythm.

4. OLDER PEOPLE AT HOME AND IN LONG-TERM CARE FACILITIES

4.1. Older people ageing-in-place

Ageing in place is a concept that allows older adults to remain in their own homes as they age, even if their health and mobility change. Home refers to the unit, the community, the street and the social network. Aging in place also involves having access to care, as well as living in an age-friendly city or neighborhood and a supportive home environment (Raymundo et al., 2024).

General functional and mental decline restricts older people to age-in-place. As people age, many prefer to continue living in their (family) homes, and most countries support this preference through health policies aimed at ageing citizens. Policies alone do not help. Knowledge of risks and validated interventions are needed to support ageing citizens. Interventions could be on a city level, comprising the design of walking and cycling pathways, as well as the position of parks for leisure activities and social connections and the distance to public transportation and facilities. Vitality as loneliness can be mediated by the vicinity of green spaces resulting in physical activities (van den Berg et al., 2019).

In general, it is known that environmental adaptations and improvements and the use of assistive technologies support the independence of older people and increase their quality of life (Lansley et al., 2004). Therefore, more in-depth knowledge is needed about the effect of the built environment on supporting ageing in place.

Older people will experience mental and functional decline. Also, visual decline due to biological ageing and eye or NCDs-related pathologies will occur. The ageing eyes will result in dry-eye symptoms, which could be compensated by medication (eye drops) and interventions in the indoor environment (van Tilborg et al., 2017). Interventions in the indoor environment include maintaining optimal humidity levels, which can help reduce tear evaporation. Minimizing direct airflow from fans or air conditioning units can prevent the exacerbation of dry eye symptoms as well (van Tilborg et al., 2015).
Dry eye symptoms could limit work performance. In another domain, we also see changing requirements regarding thermal comfort due to age and frailty (Schellen et al., 2010; Zhou et al., 2024).

A major issue in ageing-in-place concerns the risk of falls due to eye aging. The anatomy and function of the eye will change over the course of life. A relevant eye function is contrast sensitivity, which discriminates two luminance levels and helps to detect objects in the environment. It also relates to past occurrences of falls and predicts future falls (Saftari et al., 2028). Understanding this relationship in combination with the knowledge of the visual acuity of the ageing eye, the home environment layout, and light conditions will contribute to design solutions for ageing-in-place.

4.2. Indoor environment quality and sleep when having dementia

People with dementia do not always voice their wishes and needs. We have to realize, though, that there are many manifestations of dementia and a majority of people living with dementia (PlwD) are active within their functional and mental capacity. They accommodate strategies to cope with the challenges (Huizenga et al., 2022). Still, they face many challenges in the Built Environment.

A major challenge when having dementia is sleep. This has been identified as a primary reason

for moving people to long-term care facilities. Over time, dementia progresses and will affect sleep disturbance, resulting in displaying challenging behaviors that contribute to increasing the care load of their family carers. Previous studies have shown that non-pharmacological interventions comprising improvement of the IAQ can positively influence sleep quality and next-day performance of older people and youngsters, respectively (Strøm-Tejsen et al., 2016; van der Veen et al., 2021; Mishra et al., 2018). In a future study, the influence of this and other domains of the indoor environment on PlwD will be examined to gain more in-depth knowledge of sleep problems when having dementia and to give directions to design and system solutions.

5. CONCLUSION

Research in the combined domain of health and the built environment addresses developing solutions for several societal challenges over the life course. In addition, gaining competencies in different methodologies and approaches will be a prerequisite. This, however, may not be feasible for most research projects due to time constraints. Therefore, multidisciplinary teams will need to rely on trust, respect, and recognition of each other's expertise.

ACKNOWLEDGEMENTS

We extend our gratitude to all current and past Health in Built Environment Community researchers for their contributions to this interdisciplinary field.

SUMMARY

Integrating solar heating system with building envelopes has become an effective means of realizing energy savings and carbon emission reduction in the built environment. However, the traditional passive solar collector walls are limited by inadequate heating regulation and seasonal operation. This study proposes a modular solar collection and storage component integrated with light-absorbing nano-composite phase change materials (NPCMs) that, when combined with existing building walls, can provide flexible solar heating. The NPCM-integrated solar heating system was experimentally investigated for its performance in solar thermal collection and storage as well as space heating. The results indicate that the nano-composite PCM-integrated solar collection system has advantages to achieve higher heating stability. The maximum instantaneous thermal efficiency of the component reaches 78.94%. The ventilation rate of 1.0 m/s resulted in an enhancement of the heating performance of the solar collector-conditioner wall, enabling the wall to maintain a set temperature of 20 ℃ for a duration of 13 hours.

Keywords: Nano-composite PCM; the NPCM-integrated solar collection component; solar heating and ventilation

1. INTRODUCTION

Building energy consumption accounts for a large proportion of global energy use. Therefore, implementing energy-saving measures is essential for reducing carbon emissions. The integration of solar energy into building practices offers a promising approach for decreasing both building energy consumption and associated emissions (Bosu et al. 2023). Passive solar buildings, such as those equipped with Trombe walls (TW), are cost-effective and well-suited for cold climates (Lan et al. 2022;).The application of TW technology mitigates heating demands. The renowned Trombe wall, designed by French architect Felix Trombe (Xue et al. 2010), is the archetypal heat-collecting wall that passively captures solar energy for heating purposes. Subsequent research has focused on refining and enhancing this concept through advancements in wall materials and optimization of structural designs (Corasaniti et al. 2017). Nonetheless, challenges persist with Trombe walls, such as inconsistent heating performance during winter and potential overheating issues in summer conditions (Xiao et al. 2024).

On the other hand, extensive research has been conducted on the incorporation of phase change materials (PCMs) into building fabric, such as walls and roofs. The integration of PCM in building structures enhances thermal capacity, stabilizes indoor temperature, and consequently reduces the total annual cooling and heating loads. Wu et al. (2024) investigated a composite phase-change material comprising three phase-change substances. Their findings revealed that the application of this material resulted in a significant reduction

in temperature fluctuations, achieving a decrease of 31.91% during winter and 54.51% during summer. While prior research has made significant advancements in optimizing PCM wall structures and materials (e.g., enhancing thermal conductivity and phase-change enthalpy), traditional passive solar collector walls or PCM walls are constrained by inadequate heating regulation, seasonal operation constraints, and challenges in retrofitting existing buildings. Additionally, issues such as peeling of solar collector coating, delayed response to thermal regulation are prevalent, and the solar energy utilization efficiency need improved (Askari et al. 2023).

In this paper, a modular solar thermal storage component is proposed, which uses light-absorbing nano-composite phase change material (NPCM) inside. Combined with the existing building walls and other envelope structures, the air supply volume can be flexibly adjusted according to the indoor load, so as to realize the integration of solar collection-heat storage and heating ventilation and reduce the building heating energy consumption and carbon emission.

2. METHODS

2.1. System description

Fig. 1 shows the schematic configuration of the NPCM-integrated solar collection component and its applications in building heating. The solar collection component consists of double insulating glazing, NPCM thermal storage layer, plate metal, air channel. The baseplate is enclosed by the wall to form an air channel.

The NPCM absorbs solar radiation and converts it into thermal energy, which is stored as sensible and latent heat. As the indoor return air or outdoor fresh air flows through the channel, it is heated by the NPCM attached to the inside surface of the metal corrugated baseplate. Subsequently, this warmed air is circulated into the room for space heating.

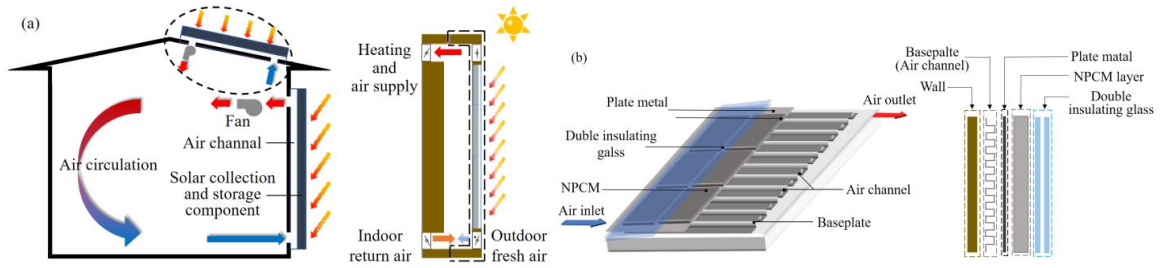

Figure 1. (a) Schematic configuration of the NPCM-integrated solar heating system in building applications, (b) Structure of the NPCM-integrated solar collection component

As shown in Fig. 2, the operation of the system can be divided into four different modes via the precise adjustment of the channel valve, namely: (a) space heating mode; (b) insulation mode, (c)Ventilation and heat insulation mode; (d) The optional mode for water heating. The optional water heating mode can significantly contribute to reducing energy consumption for domestic hot water production during periods when space heating is not required.

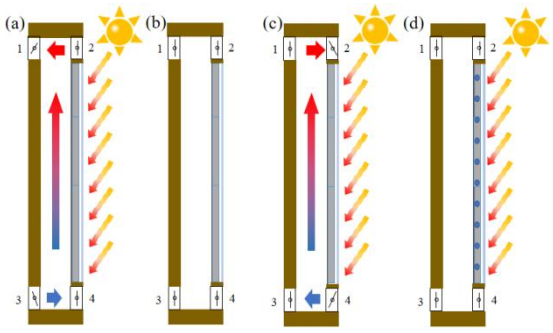

Figure 2. Operation modes: (a) Space heating mode, (b) Insulation mode, (c)Ventilation and heat insulation mode, (d) The optional mode for water heating

2.2. Experiments

To evaluate the heat transfer performance of the NPCM-integrated solar collection component across various operating conditions and parameters, a solar thermal performance test platform was developed. This platform consists of a temperature control system, a NPCM-integrated solar collection component ($0.8m^2$) and a data acquisition system. The experimental setup are shown in Fig. 3.

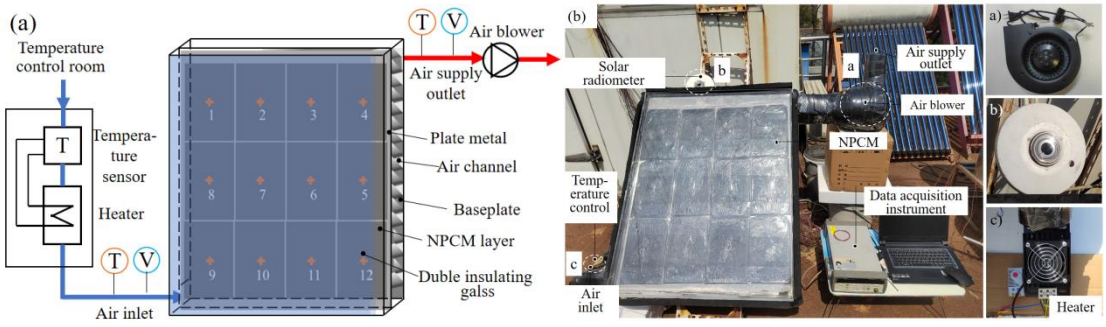

Figure 3. (a) Schematic layout of measurement points, (b) Experimental setup

As shown in Fig. 3, 12 temperature measurement points were uniformly distributed across the central region of the NPCM-integrated solar collection component. Each air inlet and outlet was equipped with temperature and wind speed measurement points to monitor internal temperature variations within the system. The arrangement and nomenclature of the temperature measurement points are illustrated in Fig. 3(a). T_{air} and T_{PCM} were measured using T-type thermocouples (accuracy: ±0.2 ℃, range: -200℃ to 350 ℃). Wind speeds at the inlet and outlet of the channel were measured using a hot-wire anemometer (accuracy: ± 0.1 m/s, range: 0.05 m/s to 50 m/s).

This study aims to enhance light absorption by developing NPCM incorporating graphene. The prepared 0.01 wt% NPCM exhibits both high energy storage density and excellent photothermal conversion performance. The physical properties of the prepared 0.01 wt% NPCM are listed in Table 1.

Table 1. Physical parameters of 0.01%wt% NPCM.

Parameters	Solid	Liquid

Phase change temperature, T/(℃)	51-61	
Latent heat, h/(kJ/kg)	171	
Thermal conductivity, λ[W/(m·℃)]	0.258	0.165
Density, ρ/(kg/m3)	915	880
Absorption Coefficient, Ka/(m-1)	650	350
absorptivity	0.9999	0.9991

2.3. Theoretical Modeling

In the space heating mode, the instantaneous collector efficiency of the NPCM-integrated solar collection component is defined as the ratio of (the daily heat supply to the room (Q_{air}) + the heat stored in the NPCM (Q_{pcm}) to the daily cumulative solar irradiation, as shown in Eq. (1).

$$\eta_i = \frac{Q_{pcm}+Q_{air}}{Q_{sun}} \tag{1}$$

The heat transfer process of collecting wall is shown in Fig. 4, including phase transition and temperature rise of PCM, convection heat transfer inside ventilation holes and conduction heat transfer in PCM. The heat balance equation is expressed in Eq. (2).

$$Q_{sun} = Q_{loss}+Q_{pcm}+Q_{air}+Q_{in} \tag{2}$$

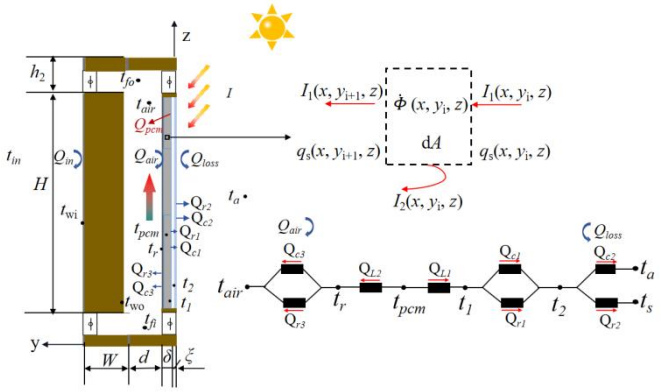

Figure 4. Schematic diagram of heat transfer process for the collecting wall.

The heat exchange amount from the wall to ventilation channel(Q_{air}) is calculated by Eq. (3) .

$$Q_{air} = \int_{\tau_0}^{\tau} h_{ch}A_r(t_r - t_{air})\,d\tau + \int_{\tau_0}^{\tau} \sigma\varepsilon A_r\left(t_r^4 - t_{air}^4\right)d\tau \tag{3}$$

Where h_{ch} is the heat transfer coefficient of the heat transfer surface of the air flow channel, W/(m^2·℃); A_r is the total area of the metal plate in the air flow channel, m^2; t_r, t_{air} are the temperature of the metal plate and the temperature of the air in the air flow channel, ℃; τ is the time.

The heat converted by NPCM from solar radiation (Q_{sun}) and heat stored in NPCM(Q_{pcm}) is

calculated by Eq. (4), (5) respectively.

$$Q_{\text{sun}} = \int_{\tau_0}^{\tau} A_{\text{c}} I \alpha_{\text{nf}} \, d\tau \tag{4}$$

$$Q_{\text{pcm}} = m_{\text{pcm}} c_{\text{pcm}} (t_{\text{i}} - t_{\text{ini}}) + m_{\text{pcm}} + \beta L \tag{5}$$

Where A_{c} is the total lighting area, m^2; α_{nf} is the percentage of radiation absorption of light-absorbing PCM; I is the total solar radiation acting on the outer surface of double insulating glass, W/m^2; t_{ini} is the initial temperature of the NPCM, ℃; t_{i} is the instantaneous temperature of the NPCM at i, ℃; L is the latent heat of phase change of the NPCM, J/kg; and β_{i} is the liquid phase rate of the NPCM at i.

The heat lost to the environment(Q_{loss}) and heat conducted into the room(Q_{in}) is calculated by Eq.(6).(7) respectively.

$$Q_{\text{loss}} = \int_{\tau_0}^{\tau} h_{\text{out}} A_{\text{c}} (t_2 - t_a) \, d\tau + \int_{\tau_0}^{\tau} \sigma \varepsilon A_{\text{c}} \frac{\nu_{\text{fi}} + \nu_{\text{fo}}}{2} (t_2^4 - t_{\text{a}}^4) \, d\tau \tag{6}$$

$$Q_{in} = \int_{\tau_0}^{\tau} h_{in} A_w (t_{wi} - t_{in}) \, d\tau \tag{7}$$

Where h_{out}, h_{in} are the surface heat transfer coefficients of the external wall surface and the internal wall surface, respectively, $\text{W/(m}^2\cdot\text{℃)}$; A_{w} is the internal surface area of the existing wall, m^2; t_2, t_{wi} are the temperature of the external wall surface of the double glazing and the temperature of the internal wall surface of the wall, respectively, ℃; t_{a} is the ambient temperature, ℃; ε is the emissivity of the external wall surface.

3. RESULTS

3.1 Thermal performance of t the NPCM-integrated solar collection component

Fig. 5(a) depicts the variations in outdoor solar radiation intensity and ambient temperature. The period from 13:12 to 17:00 is identified as the heat-release stage, during which the stored heat in the NPCM is released for heating due to the weakened solar radiation. The average ambient temperature measured 13.3 ℃ during the heat-collection phase and 11.5 ℃ during the heat-release phase. The experiment employed a constant air volume heating operation, with an airflow rate of 0.024 m^3/s.

Fig. 5(b) illustrates the temperature variations at the measurement points within the NPCM during the experiment. In the storage-heating phase, the NPCM's temperature rises as it absorbs solar radiation. When the temperature zone reached 51 - 61 ℃ , the heating mode changes to latent heat storage, resulting in a slow temperature rise. After the complete phase change, the heating rate accelerates once more. During the release-heating phase, the NPCM's temperature decreases due to heat exchange with air in the channel. Furthermore, horizontal temperature stratification occurs within the component. The air enters the channel at a lower temperature. As it exchanges heat with the NPCM, the air's temperature rises, diminishing the temperature difference between the air and the NPCM. As a result, the heat exchange intensity is reduced on the outlet side compared to the inlet side.

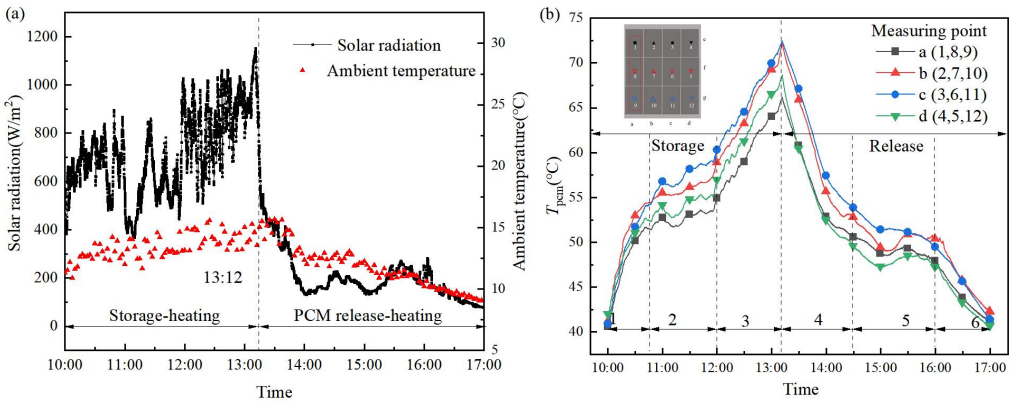

Figure 5. (a)The change in outdoor solar radiation intensity and ambient temperature, (b)Temperature variations of of NPCM at different measuring points

Fig. 6 depicts the solar radiation intensity (Q_{sun}) and heat supply (Q_{air}) across different time periods. The effective output energy of the NPCM-integrated solar collection component with a lighting area of 0.8 m^2 is 6.43 MJ (accounting for about 72.4% of the received solar radiation), which improves the stability of solar heating. Among them, the heat supply in the heat storage section is 3.52 MJ (with a heating power of 305.6 W), and the heat supply in the heat release section of the PCM is 2.90 MJ (with a heating power of 212 W). Notably, due to significant fluctuations in solar radiation, the collector and heating performance varies greatly across different time periods. For instance, the supply air temperature difference before 14:00 can reach 15.4 ℃, with the maximum supply air temperature approaching 40 ℃. However, after 14:00, the heating temperature is mostly below 25 ℃.

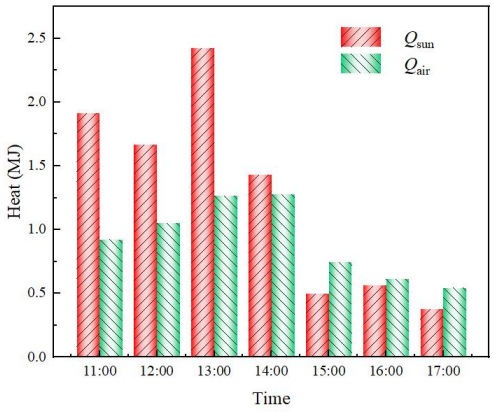

Figure 6. The comparison of Q_{air} and Q_{sun}

3.2 The influence of ventilation rate on the heating

We analyzed the heating performance for a 24 m^2 room with an 18 m^2 NPCM-integrated solar collection component integrated into the south wall. Using DEST software and data from a typical winter day, the room's daily energy load is approximately 130 MJ. The target indoor temperature is 20 ℃, with an air supply rate of 450 m^3 /h. The impact of ventilation speed on heating performance was investigated by systematically altering its rate.

It can be observed from Fig. 7(a) that the supply air temperature decreases as the ventilation rate increases under typical meteorological conditions. At low ventilation rates, the retention time is extended, which facilitates sufficient heat exchange; however, the

intensity of heat exchange remains relatively low, thereby limiting heat removal by the air at the runner side and allowing for predominant accumulation of absorbed heat in the NPCM.

Fig. 7(b) depicts cumulative heat supply over time for different ventilation rates. The dotted line represents the cumulative heat supply required to maintain a set temperature of 20 ℃ within the room. The duration required for indoor temperatures to reach set points varies with different ventilation speeds. The time required for the room temperature to reach the set point when the ventilation speed is 0.6 m/s, 1.0 m/s, 1.4 m/s and 1.8 m/s, respectively, is 19:00 to 01:00 (the following day), respectively. The heating period is guaranteed to last for a minimum of six hours, 13 hours, 14 hours and 15 hours.

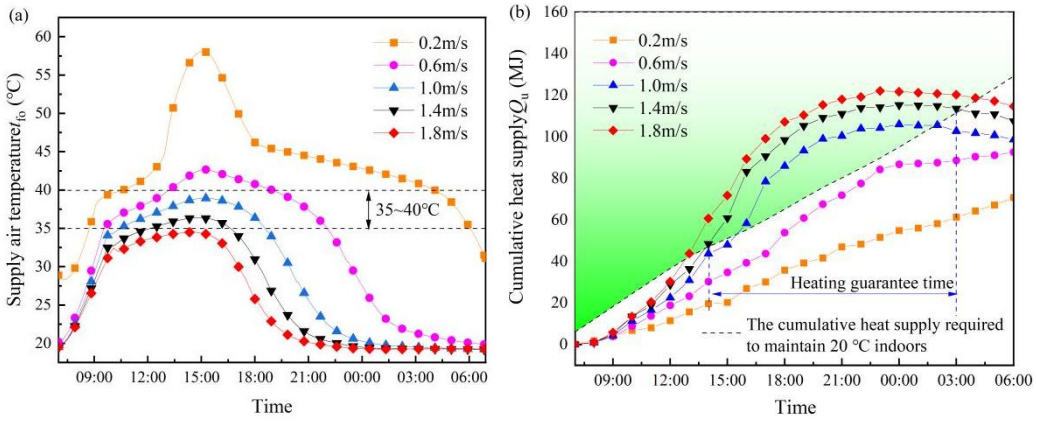

Figure 7. (a) Supply air temperature at different ventilation rates, (b) Variation of heat supply at different ventilation rates over time

Fig. 8 illustrates the daily heat supply and thermal efficiency at various ventilation rates. It is evident that as the ventilation rate increases, there is a corresponding rise in the daily heat supply to the room, average daily thermal efficiency, and guaranteed heating rate, which facilitates greater heat transfer into the room. When the ventilation rate was decreased from 1.8 m/s to 0.2 m/s, all three parameters-daily heat supply, average daily thermal efficiency, and guaranteed heating rate—experienced an approximate reduction of 35.1%.

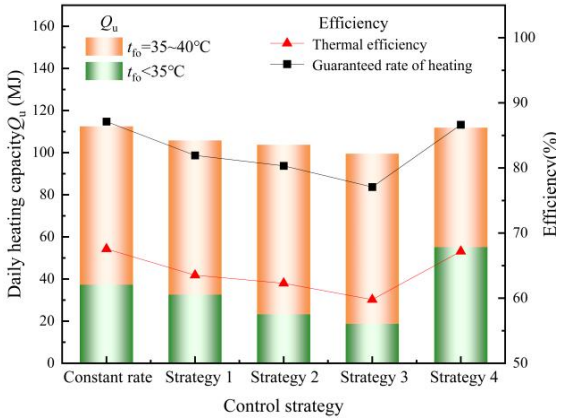

Figure 8. Daily heating capacity and thermal efficiency at different ventilation speeds

At a ventilation speed of 1.0 m/s, the solar collector-storage ventilated thermal wall

demonstrates exceptional heating performance; specifically, it provides a daily heat supply of 112.6 MJ along with an average daily thermal efficiency of 67.6% and a heating guarantee rate of 87.2%. Under these conditions, indoor spaces are capable of achieving a set temperature of 20 ℃ for up to 13 hours.

4. Conclusions

This study proposed a the NPCM-integrated solar collection component integrating solar energy and PCM, and investigated its thermal performance, with a focus on winter heating. The main conclusions drawn in this study are as follows:

During the heating experiment of the NPCM-integrated solar collection component, the maximum instantaneous collector efficiency reached 78.94%. This component delivered 6.43 MJ of heat, accounting for approximately 72.4% of the received solar radiation. Specifically, the storage-heating phase contributed 3.52 MJ (heating power: 305.6 W), while the release-heating phase supplied 2.90 MJ (heating power: 305.6 W), collectively enhancing the stability of solar-assisted heating. When the ventilation speed of the solar collector wall is 1.0m /s, the heating performance is excellent. Its daily heating capacity, daily average thermal efficiency and heating guarantee rate are 112.5MJ, 67.6% and 90.0% respectively, and the room can reach the set temperature of 20 ℃ 13 h.

Compared to traditional systems, the NPCM-integrated solar collection component offers higher heating stability and solar energy utilization efficiency. Its modular design allows for effective adjustment of heat storage and release according to indoor thermal demands.

SUMMARY
This paper studies life cycle assessment (LCA) of a townhouse in Cambodia as a case study and compares carbon emission (CE) of green building scenarios generated with two types of LCA: screening and simplified. The research methodology is based on the building modelled in SimaPro software using ecoinvent 3 databases to assess life cycle CE of case study and different selected scenarios. The simplified LCA result show that the building produced a CE of 1276 kg CO_2-eq/m^2 and the average difference between the screening result and that of the simplified LCA is 2.8%, ranging from 1.9% to 4.9% according to the design scenario studied. The combination of the four tested strategies reduced the building's CE by 42% compared to the existing house. The results show the potential for integrating LCA into green building design in Cambodia. The screening LCA can be a useful tool to pre-size the GHG emissions produced by building and test different decarbonization options during the design stage.

Keywords: carbon footprint, screening LCA, residential building.

1. INTRODUCTION

In Cambodia, with a rising urban population and a construction sector growing at 18.1% between 2014 and 2019, GHG emissions from buildings are expected to increase rapidly (GGGI, 2021). To minimize the environmental impact (EI) of the building sector and promote green building design, the approach of LCA helps estimate the EI generated by a building throughout its whole life cycle. While the building LCA has reached an advanced stage of development in many developed countries, there remains a considerable need to enhance its adoption in developing countries, especially in Southeast Asia (Jayawardana et al., 2023). LCA has recently been introduced in Cambodia, primarily applied to sectors such as hydropower plants, cement production plants, and food production system to assess the EI, emissions to air pollution, and CO_2 emissions, respectively (Chhun et al., 2021; Chea et al., 2022; Hor et al., 2021). However, the application of LCA to buildings has not yet been implemented in the country. This study constitutes a valuable innovation for the local construction sector, providing a representative benchmark for developing green building guidelines and a practical method for simplifying LCA.

The ISO 14040 describes principles and framework of LCA and ISO 14044 describe the requirements and guidelines of LCA (ISO, 2006a; ISO 2006b). The European Standards for LCA of buildings: EN 15978 and EN 15804 provide guidance on how to apply LCA to buildings, divide the life cycles of building into five stages, define system boundaries, and allocation methods (CEN,

2012a; CEN, 2012b). Architects and planning professionals recognized LCA in supporting decision-making process in building design and assisting in materials selection (Mateus et al., 2011). Decisions made during the early design stages critically determine a building's EI, and LCA helps designers, faced with many decisions, choose those that are significant regarding the building's EI (Basbagill et al., 2013).

For building LCA, there are two types of simplification to facilitate the completion of a LCA study, used by stakeholder and practitioners for the early design stage of a building: screening and simplified LCA (Wittstock et al., 2012). The simplified LCA was conducted to obtain a more detailed and thorough assessment compared to the screening LCA. Full LCA can be hardly accomplished since it is time-consuming and resource-intensive, and often faces a lack of data, so that it is recommended to use simplification in LCA (Hochschorner et al., 2003; Gradin et al., 2021). The simplification of LCA methods is essential if practitioners aim to include environmental aspects in an early stage of product development and improvement.

SimaPro software is particularly suitable for estimating the global warming potential (GWP) of a building during production phase and is considered the most widely used LCA database-software combination in the building sector (Gu et al., 2024; Emami et al., 2019). The software includes several databases, among which ecoinvent is the most widely utilized in building sector. Furthermore, SimaPro allows users to modify input data to reflect regional conditions not explicitly included in the default database options. The environmental LCA of a single house in India was modeled in SimaPro using the ecoinvent database, which integrated the European Life Cycle Database (Pinky and Palaniappan, 2012). A similar study, analysing the EI of a residential building in Malaysia, was conducted using LCA in SimaPro and the Malaysian Life Cycle Inventory Database, adapted from ecoinvent database (Abd Rashid et al., 2017).

2. METHODOLOGY

An LCA model was developed and analysed using SimaPro V9.4.0.2 software due to its popularity and leading LCA software used as a decision tool (Herrmann et al., 2015). The ecoinvent 3 database is selected to model the inventory of the housing unit, considering all inputs of material manufacturing (gradle-to-gate) and energy involved in life cycles, as no database specific to materials in Cambodia has yet been developed. This database was chosen for the study due to its status as the largest transparent unit-process Life Cycle Inventory database globally, distinguished by its integrity, usability, and completeness (Wernet et al., 2016; Martínez-Rocamora et al., 2016). The CE in this study is the amount of GHG produced throughout the building life cycle and it was calculated in kg CO_2-eq/m^2.

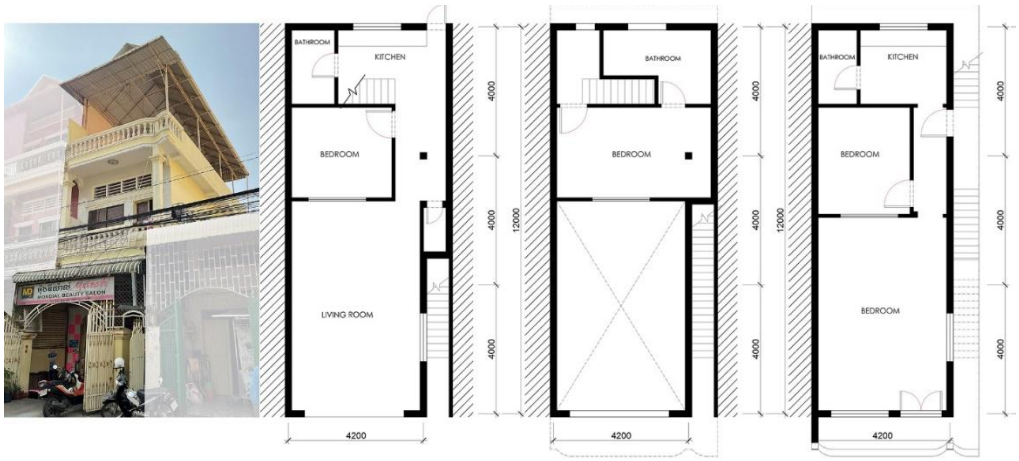

Figure 1. Streetview photo and floor plans of the building case study.

The selected building case study is a three-storey townhouse with a gross floor area (GFA) of 157 m^2 as shown in Fig. 1 and located in Cambodia, a hot and humid tropical climate. The construction techniques and materials are common in Cambodia: reinforced concrete structural frames and brick masonry walls without insulation. The annual electricity and water consumption is 6,480 kWh and 1,200,000 liters. The case study was selected based on the fact that this housing type is mostly built in urban areas, an important part of current city development and suitable for the Cambodian context (Taing et al., 2023; Khoan et al., 2022). The number of constructions this townhouse type increased by more than 34% from 2020 to 2021 in Cambodia (Choun et al., 2022).

This study follows the LCA method standardised by ISO 14040 and 14044 standards, using the screening and simplified LCA based on EN 15978, which includes four stages as follows: goal and scope definition, life cycle inventory, life cycle impact assessment, interpretation. The two simplification types of LCA studies are applied on the one hand to the reference building, selected as a case study, and on the other hand to five environmental improvement strategies described below.

2.1. Goal and scope definition

The goal of this study was to evaluate the CE of a townhouse in Cambodia using two types of LCA: screening and simplified LCA, taking into account the production and use phase within specific system boundaries as shown in Table 1. Other LCA impact categories were not considered, as there is an urgent need for research on embodied carbon in developing countries, where the CE is the most widely recognized emission indicator (Nawarathna et al., 2021). Additionally, the selected impact method focuses exclusively on CO_2 emissions. The construction and end of life phase were not taken into account due to the study's system boundary, building's data, and references limitation. Although waste processing and disposal are defined as mandatory modules, they were excluded from the assessment due to the absence of data and information regarding the building's end of life phase. Neglecting the end of life phase is acceptable because their impacts are very low compared to the CE on its entire life cycle (Sharma et al., 2011). The building functional unit selected was 1 m^2 of GFA and its lifespan assumed to be 50 years as recognized in building industry (Abd Rashid and Yusoff, 2015).

Table 1. Life cycle phases to be considered for screening and simplified LCA type (based on EN 15978).

Production			Const-ruction		Use							End of life				Benefits and loads beyond the system boundaries

2.2. Life cycle inventory (LCI)

2.2.1 Production phase

The inputs for the production phase were obtained from on-site measurements and survey with house owner. Following detailed measurements of each building component, the construction materials used for each component were estimated with the assistance of construction engineers, as no technical drawings or plans were available for the building. The ratio of each building material's component was divided per m^2 of GFA. The LCI data for the production phase were modelled by calculating the detailed build-up elements of the building components, and are presented in Table 2.

Table 2. LCI of materials in production phase.

Components	Materials	Amount	Unit	Ratio (kg/m^2 or m^3/m^2)
Internal walls	Ceramic tile	1225.35	kg	7.80
	Clay brick	2839.2	kg	18.08
	Cement mortar	2028	kg	12.92
	Base plaster	930	kg	5.92
External walls	Ceramic tile	1278.83	kg	8.15
	Clay brick	14196	kg	90.42
	Cement mortar	5371	kg	34.21
	Base plaster	2580	kg	16.43
Structures (slab, column, and beam)	Ceramic tile	4761.40	kg	30.33
	Normal concrete	31.75	m^3	0.20
	Reinforcing steel	2715.28	kg	17.29
	Base plaster	1670	kg	10.64
	Cement mortar	716.22	kg	4.56
Stairs	Steel	69	kg	0.44
	Alkyd paint	2.5	kg	0.02
	Normal concrete	1.36	m^3	0.01
	Reinforcing steel	16.74	kg	0.11
Roof shelter	Zinc	300	kg	1.91
	Steel	412.80	kg	2.63
Doors	Polyvinylchloride	27	kg	0.17
	Wood	4.8	m^2	0.03

	Alkyd paint	3.2	kg	0.02
	Steel	92	kg	0.59
	Coated flat glass	30.8	kg	0.20
Windows	Aluminum frame	4.95	m^2	0.03
	Coated flat glass	84.24	kg	0.54
	Steel	200.82	kg	1.28
	Alkyd paint	3.6	kg	0.02

The main building components to be considered in the screening LCA included exterior walls, windows, roof and floor slab, and load-bearing walls and structure (Hollberg, 2016). For simplified LCA, foundations, interior walls, building services, and finishing are added to the components listed in the screening LCA.

The transportation of virgin materials to the factory gate was taken into account in the production phase and the average distance per trip was assumed to be 130 kilometers (Decorte et al., 2020).

2.2.2. Use phase

The inputs for the use phase were obtained from bills of electricity and water consumption given by the house owner. Electricity is the only form of energy consumed during the building's use phase, as no active mechanical systems are installed. It is mainly used for cooling (electrical and ceiling fan), lighting, and appliances. Energy for water heating is not required, as hot water is not provided within the building. The electricity and water consumption were modelled by the total amount of electricity (kWh) and water (kg) consumed per year, multiplied by 50 years and expressed by m^2 of GFA. The CE associated with these operational phases were calculated based on the embodied emissions resulting from the building operation, included electricity and water use.

Maintenance inputs were modelled based on the potential of replacement, reapplying, and change of each component. Painting, windows, and solar PV panels were considered in the use phase maintenance. The replacement of roofing materials, floor tiles, and electrical and plumbing fixtures was not included. The number of replacements in 50 years of painting and windows are 4 times and 1 time, respectively (Abd Rashid et al., 2017; Ortiz-Rodríguez et al., 2010). The used PV panels will be replaced 1 time in 50 years due to their lifetime of 25 years (Chowdhury et al., 2020). The CE calculation for this phase accounts for all modules within the production phase of the selected components.

2.3. Life cycle impact assessment (LCIA)

The CE of the case study were assessed using the IPCC 2021 GWP100 method considering and quantifying only the Global Warming Potential indicator for a timeframe of 100 years (GWP100) with climate change factors of IPCC (PRé Sustainability-SimaPro, 2023).

2.4. Interpretation

The LCIA results were interpreted according to the goal and scope of the study and made it possible to identify the significant potential of improvements of the studied scenarios.

2.5. Building studied scenarios

The studied scenarios were designed to reduce the CE of the case study and other residential buildings in Cambodia. LCA modelling of the scenarios applied to the case study are carried out

and analysed, following the same methodological framework as for the existing house's LCA. The description and aim of each scenario are listed in Table 3.

Table 3. Building studied scenarios and their descriptions.

Scenario	Description
Reference	• Existing situation of the building case study
Strategy 1: removing unnecessary materials	• Removing ceramic tiles from the external walls and steel bars from exterior windows and doors, aiming to minimize the excessive materials consumption for decoration
Strategy 2: using environmental manufacturing and bio-based materials	• Replacing of normal reinforced concrete by lean concrete and aluminum window frames by wooden frames
Strategy 3: using lightweight timber frames	• Replacing brick masonry walls by lightweight timber frames for the external walls only
Strategy 4: installing solar PV panels	• Implementing the solar panels on the existing roof shelter, generating solar energy that cover about 51% of the annual energy consumption. This value was calculated based on the installation of 24 solar panels, each with a power output of 380 W and an efficiency of 20%, at a location receiving an average of 5 peak sun hours per day.
Strategy 5: combined strategy	• Combination of the four studied strategies to find the potential of improvement and green building solutions

3. RESULTS

Fig. 2 shows the CE comparison of the reference and four studied scenarios corresponding to the production phase by building component. The following scenarios, reference, strategy 1, strategy 2, strategy 3, and strategy 4, accounted for 175, 170, 148, 140, and 188 kg CO_2-eq/m^2 in the production stage, respectively. Among all scenarios, strategy 3 shared a lower CE than others while strategy 4 generated a higher emission.

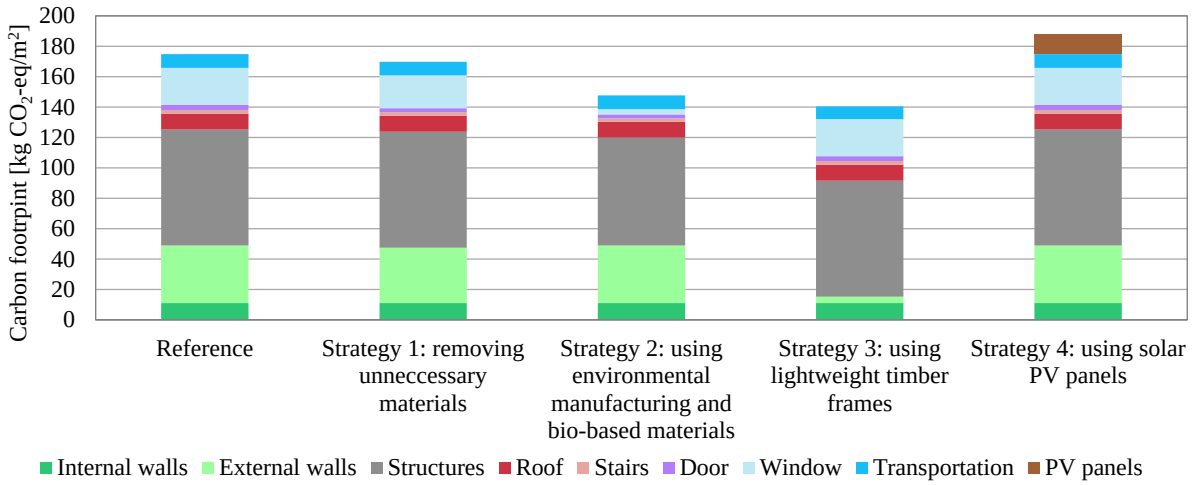

Figure 2. Carbon emission of the reference and four studied scenarios during the production phase, presented by building component.

In the reference scenario, the structure (floor slab, column, and beam) was the dominant contributor to CE, external wall ranked second, and windows ranked third compared to other components. The 35%, 22%, and 14% were shared to the total CE by the structure, external walls, and windows, respectively. Strategy 1, aiming to remove ceramic tiles from interior of the external walls, gives a slight reduction of 3% compared to the reference scenario. While strategy 2, using lean concrete in place of normal concrete and using wooden window frames in place of aluminium frames, gives a reduction of 16% compared to the reference and reduces significantly the impact of windows on the total CE. Strategy 3 replacing the masonry external walls by lightweight timber frames brings a reduction of 20% compared to the reference. This strategy generates a significant improvement in the CE of external walls and shifts its rank from the second most influential to a less dominant position. However, strategy 4, implementing solar PV panels on the roof, led to an increase of approximately 7% in CE compared to the reference.

Fig. 3 presents the overall CE comparison of the reference and four studied scenarios, calculated using screening LCA and simplified LCA. The reference scenario showed a CE of 1248 and 1276 kg CO_2-eq/m^2 for the screening and simplified LCA, respectively, with a 2.2% difference. For strategy 1, CE were 1244 (screening LCA) and 1271 kg CO_2-eq/m^2 (simplified LCA), yielding a 2.2% difference. Strategy 2 showed CE of 1226 (screening) and 1249 kg CO_2-eq/m^2 (simplified), resulting in a 1.9% difference. In strategy 3, total CE were 1214 (screening) and 1242 kg CO_2-eq/m^2 (simplified), with a 2.3% difference. Strategy 4 resulted in CE of 794 (screening) and 835 kg CO_2-eq/m^2 (simplified), with a 4.9% difference. Overall, the differences between the screening and simplified LCA across all scenarios ranged from 1.9% to 4.9%.

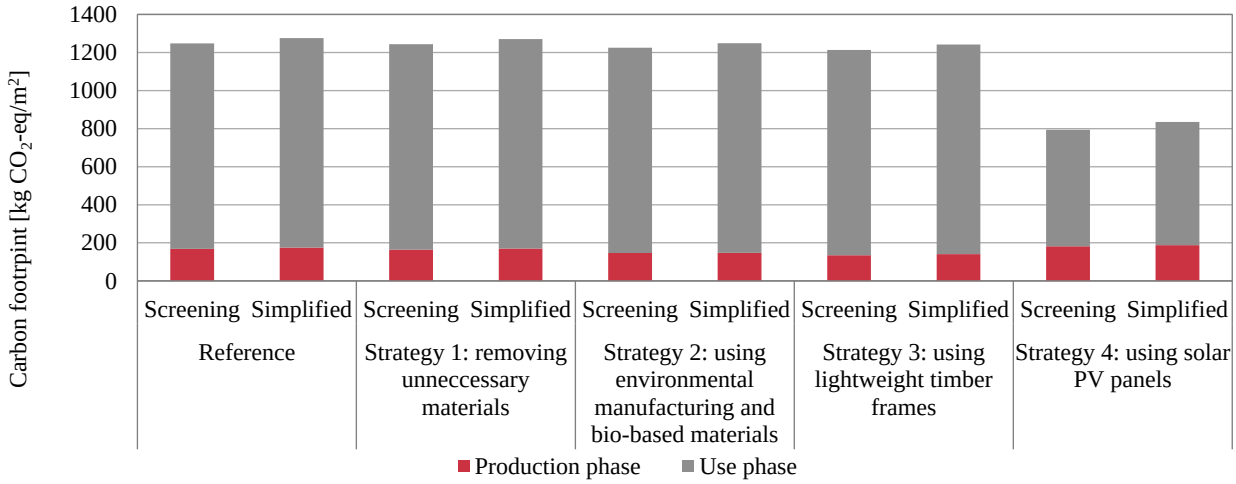

Figure 3. Carbon emission results comparison based on all the scenarios by two types of LCA.

Using screening LCA, the results of strategy 1, strategy 2, strategy 3, and strategy 4 accounted for 0.35%, 1.79%, 2.75% and 36.39% reduction in CE compared to the reference, respectively. Using simplified LCA, these scenarios accounted for 0.39%, 2.13%, 2.69%, and 34.57% reduction in CE compared to the reference, respectively. Thus, there is about 1% to 2% difference between CE reduction percentage results from the screening and simplified LCA of the reference and studied scenarios comparison. Strategy 4 generated a significantly greater reduction in CE than the other strategies.

Fig. 4 presents the overall CE comparison of the refence and combined scenarios using the screening and simplified LCA methodologies. The combination of four strategies demonstrates a significant reduction in total life cycle CE, approximately 42% of the reference building's CE. The combined strategy showed a total CE of 722 and 749 kg CO_2-eq/m^2 for the screening and simplified LCA, respectively, with a 3.6% difference. The combined strategy generates overall 42.13% and 41.67% less CE compared to the reference scenario, resulted from screening and simplified LCA, respectively.

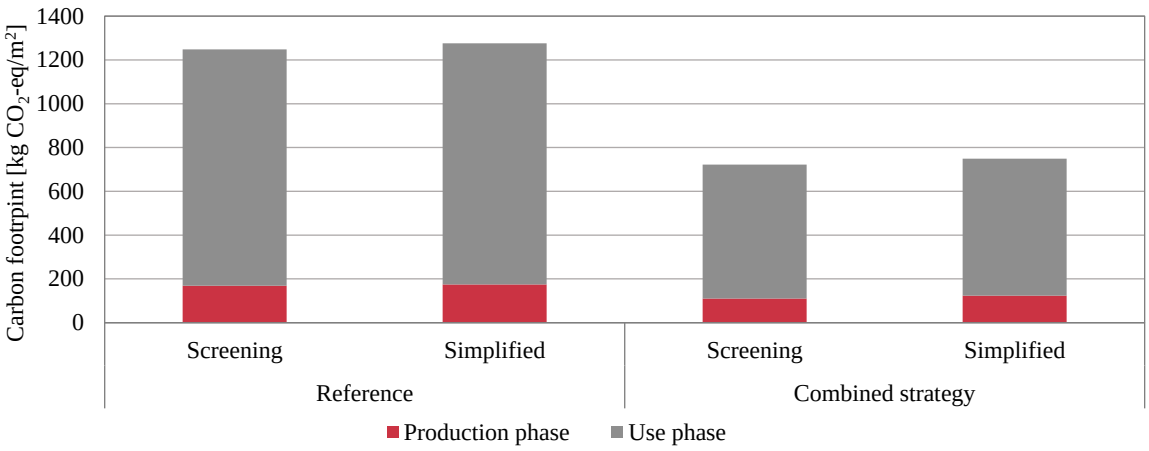

Figure 4. Carbon emission results comparison based on the reference and combined strategy.

4. DISCUSSION

The studied townhouse in Cambodia generates the highest CE during the use phase which is similar to other residential building case studies in Southeast Asia (Abd Rashid et al., 2017; Le et al., 2021) and in other developing countries (Morsi et al., 2020). Strategy 4 implementing solar PV panels is a particularly relevant solution for buildings in Southeast Asia, as there is significant potential for renewable solar energy resources in this region (Lai et al., 2023). Incorporating a broader range of energy conservation measures in future research, such as building envelope improvements, energy-efficient electrical appliances, behavioural controls, and advanced technologies, could provide valuable insights. In terms of production phase, the scenarios of removing unnecessary materials and using more environmental manufacturing and biogenic materials show a significant reduction of CE and reflect the needed effort to select more sustainable materials and minimize materials consumption to achieve sustainable building in Cambodia (Durdyev et al., 2018). However, the main drivers of the significantly reduced CE for the combined strategy are primarily related to use phase, followed by the production phase.

This study compares the CE result of the reference and combined strategy to results from the literature review on building LCA in Southeast Asia and in Egypt, another developing country, by phases of life cycle included in the LCA and its entire lifespan, as shown in Fig. 5. The CE of these cases: Morsi et al. (2020), Le et al. (2021), and Abd Rashid et al. (2017) varied at 1062, 1335, and 3327 kg CO_2-eq/m^2, respectively. The reference result of this study calculated by the simplified LCA is 1276 kg CO_2-eq/m^2, which is comparable to the case of Le et al. (2021) in Vietnam, while the other cases produced a lower and higher emission. However, the second design scenario using greener materials in the study of Le et al. (2021) produced 834 kg CO_2-eq/m^2 of CE based on

production and use phase, which is a higher CE reduction than the combination of the first 3 strategies related to greener materials in this study, but is a lower CE reduction than the combined strategy of this study considering greener materials and PV panels, which produces 749 kg CO_2-eq/m^2. The different CE results of all scenarios from the screening and simplified LCA studies vary minorly in a range from 1.9% to 4.9%, representing a slight difference. With these percentage values, the results of a screening LCA are reliable and results from these two types of LCA simplification are comparable.

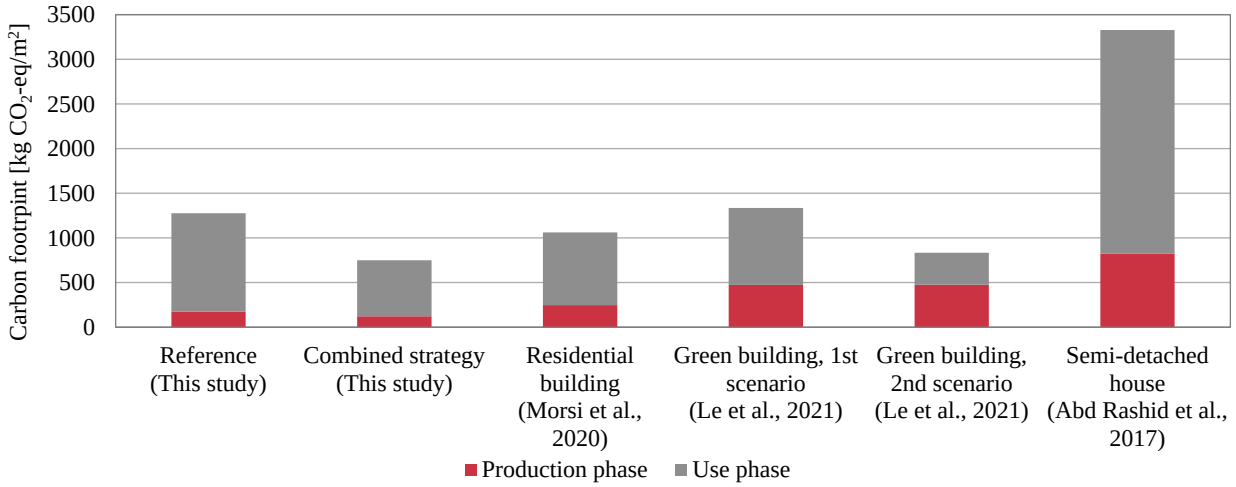

Figure 5. Carbon emission results comparison of this case study in Cambodia with other LCA studies.

The limitations of this study are related to assumptions made regarding the materials database, system boundaries, and the assessment of only a single impact category. It would be valuable to test the results obtained using the same regional database or other LCA software for comparison. Moreover, mandatory modules for the end of life phase were not included due to the lack of data on all activities and energy consumption during the building's demolition. The end of life phase of buildings is becoming critical in circular economy policies aimed at extending building service life and promoting component reuse or recycling (Giorgi et al. 2018). While using a single impact indicator may be sufficient for a specific study, it is not recommended for the holistic optimization of building designs, as it may result in suboptimal solutions (Hollberg, 2016).

5. CONCLUSION

The average difference between results of the screening and simplified LCA studies is 2.8% according to the results comparison from 6 different scenarios. All studied scenarios show a different reduction value of CE. Strategy 3 using lightweight timber frames walls in place of masonry walls presents the highest CE reduction during the production phase with approximately 20% of CE reduction during the building's production phase, while strategy 4 presents about 36% CE reduction in terms of overall life cycle compared to the reference. The combined strategy allows a significant reduction of 42% throughout its life cycle compared to the existing house. The results of this study demonstrate the potential of integrating the life cycle perspective into green buildings design in Cambodia and highlight the best strategies that should be used for future renovation and design of new residential buildings. Furthermore, this study proves that a screening LCA is a useful tool to pre-size the GHG emissions produced by a building and test different

decarbonization design options during the building design phase. However, the future study should study several environmental impacts to check the variability and accuracy of the screening LCA results concerning the total building environmental footprint compared to those of a simplified LCA.

ACKNOWLEDGEMENTS

The authors would like to thank the building owner who allowed and contributed to the building data collection process. We extend our thanks and appreciation to ARES – COMBOdIA project for funding and supporting this research. This research is carried out by three research laboratories: LEMA & LUCiD – ULiège and RIC – ITC.

The study of the impact of different land development on the street-block thermal environment in the Asia medium-sized city： A case study in tropical city, Taiwan

Jou-Man Huang [1]

[1]*Department of Landscape Architecture, National Chiayi University, Taiwan 60004; jouman@mail.ncyu.edu.com*

SUMMARY
The urban climate has seriously deteriorated with population urbanization and global climate change. The most obvious impact is the Urban Heat Island effect (UHI). In Taiwan, it was even found that in the tropical, medium-sized city of Chiayi, UHI intensity was comparable to that in large cities (4.1°C) in 2018. Therefore, this study selected Chiayi City as the object, using the CFD tool - ENVI-met to simulate land-use development types on the impacts of the thermal environment and comfort. As a result, we obtained three important conclusions：(1) The existing undeveloped environment (forest land) had a better thermal environment of 8~10°C cooler than the street in air temperature and PET. (2) Regardless of the type of development, the overall thermal environment of the block (air temperature, MRT, PET) deteriorates, with parking lot development being the most serious. (3) This research shows the importance of establishing urban development control regulations.

Keywords: urban heat island (UHI), ENVI-met, thermal environment, land-use.

1. INTRODUCTION

The urban climate has seriously deteriorated with population urbanization and global climate change (Oke, 1987; Akbari et al.,1992; Brown et al., 1995; Givoni, 1997; Kim et al.,2021). The most obvious impact is the Urban Heat Island effect (UHI). In Taiwan, a study of the Taipei area in 1999 found that heat island intensity was 1~2 °C (Lin et al., 1999) higher than that of the Tokyo area in Japan, a high-latitude country (Ministry of the Environment, Japan, 2000). In the summer of 2012, Taipei also experienced high temperatures above 38°C for three days (https://codis.cwa.gov.tw/StationData). In 2018, it was even found that in the tropical region, a medium-sized city-Chiayi City, its UHI intensity was comparable to that in large cities (4.1℃) (Huang et al., 2020). Hence, these indicated that the deterioration of the thermal environment in Taiwan cities is one of the urgent issues. Past studies on land development and thermal environment have mostly focused on the discussion of land use or land cover (LULC) (Patel et al., 2024) , and have mainly explored the differences in thermal environment based on the current status of different land use or land cover (Shen et al., 2022; Salan et al., 2024). There has been little research that explored the land development process and responded to the regulatory controls on urban land development. In addition, the methods used by these research were mostly remote sensing image analysis (Salan et al., 2024). Even some studies that use CFD as a tool almost focused on the impacts caused by different green spaces, building configurations, and building forms (Sodoudi et al., 2018; Mansouri st al, 2025). Few studies discussed the land development process that occurs in cities. This process is an issue that each city will encounter at the source of urban development. However, due to the lack of scientific verification, urban governments have

forgotten that the urban environment, especially the climate and thermal environment, can be changed from the source. Therefore, this study selected tropical, medium-sized Chiayi City as the research object, using the CFD tool - ENVI-met to simulate land-use development types on the impacts of the thermal environment. It is hoped that this study could enable government agencies for urban land development management to realize the importance of source management and establish relevant regulations to mitigate the damage caused by human development.

2. MATERAL AND MOTHED

2.1. Research Area

Chiayi City has entered a rapid growth phase since 2016, due to the entry of a chain movie studio and shopping mall (January 2016) and the development of the Huzai Nei Redevelopment Area (193.49 ha) in December of the same year. It has attracted a large number of people from neighbouring counties and cities to travel back and forth or migrate. In addition to a significant increase in the number of vehicles on the main connecting roads, urban land has also begun to be rapidly developed due to this trend. As shown in Figure 1, according to the aerial photos of Chiayi City in 2014, 2018, and 2022, the undeveloped land in the city (Figure 1(a)) was mostly woodland or grassy wasteland; and after 2016, in response to the rapid development of the city, many lands were first developed into concrete parking lots (Figure 1(b)) to obtain greater economic benefits. Later, if there was enough capital or resells it to the developer, it will be developed into 4F townhouses (a common residential development form in secondary cities of Taiwan, Figure 1(c)) or buildings with more than 7 floors (mostly commercial development).

(a) Woodland or grassy wasteland (b) Converted to concrete parking lots (c) Converted to residential buildings

Figure 1. Example of land development changes in residential areas of Chiayi City (2014~2022)

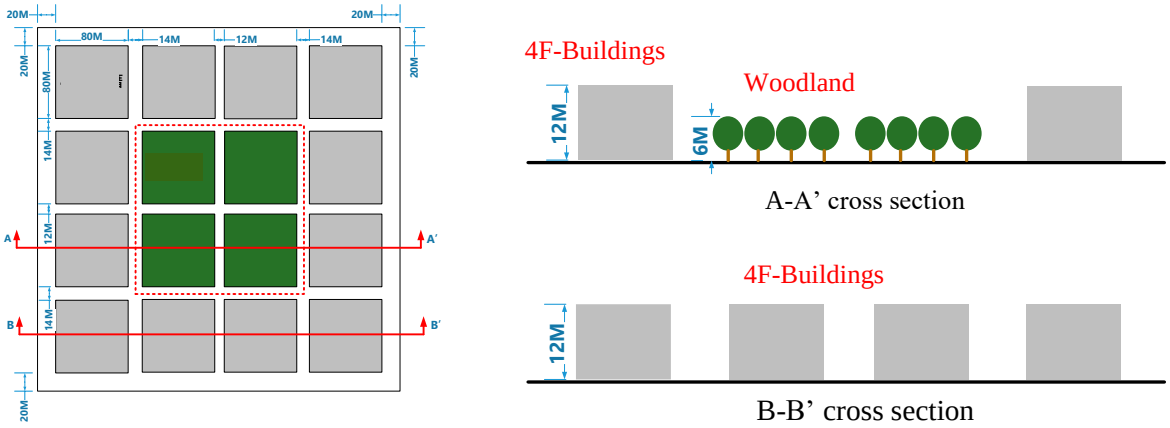
2.2. Setting of the Simulation Area

According to data from the Chiayi City Urban Planning Information Query System (https://landuse.chiayi.gov.tw/chyiurdweb/), the blocks in Chiayi City are generally divided by roads larger than 20m, the block size is approximately 400m×400m, the road width within the block is 12m, and the average size of individual urban planning land use zones is approximately 73m×73m. Therefore, the simulation area was set to 400m×400m. The surrounding streets were 20m wide, the size of the development site was 80m×80m, and the set to a 4F townhouse form. The streets in the area were evenly divided into 12~14m widths in accordance with the total grid size, which can be divided into 16 sites in total (Figure 2(a)). In addition, in order to understand the impact of different urban developments on the surrounding thermal environment during urban development, the four sites in central were set as the change areas of development type and development degree (the red dotted area in Figure 2(a)), and the original land type was woodland (including fruit tree or woodland) (Figure 2(b)). The 3D settings of development type and development ratio

configurations are shown in Table 1. The floor area ratio and building coverage ratio settings of 4F-Buildings (L2) and 7F-Buildings (L3) were set based on the Chiayi City Urban Planning Detailed Plan regulations in 2015.

2.3. Explored Variables and Research Design

This study mainly discussed the following two items: (1) Type of land development and (2) Degree of development. In terms of the development type, as mentioned above, this paper mainly discussed three common land development types in Chiayi City, a secondary city in Taiwan: (1) parking lots, (2) 4F-Buildings, and (3) 7F-Buildings. They represented the types of land development used for parking in response to urban transportation/economic needs, directly developed into 4-story buildings of residential (or mixed residential and commercial) use and developed into residential or commercial buildings (7-story buildings), respectively. In terms of development degree, in order to understand the impact of different development levels on the surrounding thermal environment, the development ratios were set 4 kinds: 25% (R1), 50% (R2), 75% (R3), and 100% (R4). The distribution of development locations is shown in Table 1.



(a) Floor plan (----Land-use/Land development type change area)

(b) Cross section

Figure 2. Basic spatial model settings of the simulation area

2.4. Simulation Scenarios and Space Setting

According to the setting in explored variables and research design of Section 2.3, there were 13 simulation schemes as shown in Figure 3. Among them, B0 represents the current situation before development, and the three development types were further divided into four development ratios, resulting in a total of 12 development scenarios. The detailed space setting of three development types is shown in Table 1.

3. RESULT

3.1. Undeveloped situation (B0)

The overall thermal environment of the block before development had a minimum air temperature of 35.04℃ in the woodland area, and a maximum air temperature of 42.78℃ almost distributed on streets parallel to the wind direction without any building shade. The overall average air temperature of the block was 38.75℃. Regarding MRT (Mean Radiant Temperature), the highest was 75.64℃ in the road area, followed by the east side of the building, which can drop to about 55℃, and the lowest was 32.68℃ in the undeveloped area. The overall average MRT of the block is 60.81℃, which was a very hot radiation environment. In terms of comfort index, PET, the lowest value was 36.46℃ in the woodland area, which

was a hot degree with a cold or hot feeling; the highest value was 52.23℃ in the street area on the west sides of the building, and the street area was almost 48.40℃, which was a very hot degree with a cold or hot feeling. The overall average PET of the block was 46.65℃, which was very hot.

Table 1. Space setting list on the type and ratio of development

Items	Parking lots(L1)	4F-Buildings (L2)*[1]	7F-Buildings (L3)*[2]
Development Type (80m×80m Site)	Concrete Pavement	4F-Buildings (60%) Space (40%)	7F-Buildings (50%) Space (50%)
Ratio and Arrangement*[3]	25% (R1)	50% (R2)	75% (R3) 100% (R4)

*1、2：According to the regulation of Chiayi City Urban Planning Detailed Plan in 2015, the building coverage ratio and the floor area ratio of Residential-Use 3 are 60% and 240%, respectively, and Commercial-Use 2 are 70% and 350%.
*3：The red area is presented as developed, and the green area is presented as undeveloped.

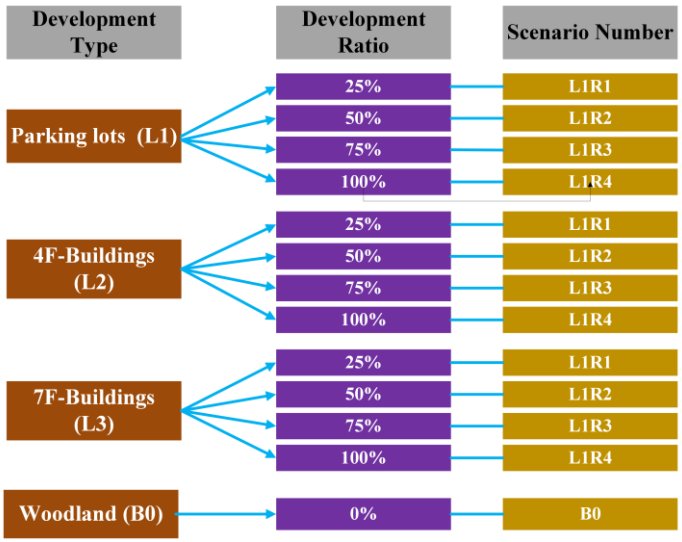


Figure 3. Simulation scenarios

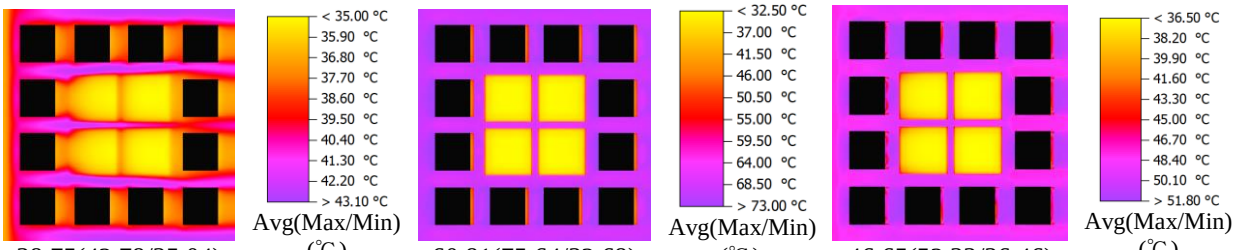

38.75(42.78/35.04) (a) AT
60.81(75.64/32.68) (b) MRT
46.65(52.33/36.46) (c) PET

Figure 4. The simulation results of the thermal environment in an undeveloped scenario (B0).

3.2. Comparison of air temperature (AT) between each scheme and the undeveloped scheme

As shown in Figure 5, in the parking lot development type (L1), as the development ratio increased, the average AT of the block increased, and the increase rate also increased equal times with the development ratio. For example, when the development ratio was 25%, it was 0.46℃, and when the development ratio became 75% (3 times), it also became 3 times to 1.37℃. The maximum warming scheme was 1.83℃ of 100% development. At the same time, when there were two continuous areas developed in parallel wind directions (L1R2~L1R4), the maximum AT increased by about 1.6~1.7℃. There was a similar trend in the 4F-residential development type (L2), and the increase also increased equal times with the development rate. The maximum warming scenario was 0.97℃ of 100% development, which was only about 1/2 of L1. At the same time, when there were two consecutive areas developed in parallel wind direction, the maximum AT increased by about 0.5~0.6℃, which was 1/3 of L1. The 7F-buildings (L3) development type also had the same trend as the above two types. The maximum hot scheme was 0.92℃ of 100% development, close to the L2 increasing value. At the same time, when there were two continuous areas developed in parallel wind directions, the maximum AT increased by about 0.9~1.1℃, which was 2/3 of L1. If we focus on the changes in the core area, we can find that whether it was developed into a parking lot, 4F-buildings or 7F-buildings, the average AT increasing in the core area was about twice that of the overall block.

3.3. Comparison of MRT between each scheme and the undeveloped scheme

As shown in Figure 6, in the parking lot development type (L1), the MRT increased rapidly by about 38℃ (L1R1) with the development. At the same time, the larger the development ratio, the larger the area where the MRT increases in the block, resulting in the average MRT of the block increasing to a maximum of 8.75℃. If we focus on the core development area, MRT increased to as much as 27.19℃. In the 4F-residential development type (L2), there was also a trend of increasing on average MRT of the block with the increase of development rate, but the increase was smaller than that of L1, about 1/2 of that. It was worth noting that when there were two continuous areas developed, there was a small MRT lowering area on the east side of the buildings in the development zone, which was about 2℃ lower (the blue area of L2R2~L2R4 in Figure 7). The development type of 7F-buildings (L3) also showed the same trend as the L2 type. The increase was also about 1/2 of L1 but slightly increased by about 0.2~0.4℃ compared to L2. If we focus on the changes in the core area, we can find that whether it was developed into any of the three types, the average MRT increase in the core area was about 3 times that of the overall block. Notably, the L2R4 and L3R4 areas even had increased by as much as 4.5 times.

3.4. Comparison of PET between each scheme and the undeveloped scheme

As shown in Figure 7, in the parking lot development type (L1), as the development ratio increased, the overall comfort index, PET, of the block increased, and the increase rate also increased equal times with the development ratio, the maximum increase was 2.84℃ of 100% development. In the 4F-residential development type (L2), there was also a trend of average PET increase with the development ratio increased, and the increase rate also increased equal times with the development rate. The maximum increase was 1.52℃ of 100% development, which is only about 1/2 of L1. The development type of 7F-buildings (L3) also showed the same trend as the other two types. The maximum warming scheme was 1.58℃ of 100% development, close to the increased value of L2. If we focus on the changes in the core areas, we can find that whether it was developed into

any of the three types, the average PET increase in the core area was about 3 times that of the overall block. Notably, the L2R4 and L3R4 even had increased by as much as 4 times.

4. CONCLUSION

As a result, we obtained the following important conclusions of five：

- The undeveloped area (woodland) had a better thermal environment, compared with the street AT of 42.78°C, it was reduced by about 8°C to 35.04°C. PET was also reduced by about 12°C to 36.46°C from 48.40°C of the street.
- Regardless of the development type, the block's overall thermal environment (AT, MRT, PET) all deteriorated.
- Among the three types of land development, the parking-lot development type had the most serious impact, with the deterioration of AT, MRT, and PET being twice that of the 4F-buildings and 7F-buildings development types.
- In the core blocks of the development area, no matter which development method was used, it all caused a more serious deterioration than the thermal environment of the overall block, with the deterioration by up to 2 times in AT and up to 3~4.5 times in MRT and PET.
- It is obvious that the undeveloped environment (woodland) had a better thermal environment. Any development method will cause serious deterioration of the thermal environment. Therefore, establishing relevant land development control regulations to prevent is a solution to improve the urban thermal environment.

ABSTRACT

In response to the climate change crisis, building-integrated photovoltaics (BIPV) has proven to be a promising technology for harnessing renewable solar energy to reduce buildings' operational carbon emissions. As widely reported, the overheating issue of BIPV systems (e.g., PV surface temperatures reaching 50-60°C), caused by the hot weather and abundant solar radiation, can significantly reduce their electrical power generation efficiency. Thus, it is important to predict and manage PV surface temperatures to enhance the electrical generation efficiency of BIPV. Using on-site data of PV systems, such as outer/inner surface temperatures of PV panel, dry-bulb air temperature, and wind speed, to train statistical models for predicting PV surface temperature is a promising approach. This work used on-site data to train grey-box models to characterize the thermal dynamics of PV panels, as grey-box modeling combines the strengths of white- and black-box models. It allows predictions with a good balance of physical interpretation and predictive accuracy, using limited on-site data. Based on a case study of a naturally ventilated BIPV curtain wall under real climate conditions, installed on a test building in Leuven, Belgium, this work initially demonstrated that the proposed grey-box models can effectively characterize and predict the thermal dynamics of BIPV system. When applied to a new test dataset, the trained grey-box model predicts the PV panel temperature closely following the measured profile, with prediction errors ranging from –3°C to +2°C under daily PV panel temperature variations between 10°C and 70°C. This study only explored a one-state grey-box model; future work could investigate two- or multi-state grey-box models for a more precise characterization of the BIPV thermal dynamics.

Keywords: Building-integrated photovoltaics (BIPV), solar radiation, grey-box model, in-situ data, statistical modeling

INTRODUCTION

The building operational energy accounts for 30% of global final energy consumption and 26% of global energy-related carbon dioxide emissions [1]. In addition to minimizing energy consumption through enhanced building energy efficiency, enhancing the share of solar renewable energy is essential for mitigating global greenhouse gas (GHG) emissions. Building-integrated photovoltaics (BIPV) have proven to be a promising technology for harnessing renewable (solar) energy, reducing building operational carbon emissions, by up to 50% in a case reported in [2]. Among the four categories of building-integrated photovoltaic (BIPV) systems, PV-wall, PV-roof, PV-window, and

PV-shading [3], the PV-roof product remains the most widely implemented option. However, limited rooftop space may be insufficient to meet a building's energy demands fully. Therefore, PV walls are attracting increasing interest, as building façades (i.e., exterior walls) typically have a larger surface area than rooftops, offering greater potential for electrical energy generation. In addition, the operating temperature of photovoltaic (PV) modules significantly impacts their performance and electrical power generation efficiency [4]. For instance, the electrical power production efficiency of crystalline silicon PV cells decreases by approximately 0.5% for every 1°C rise in PV cell temperature [5]. Currently, the three main types of modeling approaches, are white-box, black-box, and grey-box modeling [6], or physics-based, data-driven, and hybrid models [4]. Most existing studies predominantly rely on either white-box models (e.g., simulation tools) or black-box models (e.g., artificial neural networks). However, white-box models require extensive input data [7], whereas black-box models lack the physical interpretability of the parameters involved in the model, making them more applicable to power generation forecasting [8]. The grey-box model (also known as a hybrid model) integrates the advantages of both approaches, leveraging limited on-site data to balance predictive accuracy and physical interpretability. Therefore, this project aims to develop a grey-box model for forecasting BIPV performance, with an emphasis on modeling and predicting PV module operating temperature and output electrical power generation. The grey-box model proposed in this study combines experimental data with theoretical insights into the underlying physical processes, yielding a simple yet accurate model with physical interpretations of the parameters. The experimental data is collected from measurements of a real-world BIPV application, specifically a curtain wall system integrated into the façade of a test building located in Leuven, Belgium.

CASE STUDY

2.1 BIPV Curtain Wall in Vliet test building

A testbed has been set up on a BIPV curtain wall installed in the Vliet test building (50.88°N, 4.7°E) [9], located in Leuven, Belgium. This full-size BIPV curtain wall, developed by KU Leuven/EnergyVille [10], is positioned at the far left of the BIPV façade of the Vliet test building, as shown in **Figure 1**.

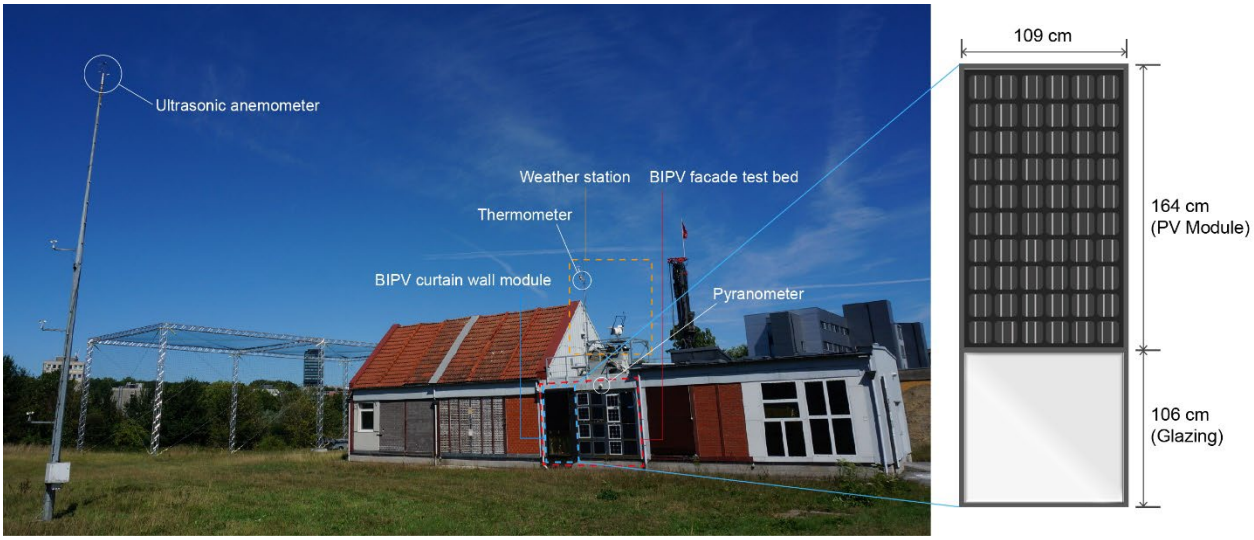

Figure 1. Vliet test building in Leuven. Belgium, with BIPV curtain wall testbed.

The curtain wall's upper section incorporates the PV module, while the bottom section consists of a triple-glazed argon window to allow sunlight into the building (**Figure 1**). The PV module consists of 60 monocrystalline silicon solar cells encapsulated in a transparent EVA layer on the front and a black EVA layer on the back. Table 1 summarizes the characteristics of the PV module used in the BIPV curtain wall.

Table 1. Main characteristics of PV modules used in the curtain wall.

Peak power (P^{STC})	244 W_p
PV module area (A_{PV})	1.09×1.64 m2
Efficiency at standard test conditions η^{STC}	13.6 %
Power temperature coefficient (μ)	0.42 %/K

2.2 PV Curtain Wall Temperature and Weather Data Monitoring

The curtain wall features four ventilation apertures on both the top and bottom sections of its sides, shown in **Figure 2**. Each aperture, with a diameter of 1 cm, allows a limited amount of ambient air to circulate within the air cavity behind the PV module. The upper section of the PV curtain consists of three layers, from exterior to interior: the PV module (Layer 1), followed by a 0.07 m air cavity, a 0.15 m mineral wool insulation layer (Layer 2), and finally, a plywood panel (Layer 3). Each of these layers is equipped with 12 type-T surface contact thermocouples, which record temperature data every second. **Figure 2** illustrates the thermocouple locations, marked as yellow dots, with the thermocouples attached to the back side of the PV module in Layer 1 and the front sides of Layers 2 and 3. In addition to temperature data, global solar irradiance, ambient dry-bulb air temperature, wind speed, and wind direction are also collected. Vertical global solar irradiance on the BIPV facade is measured every 10 seconds by a pyranometer positioned on the facade (**Figure 1**).

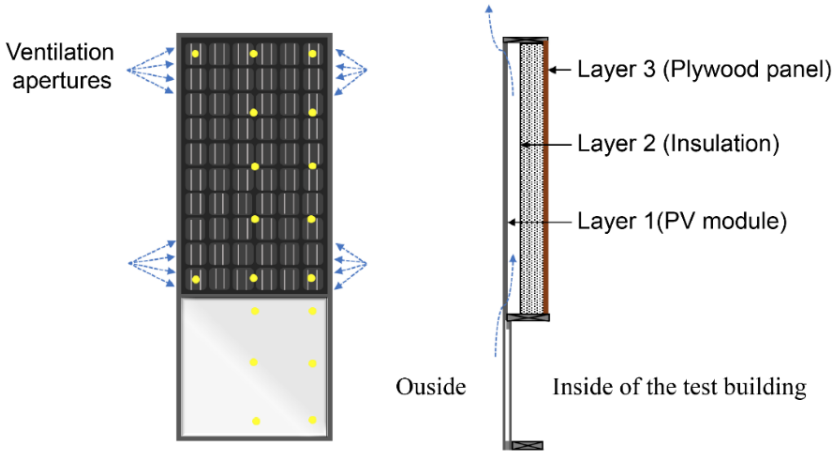

Figure 2. Curtain wall ventilation apertures and placement of thermocouples (left), section with layers (right)

Ambient air temperature is recorded every minute by a thermometer in the weather station on the rooftop of the Vliet test building (**Figure 1**). The ultrasonic anemometer located 10 meters above ground next to the test building, shown in **Figure 1**, records both wind speed and direction every 5 minutes. The readers refer to Ref. for a more detailed description of the measurement campaign. The measurements were performed over a one-year period (2019–2020), and the raw data were pre-processed and averaged into 10-minute time intervals. Moreover, two datasets are constructed as training and test datasets, referred to as Dataset 1 and Dataset 2, respectively. Their key characteristics

are summarized in Table 2. Dataset 1 is used for grey-box model training and identification, while Dataset 2 is used to validate the PV panel temperature prediction capability of the grey-box model trained and selected based on Dataset 1.

Table 2. Two pre-constructed datasets used in this study and their key features.

No.	Role	Period	Length	Sky conditions	Wind speed	Wind direction
1	Training dataset	22-27 March	6 days	clear	0.1-6.5 m/s	Leeward
2	Test dataset	20-23 April	4 days	(near) clear	0.1-6.1 m/s	Mixed

GREY-BOX MODELING

3.1 Brief Introduction of Grey-box Modeling and forward selection

In brief, a grey-box model comprises two types of equations: system equation(s) and measurement equation(s). The system equation(s) are constructed based on physical knowledge. These models estimate system parameters by fitting the model to observed data using the maximum likelihood estimation (MLE) method. In this study, forward selection is employed to determine the appropriate model complexity, starting with the simplest one-state model and progressively increasing its complexity step by step. At each step, the performance is evaluated and compared based on the values of the Log-Likelihood, Akaike Information Criterion (AIC), and Bayesian Information Criterion (BIC). Readers are referred to [11] for more details on grey-box modeling and the application of forward selection. The grey-box modeling process is executed using the Continuous Time Stochastic Modeling package in R (CTSM-R).

3.2 Heat Transfer and Energy Balance of the PV Curtain Wall

To construct the system equation(s) of grey-box models for the PV Curtain Wall, **Figure 3** visualizes the different energy/heat flux flows based on a horizontally elongated cross-section of the PV curtain wall.

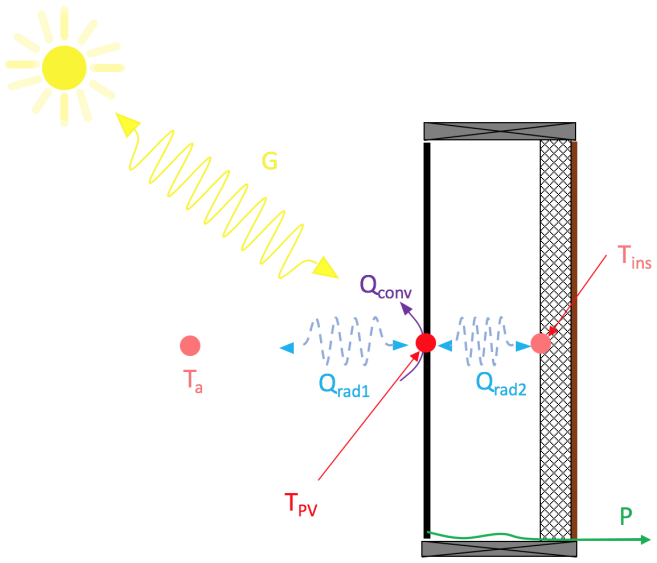

Figure 3. Energy balance and heat transfer diagram of the PV curtain wall.

3.3 Simplest Grey-box Model (T_{PV})

Based on the heat transfer and energy balance visualized in **Figure 3**, the simplest stochastic differential equation that characterizes the energy balance is Eq. (1). where C_{PV} is the heat capacity of the PV module and σ_1 an unknown model parameter characterizing the diffusion term, not to be confused with the Stefan-Boltzmann constant (σ). The observation equation is simply defined as Eq. (2). T_{PV} represents the average temperature of the solar panel, as a system state, determined by the enegy balance of the PV curtain wall. Irradiance on the PV panel (G; in W/m^2) is the system's only energy input and $(\tau\alpha)A_{PV}G$ represents the portion of solar irradiance absorbed by the PV curtain wall, where $\tau\alpha$ [-] is the absorption coefficient of solar irradiance, and A_{PV} (in m^2) is the area size of PV panel. P denotes the DC output power of the PV module.

$$C_{PV}dT_{PV} = \Big[(\tau\alpha)A_{PV}G - P - \sigma\varepsilon_{PV}A_{PV}(T_{PV}^4 - T_a^4) - \frac{\sigma A_{PV}}{1/\varepsilon_{PV}+1/\varepsilon_{ins}-1}(T_{PV}^4 - T_{ins}^4) - h_{c,e}A_{PV}(T_{PV} - T_a)\Big]dt + \sigma_1 d\omega_1 \quad (1)$$

$$T_{PV_m} = T_{PV} + e_1 \quad (2)$$

As shown in Figure 3, the radiative heat transfer from the front surface of the PV panel to the exterior is denoted as Q_{rad1} and is expressed as $\sigma\varepsilon_{PV}A_{PV}(T_{PV}^4 - T_a^4)$ in Eq. (1), under the assumption of considering the environment as a black body ($\varepsilon = 1$). ε_{PV} signifies the long-wave emissivity, set to 0.9 in this case for the EVA cover layer, and T_a referes to the temperature of the surrounding environment as perceived by the front surface of PV panel. Similarly, the radiative heat transfer from the back surface of the PV panel to the insulation layer is denoted as $Q_{rad2}\ [W]$ and estimated by Eq. (3) . It is simplified in Eq. (1) as $\frac{\sigma A_{PV}}{1/\varepsilon_{PV}+1/\varepsilon_{ins}-1}(T_{PV}^4 - T_{ins}^4)$. Specifically, the PV panel and insulation layer have the same area ($A_{PV} = A_{ins}$) and the view factor between the two surfaces is set to 1 ($F = 1$) since the distance separating them (0.07 m) is two orders of magnitude smaller than the length of the surface sides (1.09 m).

$$Q_{rad2} = \frac{\sigma\,(T_{PV}^4 - T_{ins}^4)}{\frac{1-\varepsilon_{PV}}{\varepsilon_{PV}A_{PV}} + \frac{1}{A_{PV}F} + \frac{1-\varepsilon_{ins}}{\varepsilon_{ins}A_{ins}}} \quad (3)$$

The convection-based heat exchange between the PV panel and the ambient air is expressed as $h_{c,e}A_{PV}(T_{PV} - T_a)$ in Eq. (1), where $h_{c,e}$ [W/m^{2}K] is the convective heat transfer coefficient between the PV panel and ambient air.

Building on the simplest T_{PV} model, further refinements were made to increase the complexity of the grey-box model candidates and better capture the actual thermal performance of the PV system. This study explored three approaches: (1) incorporating the incidence angle modifier (IAM); (2) accounting for the effect of wind; and 3) separating the exterior environment into sky and ground parts when modeling radiative heat transfer from between the front surface of the PV panel and the exterior environment. The three approaches lead to three more grey-box model candidates.

3.4 Inclusion of Incidence Angle Modifier (IAM) in T_{PV} Model ($T_{PV}IAM$)

The incidence angle of solar irradiance (i.e., the angle between the normal to the surface and the incoming irradiance) significantly impacts the absorption ratio of solar irradiance, as the amount of radiation reflected from the PV panel increases with the incidence angle. This effect can be

incorporated by using the incidence angle modifier (IAM), which is defined as the ratio of the irradiance absorbed by the cell at incidence angle θ_s to the irradiance absorbed by the cell at normal incidence [12], as Eq. (4), where $(\tau\alpha)_{\theta_s}$ and $(\tau\alpha)_n$ represent the fraction of solar irradiance absorbed by the cells at incidence angle θ_s and normal incidence representatively.

$$IAM = \frac{(\tau\alpha)_{\theta_s}}{(\tau\alpha)_n} \tag{4}$$

3.5 Inclusion of wind effect in T_{PV} Model ($T_{PV}W$)

Instead of treating $h_{c,e}$ as a constant value, based on the T_{PV} model, the $T_{PV}W$ further consider the impact of wind on the convective heat transfer coefficient $h_{c,e}$ via Eq. (5).

$$h_{c,e} = C_1(W)^{C_2} \tag{4}$$

Where *W* denotes the wind speed measured by ultrasonic anemometer located 10 meters above ground , as shown in **Figure 1** and C_1 and C_2 are treated as unknown parameters and will be estimated through data fitting.

3.6 Differentiation between sky and ground in T_{PV} Model ($T_{PV}Sky$)

As discussed, the T_{PV} model treats the exterior environment in aggregate, represented soley by the ambient air temperature T_a, and it models the radiative heat transfer from the front surface of the PV panel to the exterior (Q_{rad1}) as $\sigma\varepsilon_{PV}A_{PV}(T_{PV}^4 - T_a^4)$. The Q_{rad1} can be further refined by differentiating between radiation to the ground and to the sky separately in Eq. (5), leading to an expanded $T_{PV}Sky$ model.

$$Q_{rad1} = F_{gnd}\left(T_{PV}^4 - T_{gnd}^4\right) + F_{sky}\left(T_{PV}^4 - T_{sky}^4\right) \tag{5}$$

The view factors of the PV panel to the ground and sky denoted as F_{gnd} and F_{sky} respectively, are given by Eqs. (6-7), and β represents the inclination angle of the PV module (i.e., the angle between the PV panel and the horizontal), which is 90º in this case. In addition, the ground temperature (T_{gnd}) is assumed to be equal to the ambient air temperature (T_a), while the sky tempeature is treated as an unknown parameter, similar to C_1 and C_2.

$$F_{gnd} = (1 - cos\ (\beta))/2 \tag{6}$$
$$F_{sky} = (1 + cos\ (\beta))/2 \tag{7}$$

RESULTS

4.1 Forward selection results

As discussed in Section 3.1, forward selection is used to identify the most suitable single-state model, starting from the simplest T_{PV} model and step-by-step increasing its complexity by incorporating one or more of the approaches outlined in Sections 3.4–3.6. In brief, forward selection requires that each successful extension of the grey-box model results in an increased log-likelihood value and reduced AIC and BIC values, continuing until no further extension yields a significantly better fit (i.e., no

substantial increase in log-likelihood). The model selection process is visualized in **Figure 4**. The $T_{PV}WSky$ model is identified as the best-fitting model for Dataset 1 in this study. It builds upon the T_{PV} model but incorporates the effect of wind and separates the environmental impacts into sky and ground components. The $T_{PV}WSky$ incroporates Eqs. (4-5) to extend Eq. (1) as Eq. (8). The parameters C_{PV}, T_{sky}, C_1, C_2 and σ_1 are treated as unknowns to be estimated through data fitting. Specifically, the $T_{PV}WSky$ is composed of Eq. (8) and Eq. (2).

$$C_{PV}dT_{PV} = \Big[(\tau\alpha)A_{PV}G - P - \sigma\varepsilon_{PV}A_{PV}(T_{PV}^4 - T_a^4) - \frac{\sigma A_{PV}}{1/\varepsilon_{PV}+1/\varepsilon_{ins}-1}(T_{PV}^4 - T_{ins}^4) - h_{c,e}A_{PV}(T_{PV} - T_a)\Big]dt + \sigma_1 d\omega_1 \quad (8)$$

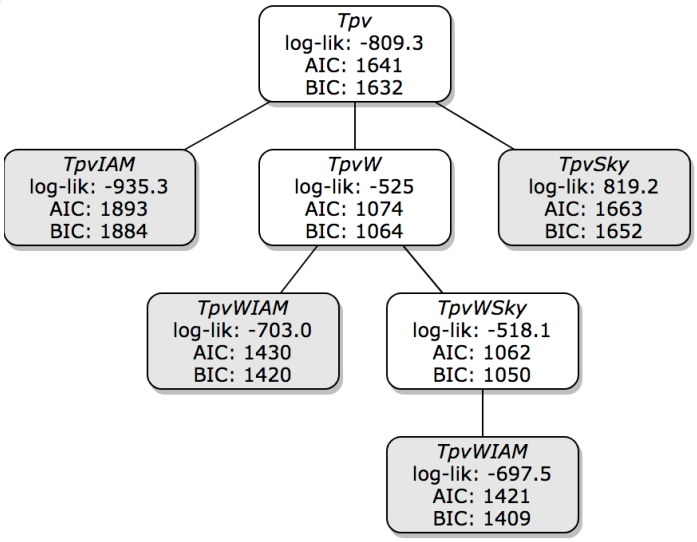

Figure 4. Summary model selection process for the first-order model

4.2 Model prediction performance using test dataset

To validate the general T_{PV} prediction capability of the trained $T_{PV}WSky$ model (based on the training dataset, Dataset 1), the model is applied to predict T_{PV} dynamics using weather data from the test dataset (Dataset 2). The input data for the $T_{PV}WSky$ model include solar irradiance, wind speed, and ambient air temperature, covering the period from April 20 to April 23, 2020. **Figure 5** shows promising T_{PV} prediction results, demonstrating that the model can reasonably predict and capture the key daily dynamics of PV panel temperature. As shown in Figure 5, the simulated temperatures follow the measured profile closely, with prediction errors ranging from –3°C to +2°C, which is acceptable in practice, considering the peak PV temperature exceeds 50°C, even approaching 70°C during this specific four-day period.

DISCUSSION AND CONCLUSION

This pilot study initially revealed the promising performance of grey-box models in predicting PV surface temperature, which plays a crucial role in estimating electrical power generation. The proposed grey-box model, trained on one dataset, was able to predict PV panel temperature dynamics with acceptable accuracy on a new test dataset collected from the same PV system during a different period. The predicted PV panel temperatures closely followed the measured temperature profile, with prediction errors ranging from –3°C to +2°C, under daily variations between 10°C and 70°C. While

this study focused on a one-state grey-box model, future research could explore two- or multi-state models to achieve a more accurate representation of BIPV thermal behavior. Additionally, future work could extend the grey-box modeling approach to predict electrical power generation.

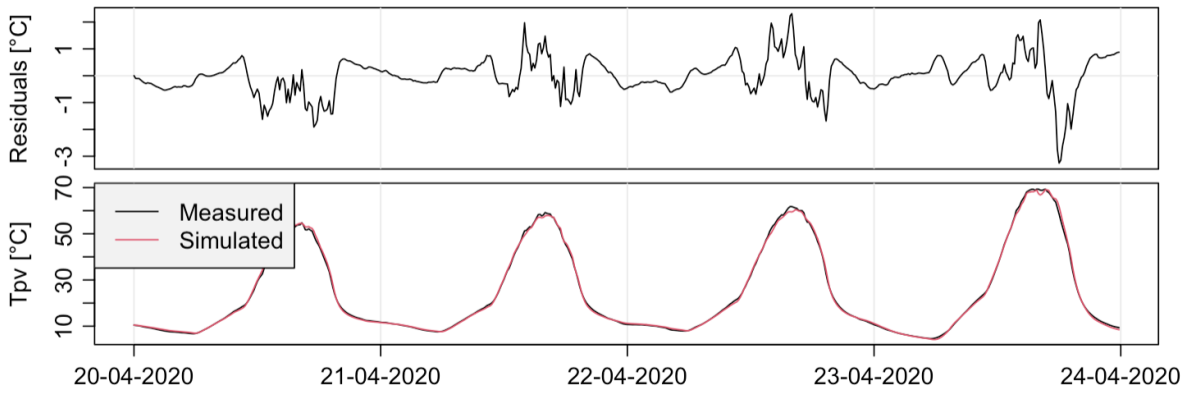

Figure 5. Prediction of PV panel tempeature (T_{PV}) with $T_{PV}WSky$ model for the test dataset (Dataset 2).

Data-driven modelling and automated optimization of multi-chiller sequencing

Qiwei Qin [1], Etienne Saloux [1]

[1]*CanmetENERGY, Natural Ressources Canada, Varennes, QC, Canada*

SUMMARY
Central cooling systems are commonly used in medium and large commercial buildings, but their energy-intensive nature necessitates efficient operation, particularly in multi-chiller sequencing. While research has focused on theoretical simulations and data-driven methods, practical deployment faces challenges such as limited sensors, computational constraints, and chiller performance degradation over time. This study proposes an automated, data-driven methodology for optimizing multi-chiller sequencing based on real measurements. Performance curves are derived using historical operational data and used in an optimization routine that identifies the most energy-efficient combination of chillers to operate. This optimal sequencing can then be integrated into existing control systems using simple control sequences, facilitating scalability and field deployment. This approach minimizes electricity use of the cooling system, including chillers, circulation pumps, and water tower fans. The method has been applied to two large buildings and results showed that electricity use was reduced by 9% and 15%. By dynamically adapting to load changes, it demonstrates the potential for sustainable, reliable, and automated building energy management.

Keywords: Multi chillers; cooling system; data-driven; energy efficiency; modelling; sequencing.

1. INTRODUCTION

Improving building controls could help reduce energy use by up to 30% with simple payback periods of around 2 years while cooling energy is projected to become predominant (Saloux et al., 2023). Central cooling systems are commonly used in medium and large commercial buildings, but their energy-intensive nature necessitates efficient operation (Liu et al., 2017). Optimal chiller sequencing can lower energy consumption of chiller while meeting building cooling load demand (Sun et al., 2009). Research has extensively focused on optimal chiller sequencing; for instance, based on theoretical simulations by using different optimization algorithms such as dynamic programming (Li et al., 2024), generic pattern search optimization algorithm (Faulkner et al., 2024) and Lagrangian method (Chang, 2004). However, challenges such as limited sensor availability, computational demands, and the inevitable performance degradation of chillers over time hinder widespread adoption. Data-driven models, which are based on sub-hourly data from building automation systems, provide an opportunity for improving existing building controls (Saloux and Zhang, 2023). These models could be used to derive data-driven rule-based controls, which are much easier to implement in existing building.

This study addresses these challenges by presenting an automated, data-driven methodology for optimizing multi-chiller sequencing based on real-world measurements. Performance curves are derived from historical operational data and are leveraged to identify the most energy-efficient combination of chillers. Furthermore, the proposed methodology not only minimizes the central cooling plant electricity use but also addresses the switching between chillers. The proposed

approach is applied to two commercial and institutional buildings and achieves significant energy efficiency improvements. By streamlining complex processes, this approach bridges the gap between theoretical methodologies and real-world applications, making optimal chiller sequencing more accessible and scalable for widespread adoption in buildings.

2. METHODS: AUTOMATED MULTI-CHILLER SEQUENCING OPTIMIZATION

A typical central chilled water system which is commonly used in medium to large commercial or institutional buildings is shown in Fig. 1 (*ASHRAE Handbook: HVAC Systems and Equipment*, 2008). To ensure redundancy and flexibility, multiple chillers are connected in parallel and a decoupler pipe is used to bypass the chiller when necessary. Primary pumps maintain constant refrigerant flow through the chillers, while variable-speed secondary pumps distribute chilled water throughout the building. In the condenser loop, constant-speed pumps reject heat via cooling towers or air condensers. The efficiency of chillers varies at cooling conditions and makes optimal sequencing critical. This study presents an automated approach for equipment mapping, data cleaning, performance modeling, and chiller sequencing. It also evaluates model accuracy and potential savings. These capabilities are integrated into a Python-based tool, under development.

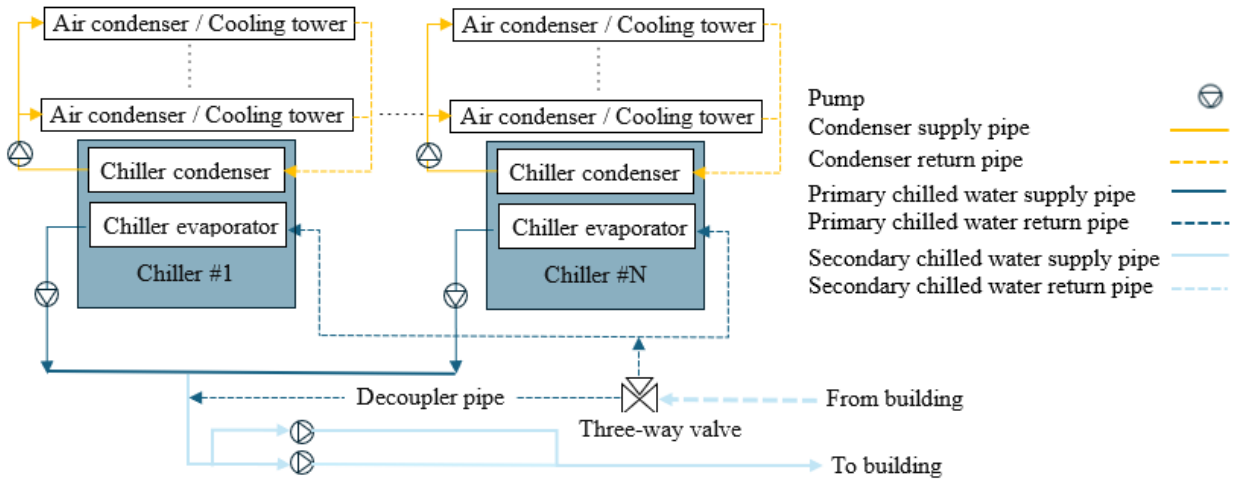

Figure 1. Schematic of a typical chilled water system, equipped with multiple chillers.

2.1 Equipment variable mapping and data cleaning

Users are required to provide basic plant information (e.g. number of chillers, nominal capacities) and sub-hourly operational data. This information is processed as follows:

1. *Data resampling*: Data is averaged at hourly intervals for deriving performance curve.
2. *Data filtering*: Cooling load is calculated using temperature difference and flow rate. To reduce noise and uncertainty, minimum threshold values below which the data is removed are used for temperature difference and flowrate, and for electric power. This threshold can be specified by the user or automatically calculated (5^{th} percentile for temperature difference and flowrate; 5% of nominal capacity for electric power).
3. *Chiller combination identification*: The operational status of each chiller (on/off) is automatically determined using electric power minimum threshold values, and combinations of chillers are identified using IDs. To remove transient operation for

deriving performance curves, for each point, the combination of chillers must have been in operation for a user-defined duration and must remain in operation for the same period. This period is set to 1 hour by default. To ensure sufficient data points, only combinations that have been in operation for a minimum number of hours are kept (default: 50 hours).

2.2 Data-driven part-load ratio performance curves

Chiller performance is primarily influenced by evaporator and condenser temperatures, as well as building cooling load. Including variables such as outdoor air temperature, humidity, or condenser inlet (air, water) temperature could improve model accuracy but may introduce practical constraints. Indeed, it may yield to more complex chiller sequencing strategies, reducing interpretability and making practical implementation more complex while possibly causing more chiller switches. Moreover, modelling might leverage more advanced black-box techniques, possibly causing overfitting while performance under extrapolation conditions might be more difficult to assess. To balance model accuracy and real-world applicability, this study adopts cooling load as the sole input variable – a commonly accepted simplification in many data-driven modeling efforts (Saloux and Zhang, 2023). While it may not capture all nuances of chiller performance under varying weather conditions, it allows for a scalable, low-cost, and practical solution facilitating implementation and large-scale adoption.

Two definitions of Coefficient of Performance (COP) are considered for determining the optimal chiller sequencing. COP_{ch} evaluates the energy consumption of the chillers only whereas COP_{sys} tackles the cooling system and accounts for chillers along with auxiliary equipment (pumps, fans):

$$COP_{ch}(t) = \frac{\dot{Q}_{cooling}}{\sum_i \dot{W}_{ch,i}} \quad \text{Eq.(1)}$$

$$COP_{sys}(t) = \frac{\dot{Q}_{cooling}}{\sum_i \dot{W}_{ch,i} + \sum_j \dot{W}_{pp,j} + \sum_k \dot{W}_{fan,k}} \quad \text{Eq.(2)}$$

where $\dot{W}_{ch,i}$ is the electric power of the i^{th} chiller in the considered combination. For the cooling system COP, $\dot{W}_{pp,j}$ is the electric power of the j^{th} pump and $\dot{W}_{fan,k}$ is the electric power of the k^{th} fan of cooling towers and air condensers. Therefore, the cooling system COP is calculated by considering all chillers and auxiliary equipment and is then filtered for each chiller combination. In theory, the equipment that is not related to a specific combination of chillers should be excluded from the calculations (e.g. the pump related to chiller #1 should not be in operation if chiller #1 is not in operation). However, in practice, it becomes cumbersome to automatically gather connection details between the different components from users and to identify the exact multi-chiller system configuration. Therefore, Eq. (2) is used and may potentially account for the operation of equipment not related to a specific chiller combination. Data-driven performance curves are determined by plotting chiller COP or cooling system COP as a function of building cooling load. Users can select linear, quadratic, or cubic models. Furthermore, for each combination, datasets are randomly divided into training (80%) and validation (20%). These models are evaluated and compared based on the coefficient of determination (R^2) and the coefficient of variation of the root mean square error (CV-RMSE). Models are automatically selected using a default metric as shown in Eq. (3), which balances model accuracy and complexity whereas users can also select the most appropriate model for each combination.

$$R^2_{adjust} = R^2 - \lambda p \quad \text{Eq.(3)}$$

where R^2 is the coefficient of determination and p is the number of parameters in the model (2 for linear model; 3 for quadratic; 4 for cubic). $\lambda > 0$ is a factor used to penalize model complexity; the penalty is set as 1.5% after trial and error.

2.3 Chiller sequencing strategy

The proposed chiller sequencing strategy optimizes cooling system energy efficiency using data-driven performance curves while minimizing equipment wear and tear:

1. *Curve fitting for each combination*: performance curves are derived for all possible chiller combinations using linear, quadratic or cubic models (Section 2.2). The combination of chillers in operation for particular loads is determined based on historical operational data. To avoid questionable values, a given combination cannot provide more cooling than the sum of 110% of the nominal capacity of each chiller. This additional 10% accounts for potentially favorable operating conditions. Similarly, a combination cannot provide less cooling than 15% of the nominal capacity of each chiller.
2. *Maximizing COP and minimizing chiller status changes*: the cooling load range is divided into 100 intervals. The strategy prioritizes energy efficiency, and the highest COP is identified for each interval; any combinations showing values higher than 97% of the highest COP are considered as optimum candidates. When multiple combinations are possible, the one with minimal chiller status changes (compared with the previous hour) is selected to enhance equipment stability.
3. *Deriving optimal control sequences*: The final output identifies threshold values indicating the switch from one combination to another. To avoid frequent switch around thresholds, a deadband of 5% is applied (e.g., a 100-kW threshold triggers a switch to a new combination at 105 kW if the cooling load increases and 95 kW if the cooling load decreases). This deadband represents the trade-off between chiller switch number and energy savings (a larger value may reduce the number of switches but also the COP).

While more complex approaches (e.g. controlling chillers, fans and pumps individually), chiller models (e.g. considering additional modelling techniques and/or variables such as temperatures) and optimization routines can be found in the literature, this method prioritizes simplicity, requires minimal data while ensuring practical adoption and scalability across multi-chiller systems.

2.4 Performance evaluation

The chiller sequencing strategy is evaluated based on cooling system electricity use, peak power, and energy costs, the number of chiller switches and the number of operating hours for each chiller. The building cooling load remains unchanged. COP models are used to estimate electricity use. For the reference case, chiller combinations were extracted from operational data.

3. CASE STUDY BUILDINGS

The approach was tested for two commercial buildings. The first building is a 36,000 m^2, 11-floor commercial building equipped with two air-cooled chillers connected to two air condensers and one water-cooled chiller connected to two wet cooling towers. The second building is a 33,000 m^2, 3-floor institutional building equipped with 5 water-cooled chillers and 5 wet-cooling towers. Both

buildings are located in the Montréal area, Canada. The data was available from Jun 1 to Aug 30, 2023 for building #1 and May 1 to Sep 13, 2021 for building #2. Electricity cost is assumed to be CAD 4.339 c/kWh. For building #1, all required measurements were obtained from the control system or electric power spot measurements. However, for building #2, chiller power was estimated from % RLA readings, while pump power was calculated from on/off status and nominal capacity, which is suitable for constant-speed pumps but not variable-speed ones. Nonetheless, variable speed pumps are in operation regardless of chiller combinations and might not affect the optimal sequencing. Therefore, supply pump powers are neglected for modelling chiller performance curve to avoid adding uncertainty.

4. RESULTS: MODEL ACCURACY AND ENERGY SAVINGS

This section discusses electricity use distribution, model accuracy and expected savings; results are presented side-by-side for both buildings to highlight differences between case studies.

4.1 Cooling system electricity use distribution

The cooling system electricity use distribution shown in Fig. 2 is a critical indicator of energy usage patterns and system efficiency. For both buildings, chillers account for the largest share (53-55%) of electricity use, which underscores the importance of optimizing the operation of chillers, but also auxiliary equipment, to maximize system efficiency. Moreover, significant differences are observed for auxiliary equipment electricity use, which can be explained by energy efficiency levels. Building #1 primarily relies on air-cooled towers, which are generally less efficient than cooling towers (15.3% vs. 8.1%); a similar observation can be made for condenser pumps (14.0% vs. 12.8%). For chilled water pumps, the contribution varies between 17.1% and 24.3% but energy use is overestimated for building #2 (variable speed pump on/off was used, see Section 3).

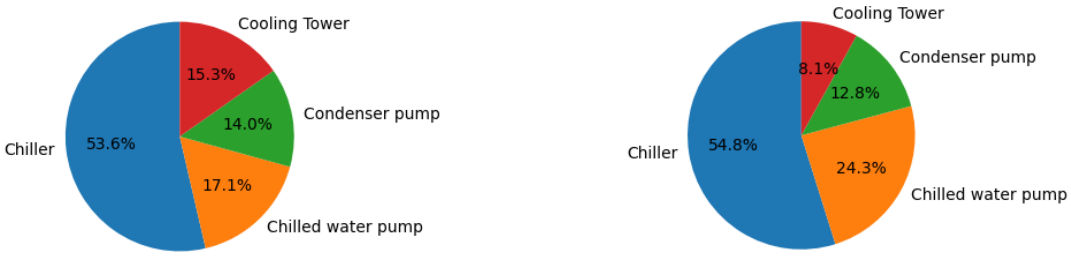

Figure 2. Cooling system electricity use distribution for building #1 (left) and #2 (right). Cooling towers account for air condensers and wet water towers; chilled water pump represents primary and secondary pumps.

4.2 Accuracy of performance curves

Fig. 3 shows performance curves for both buildings. With three chillers, 7 combinations are in theory possible for building #1, but only four have been in operation for more than 50 hours. Although identical, chillers #2 and #3 (air-cooled screw chillers) show slight differences in performance. Chiller #1 (water-cooled centrifugal chiller) is expected to be more efficient than #2-3 but real-world data indicate lower performance, revealing potential inefficiencies and the importance of empirical analysis. For building #2, with 5 chillers, only 18 chiller combinations were observed out of 31 possible ones, and just 10 showed a minimum operation of 50 hours, highlighting the impact of operational constraints or system limitations. Chillers #4-5 are smaller units for low loads, while chillers #1-3 are identical but chiller #3 demonstrates higher efficiency. Fig. 3 also complements Fig. 2 by emphasizing differences between chiller COP and system COP, especially at low loads where auxiliary equipment has a significant impact. Tables 1 and 2

summarize model accuracy metrics (R^2, CV-RMSE) for all chiller combinations. Models are considered calibrated when $R^2 > 75\%$ and CV-RMSE < 30%, although these thresholds are not necessarily suitable for data-driven models (Saloux, 2025). While CV-RMSE ranges between 4-19%, R^2 falls below 70% for 6 (system COP) and 10 (chiller COP) combinations, and can be as low as 2%, indicating low COP variations with cooling load.

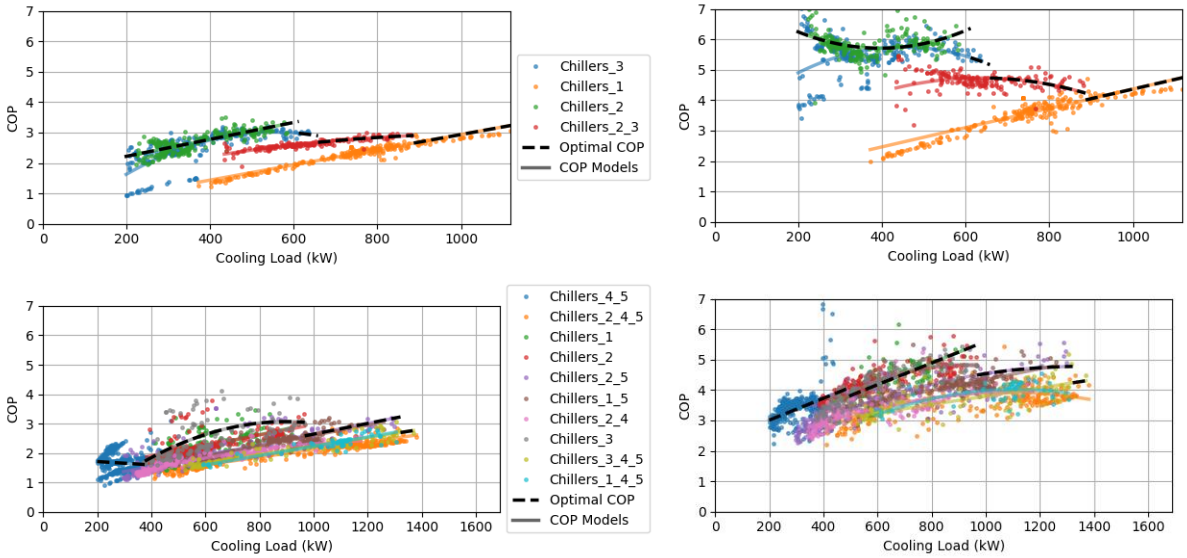

Figure 3. Measurements (dots), COP model (solid line) and optimal COP (dashed line) of different combinations of chillers based on system COP (left) and chiller COP (right) for building #1 (top) and building #2 (bottom).

Table 1. Model accuracy metrics for system COP (left) and chiller COP (right) for building #1.

Combination	Model	R^2	CV-RMSE
#3	Quadratic	62%	16%
#1	Linear	95%	5%
#2	Linear	63%	8%
#2-#3	Quadratic	80%	4%

Combination	Model	R^2	CV-RMSE
#3	Quadratic	20%	12%
#1	Linear	83%	8%
#2	Quadratic	7%	8%
#2-#3	Quadratic	33%	7%

Table 2. Model accuracy metrics for system COP (left) and chiller COP (right) for building #2.

Combination	Model	R^2	CV-RMSE
#4-#5	Linear	2%	18%
#2-#4-#5	Linear	89%	8%
#1	Linear	36%	13%
#2	Linear	44%	14%
#2-#5	Linear	70%	16%
#1-#5	Linear	73%	9%
#2 #4	Quadratic	88%	7%
#3	Quadratic	48%	19%
#3-#4-#5	Linear	85%	8%
#1 #4 #5	Linear	85%	6%

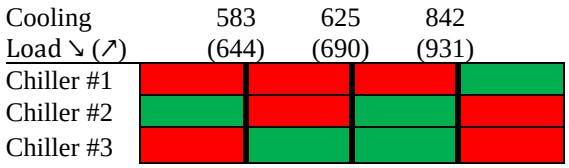
Combination	Model	R^2	CV-RMSE
#4-#5	Linear	13%	17%
#2-#4-#5	Quadratic	57%	9%
#1	Linear	64%	7%
#2	Quadratic	70%	6%
#2-#5	Quadratic	78%	10%
#1-#5	Linear	55%	8%
#2 #4	Quadratic	60%	10%
#3	Quadratic	83%	6%
#3-#4-#5	Linear	51%	10%
#1 #4 #5	Quadratic	55%	7%

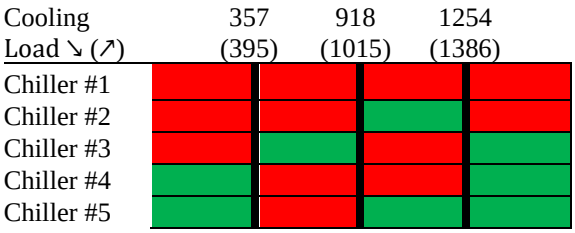
4.3 Chiller sequencing strategy

Based on the optimal COP presented in Section 4.2, Table 3 outlines the optimal chiller sequencing using chiller on/off as a function of cooling load. As discussed in Section 2, threshold values are implemented with deadbands to improve operational efficiency (cooling system COP) while

minimizing chiller switches, and reducing equipment wear and tear. For building #1, chiller #2 should be used at low cooling loads due to its higher efficiency while chiller #3 should be employed for a small load range before running both chillers #2-3 at higher loads. Chiller #1 is less efficient and is only used when chillers #2-3 cannot meet the demand. For building #2, chillers #4-5 are used at low cooling loads and are assisted by chillers #2 and #3 for higher loads; chiller #1 is never in operation.

Table 3. Chiller sequencing strategy for building #1 (left) and building #2 (right) based on optimal system COP, with thresholds for decreasing and increasing cooling load (kW) and chiller on (green) and off (red).





4.4 Performance evaluation

Table 4 shows the performance of the optimal chiller sequencing strategy. Energy savings of 9% and 15% are obtained for building #1 and #2, ultimately translating into similar cost savings, whereas the electric power peak remains unchanged. These results may be achieved by switching more or less between chillers (-51% to +30%) and by prioritizing higher-efficiency chillers (#2 for building #1; #3 for building #2), which may eventually impact equipment longevity. It shows some potential for better balancing energy efficiency and equipment lifespan in the objective function.

Table 4: Performance comparison of reference and optimal chiller sequencing for buildings #1 and #2.

	Building #1		Building #2	
	Reference	Optimal	Reference	Optimal
Seasonal system COP (-)	2.28	2.49 (+0.21)	2.1	2.48 (+0.38)
Electricity consumption (MWh)	338	309 (-9%)	989	838 (-15%)
Cooling system electric peak (kW)	396	396 (-)	588	588 (-)
Energy costs (CAD)	14,655	13,408 (-9%)	42,913	36,361 (-15%)
Number of chiller switches	472	213 (-55%)	1084	1400 (+30%)
Number of operating hours for each chiller	#1: 336 #2: 681 #3: 679	#1: 38 #2: 2048 #3: 367	#1: 904 #2: 1371 #3: 440 #4: 1638 #5: 2053	#1: 0 #2: 502 #3: 2130 #4: 678 #5: 1180

5. DISCUSSION: PRACTICAL CHALLENGES AND LESSONS LEARNED

The development of the proposed chiller sequencing strategy as an automated process introduces several practical challenges. One major issue is the variability in plant configurations, with diverse design and control capabilities. To address this, the approach relies on high-level information (e.g., type and number of components), though this may lead to inaccurate performance estimates due to auxiliary equipment interactions (e.g., a cooling tower pump operating with air-cooled chillers). Another challenge is data availability and quality—key variables such as electric power are often missing and must be estimated using %RLA, manufacturer specs, or spot measurements. While data postprocessing is automated (Section 2.1), manual efforts may be needed when results deviate from expectations. Finally, integration into existing control systems as a supervisory layer raises

additional issues, such as code modifications and legacy system compatibility. Furthermore, since the strategy reflects historical data, it must be updated regularly to capture equipment degradation or operational changes.

Despite these challenges, the strategy was validated using historical datasets, providing a reasonable estimate of expected savings. Implementation is ongoing in one case study building, alongside the development of a user-friendly tool for broader deployment. A key takeaway is that simplicity is essential for scalability and operator acceptance—supervisory strategies are preferred over those requiring full control of all components. Additionally, the use of data-driven performance curves has revealed performance deviations; for instance, chiller #1 in building #1 underperformed due to rust buildup, while anomalies in chillers #4 and #5 in building #2 suggested operational issues. Such curves offer potential for fault detection, performance tracking, and predictive maintenance (Saloux and Zhang, 2023).

6. CONCLUSIONS AND FUTURE WORK

This study demonstrates the feasibility and effectiveness of an automated data-driven chiller sequencing. This strategy has been applied to two buildings and demonstrated significant energy savings while ensuring a reasonable number of chiller switches, highlighting both energy and operational benefits. This approach leverages operational data and balances simplicity and accuracy, which makes it practical for field implementation and large-scale adoption, bridging the gap between theoretical work and practical usage. Future work can focus on the integration of new plant configurations (heat recovery between high and low temperature networks; water-based free cooling), the improvement of models, objective functions and optimization routines, and the development of predictive control strategies to improve performance. Field implementation is also critical to identify and address implementation barriers.

ABSTRACT

This paper presents a Weather-Responsive Fuzzy Control (WRFC) strategy to dynamically adjust temperature and humidity setpoints for energy-efficient HVAC operation in urban buildings. WRFC integrates external weather data, electricity prices, and occupancy levels to adapt HVAC setpoints, aligning indoor conditions with outdoor temperature and humidity variations. Using a Fuzzy Logic Controller (FLC), a control variable (w) is calculated to optimize setpoints, balancing energy use and occupant comfort. Compared to fixed setpoint strategies, WRFC significantly reduces heating and humidification demands, especially under high Air Changes per Hour (ACH) conditions. While cooling and dehumidification demands increase in summer, WRFC achieves annual energy savings of 274 [kW-hr m^{-2} $year^{-1}$] for a typical residential house. Sensitivity analysis highlights WRFC's effectiveness across diverse building types, particularly older and less airtight structures. These results demonstrate that weather-responsive setpoint control enhances HVAC sustainability and energy efficiency in urban environments.

Keywords: Building Energy Modeling, Fuzzy Control, Sensible and Latent Loads.

INTRODUCTION

The growing need for energy-efficient technologies underscores the importance of optimizing Heating, Ventilation, and Air Conditioning (HVAC) systems, which are major energy consumers and vital for maintaining indoor comfort and health. Temperature and humidity, the most critical parameters for Indoor Environmental Quality (IEQ) and thermal comfort must be carefully managed. Proper control prevents damage to buildings and HVAC equipment while adapting operations to occupancy and external conditions . Setpoint control, which involves maintaining target temperature and humidity levels, plays a key role in HVAC performance. Optimizing these setpoints allows operators to reduce energy use without compromising indoor conditions [5].

Control strategies for building energy management include On/Off, PID, MPC, and FLC . PID and On/Off are simple but struggle with nonlinearities and tuning issues. MPC is more advanced but limited by high computational demands. FLC handles uncertainties and nonlinearities effectively, making it suitable for dynamic environments. Hybrid methods like Fuzzy-PID and NN-MPC com-

bine strengths to improve performance. Recent works [3] show FLC's potential in energy-efficient temperature and humidity control [4].

Most existing controllers and smart building research focus on systems that adjust setpoints based on occupancy detection [10]. These systems often overlook other environmental factors. The concept of a physically intelligent building that adapts setpoints based on occupancy, outdoor conditions, electricity pricing, and latent heat remains under explored, but it could significantly enhance energy efficiency and comfort. Traditional HVAC control strategies typically rely on fixed setpoints, missing opportunities to use favorable outdoor conditions and reduce HVAC loads.

This study proposes a Weather-Responsive Fuzzy Control (WRFC) strategy that dynamically adjusts temperature and humidity setpoints using real-time data, including outdoor conditions, occupancy, and electricity prices. WRFC continuously adapts to optimize HVAC performance in both peak occupancy and energy-saving modes, reducing energy use while maintaining comfort. It integrates both sensible and latent loads, improving energy efficiency and occupant comfort, advancing HVAC setpoint decision-making and creating a physically intelligent building.

1. METHODOLOGY

1.1. Model Description

This study simulates urban physics using the Vertical City Weather Generator (VCWG v3.0.0), a multi-physics model that integrates processes for momentum, heat, humidity, and water exchanges through urban surfaces, soil, and the atmosphere. VCWG uses models like the Resistance Capacitance thermal network, Navier-Stokes transport, and Monin-Obukhov Similarity Theory (MOST) [1] to predict urban climate and building performance. For weather boundary conditions, the Vatic Weather File Generator (VWFG v1.0.0) provides data using the ERA5 datasets. VCWG's results for a base building were validated against real-world data from London, Ontario [9]. This paper extends the model by integrating a Fuzzy Logic Controller (FLC) and running it for Toronto in 2020. For more details, refer to earlier publications [7, 2, 8].

Figure 1 shows the arrangement of single detached residential buildings considered in this study. Such houses are prevalent in North America and account for 52.6% and 64% of residential building stock in Canada and the United States, respectively. The building features for each city are based on common codes and standards such as the National Energy Code of Canada for Buildings (NECB), the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) 62.1, ASHRAE 62.2, ASHRAE 90.1, and ASHRAE 90.2.

1.2. Weather-Responsive Fuzzy Control (WRFC)

This study introduces a novel real-time control strategy known as Weather-Adaptive Fuzzy Control (WRFC), designed to dynamically manage indoor temperature and humidity setpoints within a building. This method has been integrated with the VCWG software according to the flowchart in figure 3. The core principle of this method is to closely track external conditions and adjust the indoor setpoint accordingly whenever feasible. For instance, when outdoor conditions fall outside the human comfort range but occupancy levels are low, the system gradually adjusts the indoor setpoint to align with the outdoor temperature or humidity, provided it remains within predefined setback limits. Conversely, if outdoor conditions are within the comfort zone, the indoor setpoint

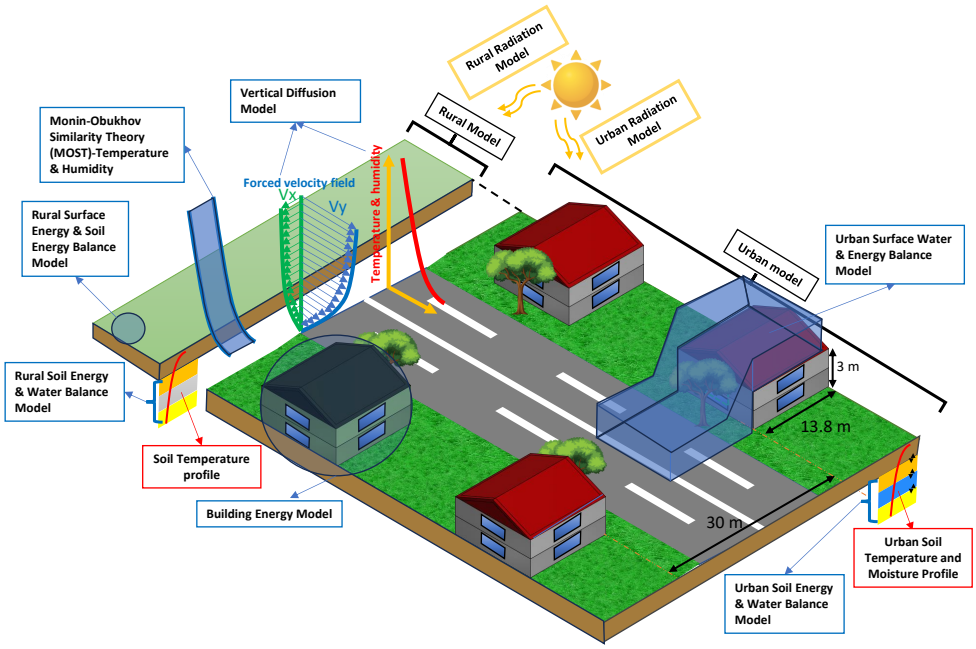

Figure 1. Illustration of the Vertical City Weather Generator (VCWG v3.0.0) model and the constituent sub-models.

is maintained in close proximity to the external conditions to eliminate the need for HVAC system operation. A basic description of the algorithm can be found in the flowchart in Figures 3 and 8. Another innovative aspect of this approach involves an integration of a fuzzy inference system that uses linguistic variables to evaluate the impact of external, uncontrollable factors, enabling a more refined and adaptive control of indoor environmental conditions for higher energy savings. The comfort ranges are defined in Figure 2 for humidity and temperature. It should also be noted that the basic thermostat mode for cooling setpoint is 27 °C and for heating setpoint is 22 °C.

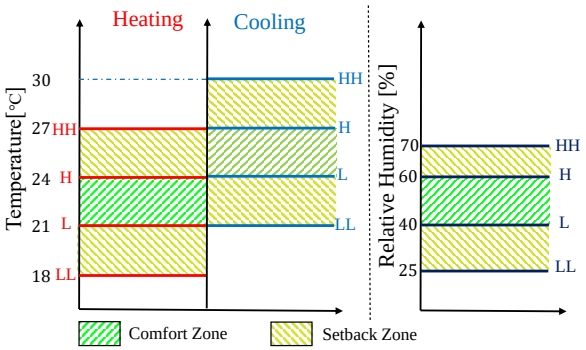

Figure 2. Illustration of the comfort and setback ranged for indoor temperature and humidity.

According to the FLC process diagram illustrated in the Figure 3 which follows Mamdani's Fuzzy Inference System (FIS) [6] the controller employs FLC to determine the w parameter, which governs the adaptation of setpoints by creating an adjustment value based on current input values.

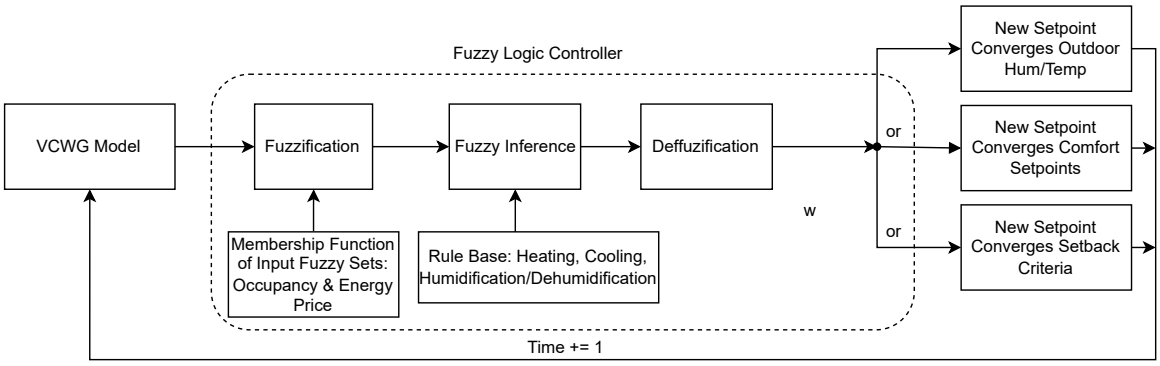

Figure 3. Flowchart illustrating the integration of the Weather-Adaptive Fuzzy Control (WRFC) with the Vertical City Weather Generator (VCWG) software

To do so, first the system uses predefined membership functions to assess the input's degree of membership. The controller uses two fuzzy variables as occupancy level [Person m^{-2}], and time of day [hr]. It is assumed in this study that three persons are living in a residential detached house of 100 m^2 with membership functions defined for low, medium, and high that any density more than 0.03 Person m^{-2} would be considered as a high occupancy level. For electricity price we have used the Time-Of-Use (TOU) pricing scheme in Ontario, Canada, as an example reflecting different electricity costs during different periods of the day and season. It is important to note that the differences in electricity prices between Winter and Summer, as well as between weekdays and weekends, have been accounted for in this study. These two inputs, with their respective levels in Figures 4 and 5, are mapped using trapezoidal and triangular membership functions to capture the varying degrees of occupancy and TOU.

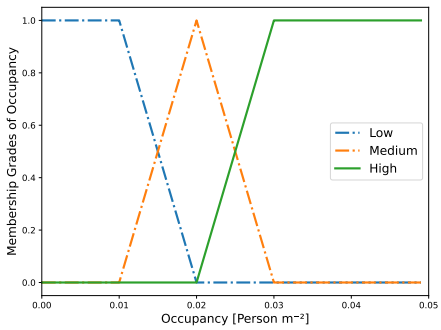

Figure 4. Fuzzy membership functions for the occupancy variable in the building.

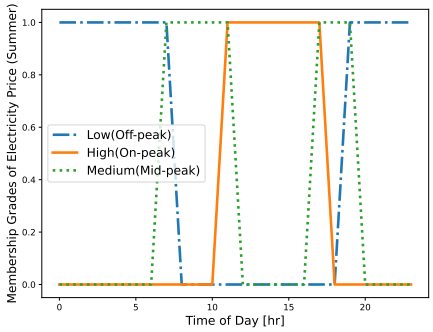

Figure 5. Fuzzy membership functions for the price variable in Summer.

Following the fuzzy inference process, we apply the fuzzy rules defined in Table 1 to the fuzzified input variables (electricity price and occupancy level) to determine the output variable w. These rules differentiate between weekday and weekend strategies for the Summer and Winter. Specifically, weekend rules do not account for electricity price fluctuations since rates remain constant throughout the day and night. In contrast, heating and humidification rules are not dependent on electricity price fluctuations, as these processes utilize natural gas in the HVAC system. Given

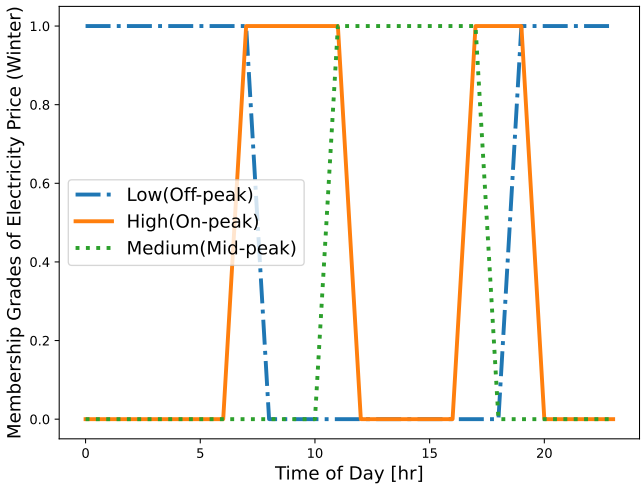

Figure 6. Fuzzy membership functions for the price variable in Winter

that gas prices remain constant throughout the day and night in Canada, gas price has not been considered a fuzzy input for these processes. Conversely, cooling and dehumidification require a refrigeration cycle, and thus electricity, so the corresponding rules depend on electricity price. In this table N means the setpoints should converge to outdoor condition, P means the setpoints should converge to comfort levels, and Z means no change.

Regarding Table 1 for cooling during weekdays, when occupancy is low and electricity price is low, medium, or high, the system should attempt to converge to the outdoor conditions, which is likely higher than the indoor and comfort setpoints. This corresponds to the linguistic variable N in our rule definition. In this scenario, energy efficiency takes precedence over comfort considerations when occupancy is low. Subsequently, when occupancy is medium and the price is low, the system converges to the comfort level P, while a medium price results in no change Z, and a high price increases convergence to the outdoor level N. Finally, high occupancy with low, medium, and high prices prompts convergence to the comfort level P. It should be noted that in this study Max operator has been used for decision-making process [11]. With the Max operation method, the output value for the linguistic variables corresponds directly to the highest activation levels.

In this step, the fuzzy outputs obtained earlier are converted into a crisp value (w) that can be utilized to adjust the setpoints.

The fuzzy output membership function employed in this study is a triangular membership function designed to calculate w, which controls the heating, cooling, humidification, or dehumidification setpoints (Figure 7). It includes three categories: N, Z, and P, ensuring a consistent and adaptable control strategy across all of these processes. The P and N values of these membership functions determine whether the smart setpoint should follow outdoor conditions or adhere to predefined comfort setpoints, dynamically adjusting the setpoints based on real-time input data.

The defuzzification process utilizes the centroid method, also known as the center of gravity or center of area method, to compute a specific numerical output for the w variable (Figure 8).

Table 1. Combined rules for HVAC adjustments based on occupancy presence, electricity price, and day type (weekdays and weekends): N: Converging to outdoor, Z: No change, P: Converging to comfort setpoint

Function	Day Type	Occupancy	Electricity Price	w Adjustment
Cooling/Dehumidification	Weekday	Low	Low	N
		Low	Medium	N
		Low	High	N
		Medium	Low	P
		Medium	Medium	Z
		Medium	High	N
		High	Low	P
		High	Medium	P
		High	High	P
	Weekend	Low	-	N
		Medium	-	Z
		High	-	P
Heating/Humidification	All Days	Low	-	N
		Medium	-	Z
		High	-	P

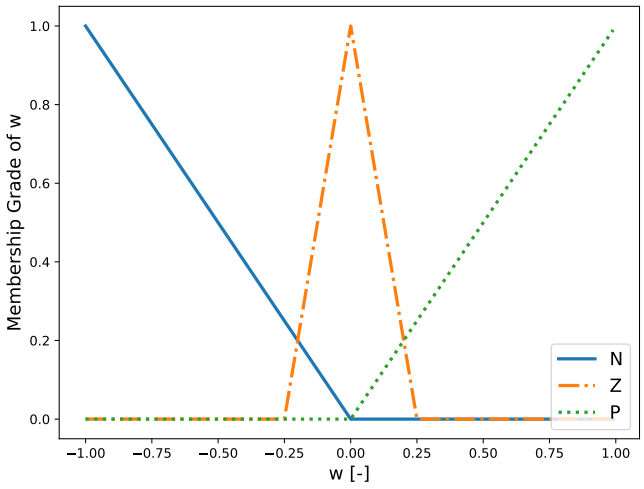

Figure 7. Fuzzy membership functions for temperature and humidity setpoints' adjustments. Both temperature and humidity adjustments use similar membership functions categorized into Negative (N), Zero (Z), and Positive (P) to guide the control of HVAC system setpoints.

2. RESULTS AND DISCUSSION

2.1. Performance of the Weather-Responsive Fuzzy Control (WRFC)

The model was run for a full year with a runtime of about 30 minutes on a single CPU, demonstrating its efficiency for a comprehensive urban physics simulation. Results for selected months with Air Changes per Hour (ACH) set at 1.5 hr^{-1} highlight its operation.

In May, a shoulder season with mixed heating, cooling, and neutral modes, the system's response is complex. Figure 9 (a) shows temperature behavior, while Figure 9 (b) illustrates the corresponding sensible heating and cooling loads. Early in the month, the system predominantly heats the building, keeping indoor temperatures within the comfort and setback thresholds (blue lines) during high occupancy. As outdoor temperatures rise later in the month, the system occasionally

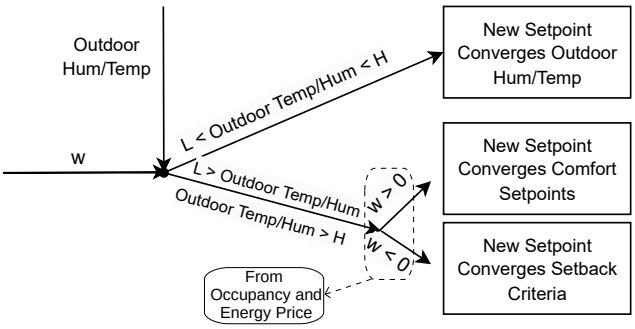

Figure 8. Decision tree illustrating how a value of w forces the smart setpoint to move toward comfort or outdoor conditions by adjusting the setpoint accordingly.

enters neutral mode, requiring no heating or cooling, with indoor temperatures naturally aligning within the comfort zone. When occupancy is low, indoor temperatures are allowed to drift outside comfort limits, prioritizing energy efficiency.

The system dynamically adjusts to outdoor temperature fluctuations. Around 700 hr, the outdoor temperature rises to 28°C, and the indoor temperature aligns with the comfort range (L to H). As outdoor temperatures exceed the H threshold, indoor conditions follow until occupancy increases, prompting the system to maintain comfort. This adaptive behavior repeats, balancing comfort and energy efficiency.

Smart humidity control also adapts effectively to dynamic conditions. Figure 10 (a) shows relative humidity (RH) behavior, while Figure 10 (b) displays humidification and dehumidification loads. When outdoor RH exceeds comfort thresholds, indoor RH adjusts to conserve energy during low occupancy. Conversely, when conditions demand, the system prioritizes comfort by maintaining indoor RH within acceptable ranges, showcasing its flexibility in balancing efficiency and comfort.

3. CONCLUSION

This study evaluated the impact of smart thermostat and humidistat configurations on building energy efficiency, focusing on seasonal variations in heating, cooling, humidification, and dehumidification under different air change rates (ACH). By integrating a Fuzzy Logic Control (FLC) system into the Vertical City Weather Generator (VCWG v3.0.0), we simulated a detached residential building in Toronto over a full year (2020). The findings highlight both the potential and the limitations of dynamic setpoint adjustments based on environmental, occupancy, and energy price inputs.

- Smart control yielded significant energy savings, reducing heating loads by up to 132.8 [kW-hr m^{-2} $year^{-1}$] during colder months and saving 141.5 [kW-hr m^{-2} $year^{-1}$] for humidification by aligning indoor relative humidity (RH) with outdoor conditions, particularly in leakier buildings.
- During peak summer months, cooling demand increased by 31.4 [kW-hr m^{-2} $year^{-1}$], and dehumidification demand rose by 5.3 [kW-hr m^{-2} $year^{-1}$], due to fluctuations and higher mass loads. These results indicate reduced effectiveness of the smart control in warm sea-

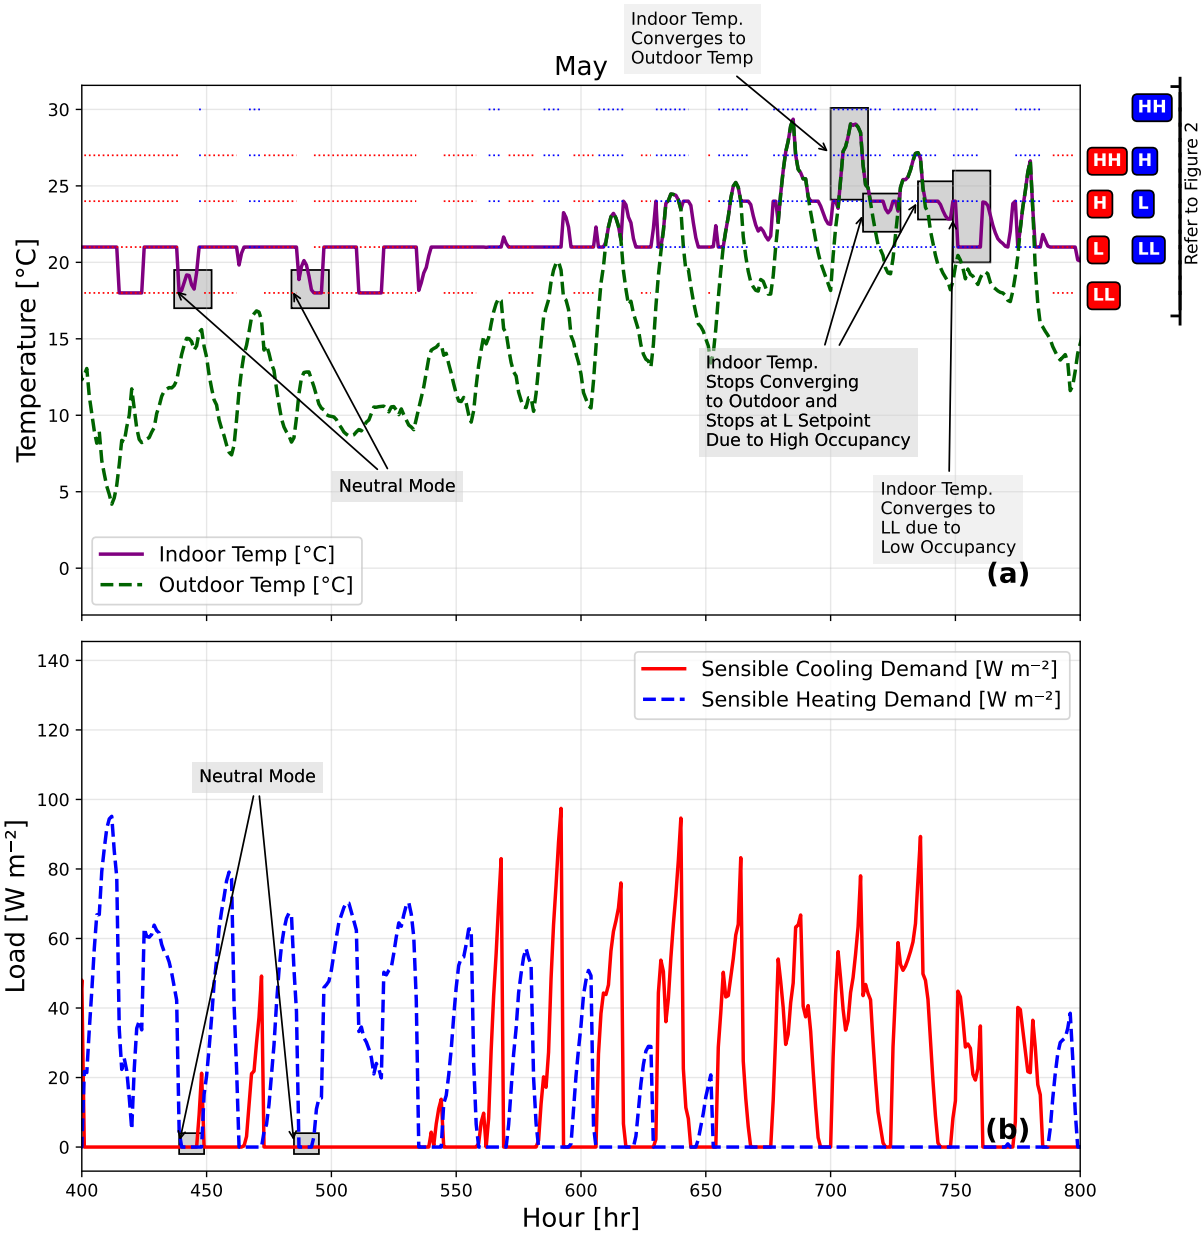

Figure 9. (a) Indoor temperature variations and (b) sensible heating and cooling load variations, both for May, showing the system's response to occupancy changes, electricity prices, and outdoor conditions.

sons.

- Year-round smart control achieved a net saving of 237 [kW-hr m^{-2} $year^{-1}$]. A hybrid approach, disabling smart features in summer, increased savings to 274 [kW-hr m^{-2} $year^{-1}$], demonstrating the advantages of a seasonal, adaptive strategy.
- Unlike conventional systems requiring airtightness, this approach proved effective in older, leakier buildings, reducing energy loads through better air exchange management.

In summary, while the smart control strategy excelled in heating and humidification, challenges

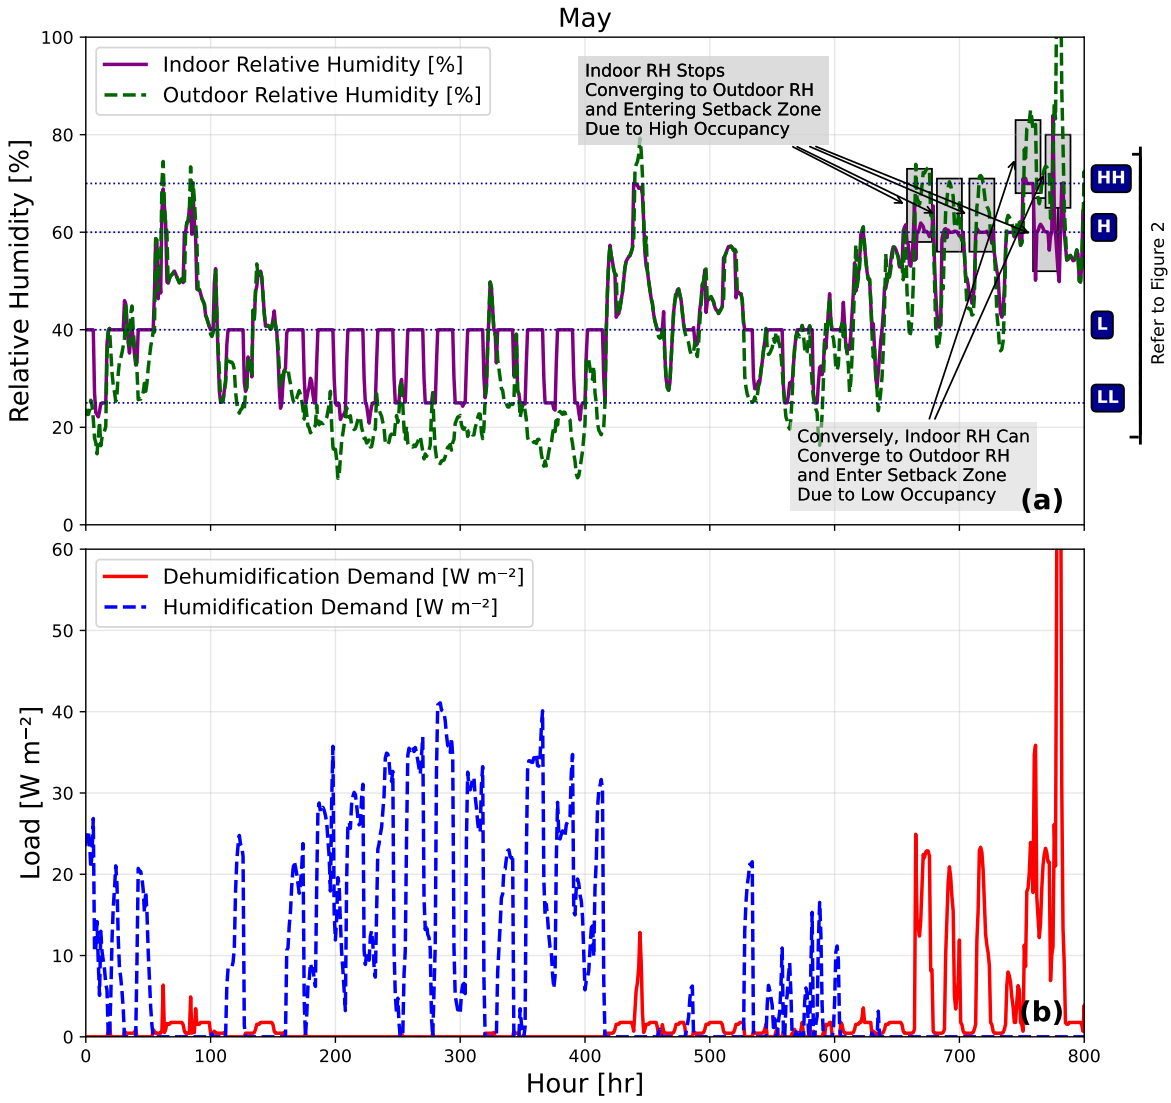

Figure 10. (a) Indoor RH variations and (b) latent (Humidification/Dehumidification) load variations, both for May, showing the system's response to occupancy changes, electricity prices, and outdoor conditions.

in cooling and dehumidification suggest the value of a hybrid approach, applying smart features selectively by season. This adaptable strategy enhances energy efficiency in diverse building types and supports sustainable HVAC energy management. Future research could extend these findings to other climate zones and building configurations.

SUMMARY
The regeneration process of frost-free air-source heat pumps (FFASHPs) consumes energy and affects the overall efficiency of the heat pump. There are numerous studies on different solution regeneration methods, none have clarified their thermodynamic limits, though. This study employs finite-time thermodynamics to study the influence of solution concentration, regeneration ratio, heat source temperature, ambient temperature, heat transfer capacity-to-mass flow coefficient, and internal reversibility coefficient on the minimum regeneration energy. The minimum specific regeneration heat and work are 87.67 and 15.79 kWh/t, respectively, under conditions where heat transfer capacity-to-mass flow coefficient reaches its minimum value. The recommended heat transfer capacity-to-mass flow coefficient is 6. When the total heat transfer capacity-to-mass flow coefficient is 10, the best high temperature-low temperature heat transfer capacity ratio is 0.81, corresponding to a W_{min} of 8.84 kWh/t.

Keywords: frost-free air-source heat pump, antifreeze regeneration, finite- time thermodynamics analysis, thermal regeneration.

1. INTRODUCTION

Heat pumps are considered one of the primary pathways for decarbonizing and electrifying of space heating and cooling due to their capability to effectively utilize low-grade heat sources (J. Zhang et al., 2016; Y. Zhang et al., 2018). Frost-free air-source heat pump (FFASHP), which utilizes a solution circulation between the evaporator and outdoor air to fundamentally solve the frosting problem, is considered to a promising heat pump technology (Lin et al., 2019).

As the solution absorbs latent heat from the air, the condensation of water vapor leads to dilution of the solution and an increase in its freezing point(Huang et al., 2023). There is a risk of freezing when the solution's freezing point approaches the lowest temperature in the system (typically the evaporator temperature) if it is not regenerated promptly. Liang at al. investigated the regeneration performance under three modes and the influence of input heat, outdoor air temperature and humidity(Liang et al., 2014). Huang et al. experimentally investigated the coupled heat and mass transfer characteristics of ethylene glycol solution ADE regeneration process, and the regeneration specific energy consumption (SEC) ranged from 712 kWh/t to 1206 kWh/t(Huang et al.et al., 2018). Song et al. conducted experimental studies on the performance of calcium chloride solution ADE regeneration process, and reported that the SEC ranged from 952 kWh/t to 2778 kWh/t(Song et al., 2019). The most commonly used regeneration method at present is thermal regeneration. There are also many other studies on system optimization of thermal regeneration methods, but there are currently no studies on their thermodynamic limits.

Finite-time thermodynamics (FTT) is an important branch of modern thermodynamics which combines into simple models the most basic concepts of heat transfer, fluid mechanics, and thermodynamics(Andresen et al., 1984). FTT seeks to optimize thermodynamic cycles or processes under conditions of limited time and size, offering a more practical approach to thermodynamic analysis. The concept of FTT was first introduced by Curzon and Ahlborn, who derived the efficiency of a power plant when the output power is maximized(Curzon et al., 1975). This efficiency is lower than the well-known Carnot efficiency, yet it is easier to approach. Due to its strong practical relevance, FTT has been widely applied in various fields(Guo et al., 2021; Sukin et al., 2022; Yaqi et al., 2011). However, in the area of solution regeneration or concentration, there is still a lack of analytical studies from the perspective of FTT. Similar studies have been conducted in the field of separation processes: Berry et al. utilized FTT to analyze thermally driven separation processes, deriving an analytical expression for the minimum average heat consumption in an isothermal heat-source-driven separation process(Orlov & Berry, 1991).

In this study, FTT is applied to derive expressions for the minimum separation heat and work of an internally reversible heat-driven regeneration process. We calculated and investigated the effects of several parameters on the regeneration work of the heat-driven regeneration system. Based on the research results, optimization suggestions for the design of heat-driven antifreeze regeneration systems are proposed.

2. SYSTEM AND DERIVATION

2.1. Internally reversible regeneration system

As shown in Fig. 1 is an internally reversible solution thermal regeneration process. The temperature and pressure of the inlet and outlet solutions are equal, and all processes within the regeneration system are reversible. Assuming the temperatures during heat exchange with the external environment remain constant: the temperature during heat exchange with the heat source is T_1, and the temperature during heat exchange with the environment is T_2. Assuming the heat transfer coefficients at the hot and cold ends of the heat exchangers are fixed values, α_H and α_L, respectively, the heat transfer amounts at the hot and cold ends are as Eq. (1) and Eq. (2).

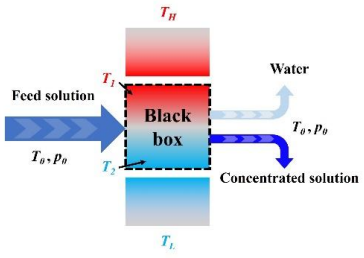

Figure 1. Internally reversible antifreeze thermal regeneration system

$$Q_H = \alpha_H(T_H - T_1) \tag{1}$$

$$Q_L = \alpha_L(T_2 - T_L) \tag{2}$$

Where T_H and T_L represent the temperatures of the heat source and the cold source, respectively, with T_L assumed to be equal to the ambient temperature T_0 in this study. According to the first and second law of thermodynamics:

$$Q_H - Q_L = \dot{m}_w h_w + \dot{m}_c h_c - \dot{m}_f h_f \tag{3}$$

$$\frac{Q_H}{T_1} - \frac{Q_L}{T_2} = \dot{m}_w s_w + \dot{m}_c s_c - \dot{m}_f s_f \tag{4}$$

Where $\dot{m}$ is the mass flow rate, h is the specific enthalpy, and s is the specific entropy. The subscripts w, c and f represent water, the regenerated concentrated solution, and the feed solution, respectively. We define enthalpy flow and entropy the following:

$$\dot{H} = \dot{m}_w h_w + \dot{m}_c h_c - \dot{m}_f h_f \tag{5}$$

$$\dot{S} = \dot{m}_w s_w + \dot{m}_c s_c - \dot{m}_f s_f \tag{6}$$

2.2. Derivation of the minimum regeneration heat

Our goal is to first obtain the minimum value of Q_H, denoted as Q_{min}, for a given regeneration process, where m_f, x_f, and r are fixed. By constructing the Lagrange function Eq. (7), the problem is transformed into finding the minimum value of the function. Substituting Eq. (1) and Eq. (2) into Eq. (7) yields Eq. (8).

$$L = Q_H - \lambda\left(\frac{Q_H}{T_1} - \frac{Q_L}{T_2} - \dot{S}\right) - l(Q_H - Q_L - \dot{H}) \tag{7}$$

$$L = -\alpha_H\left(l - 1 + \frac{\lambda}{T_1}\right)(T_H - T_1) + \alpha_L\left(l + \frac{\lambda}{T_2}\right)(T_2 - T_L) + \lambda\,\dot{S} + l\,\dot{H} \tag{8}$$

First, by optimizing T_1 and T_2, we obtain:

$$L_{\min}\ (\lambda,\ l)\ = -\alpha_H\left[\sqrt{T_H(l-1)} - \sqrt{-\lambda}\right]^2 - \alpha_L\left[\sqrt{T_L\,l} - \sqrt{-\lambda}\right]^2 + \lambda\,\dot{S} + l\,\dot{H} \tag{9}$$

Next, we obtain the optimized λ by taking the partial derivative of L with respect to λ, which satisfies Eq. (8). It is evident that $\hat{\lambda} < 0$.

$$\sqrt{-\hat{\lambda}} = \frac{\alpha_H\sqrt{T_H(l-1)} + \alpha_L\sqrt{T_L\,l}}{\alpha_H + \alpha_L + \dot{S}} \tag{10}$$

Then we have:

$$L_{\min}\ (l)\ = -\alpha_H \left[\sqrt{T_H(l-1)} - \sqrt{-\hat{\lambda}}\right]^2 - \alpha_L \left[\sqrt{T_L\, l} - \sqrt{-\hat{\lambda}}\right]^2 + \hat{\lambda}\,\dot{S} + l\,\dot{H} \tag{11}$$

Finally, we take the derivative of L with respect to l, and obtain:

$$\frac{dL_{min}(l)}{dl} = -2\,\alpha_H \left[\sqrt{T_H(l-1)} - \sqrt{-\hat{\lambda}}\right]\left[\frac{T_H}{2\sqrt{T_H(l-1)}} - \frac{d\sqrt{-\hat{\lambda}}}{dl}\right] - 2\,\alpha_L \left[\sqrt{T_L l} - \sqrt{-\hat{\lambda}}\right]\left[\frac{T_L}{2\sqrt{T_L l}} - \frac{d\sqrt{-\hat{\lambda}}}{dl}\right] - 2\sqrt{-\hat{\lambda}}\,\dot{S}\frac{d\sqrt{-\hat{\lambda}}}{dl} + \dot{H} \tag{12}$$

It is evident that $l > 1$. As l approaches 1, equation (12) tends to negative infinity; as l approaches positive infinity, equation (12) becomes greater than 0. Therefore, equation (11) must have an extremum. Setting equation (12) equal to 0, the optimized l can be obtained using numerical methods, and by substituting this value into equation (11), Q_{min} can be determined. Then we can determine specific energy consumption (SEC), including specific heat consumption and specific work consumption:

$$q_{min} = \frac{Q_{min}}{\dot{m}_w} \tag{13}$$

$$w_{min} = q_{min}\,(1 - \frac{T_0}{T_H}) \tag{14}$$

We define:

$$\theta_H = \frac{\alpha_H}{\dot{m}_f} \tag{15}$$

$$\theta_L = \frac{\alpha_L}{\dot{m}_f} \tag{16}$$

2.3. Parameters

This study investigates the effects of feed solution concentration, regeneration ratio, heat source temperature, ambient temperature, and θ on regeneration performance. The basic parameter settings are shown in Table 1.

Table 1. Basic parameter settings.

X_f (%)	r	T_H (K)	T_L (K)	θ_H (J/(kg·K))	θ_L (J/(kg·K))
0.19	0.05	333.15	273.15	10	10

3. RESULTS AND DISSCUSSION

As shown in Fig. 2(a), the derivative of $L_{\min}$ with respect to l is monotonically increasing, with at most one zero point. When a zero point exists, $L_{\min}$ first decreases and then increases, indicating the presence of a minimum value. This validates the soundness of our derivation. Fig. 2(b) illustrates some solutions for l and λ under different θ values based on the fundamental parameters.

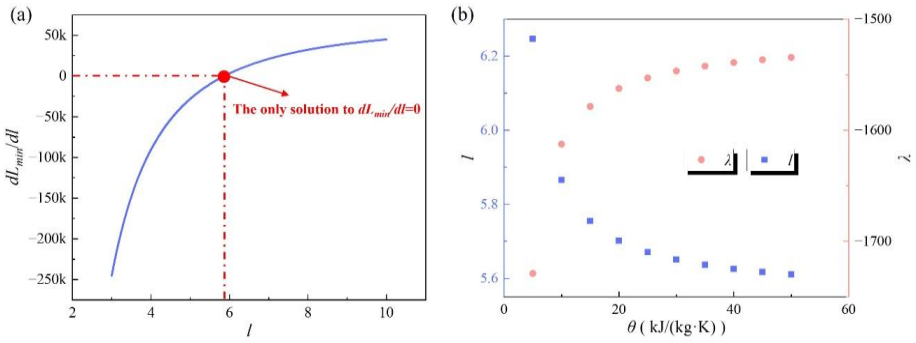

Figure 2. Partial solutions for l and λ

3.1. Influence of feed solution concentration

As shown in Fig. 3(a), q_{min} and w_{min} increase significantly with the rise in feed solution concentration. This is in accordance with general knowledge: the higher the solution concentration, the more difficult the regeneration process. Fig. 3(b) shows how the temperature differences at the hot and cold ends of the heat exchanger change with the solution concentration. The required temperature difference for heat exchange becomes larger as the concentration increases.

3.2. Influence of regeneration ratio

As shown in Fig. 3(c), as the regeneration ratio increases, both q_{min} and w_{min} increase to some extent. When the regeneration ratio increases from 0.0001 to 0.1, the minimum regeneration heat and work increase by approximately 19%. This is because, with the increase in the regeneration ratio, the solution concentration gradually rises, making regeneration more difficult.

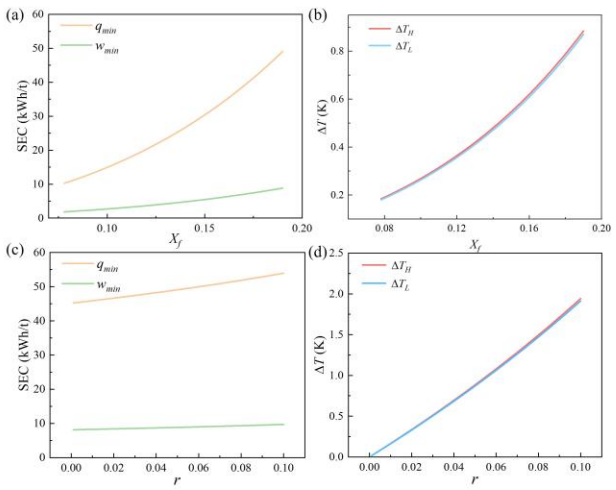

Figure 3. Influence of X_f and r

3.3. Influence of heat source temperature

It can be observed form Fig. 4(a) that as the heat source temperature increases, q_{min} initially decreases rapidly, then more slowly. However, w_{min} remains nearly unchanged. This suggests that

while increasing the heat source temperature reduces the heat demand, it comes at the cost of raising the energy quality, and fundamentally, no true energy savings are achieved in thermodynamic terms. The temperature differences for heat transfer decrease as the heat source temperature rises as shown in Fig. 4(b).

3.4. Influence of ambient temperature

Fig. 4(c) shows that q_{min} increases with the rise in ambient temperature, while the minimum regeneration work remains almost unchanged. Since the temperature of the heat source is fixed, although the ambient temperature has little effect on energy efficiency from a thermodynamic perspective, it suggests less energy costs under lower ambient temperature. The temperature differences for heat transfer increase as the heat source temperature rises as shown in Fig. 4(d).

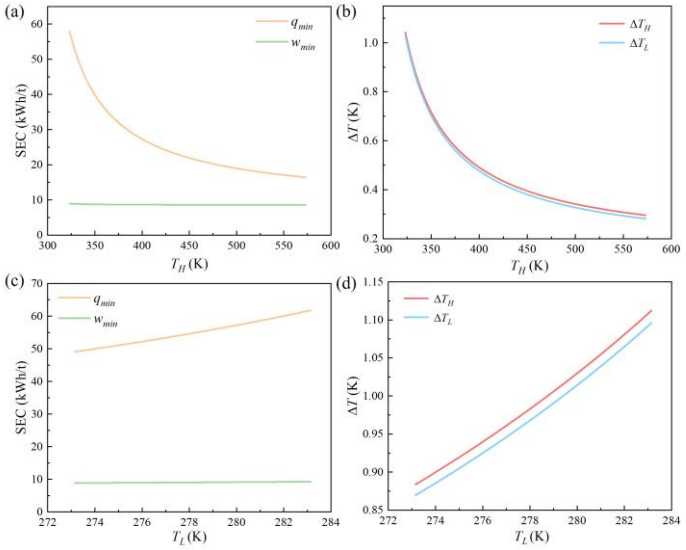

Figure 4. Influence of T_H and T_L

3.5. Influence of heat transfer capacity-mass flow coefficient

Fig. 5(a) shows that as θ increases, both q_{min} and w_{min} exhibit a rapid decrease followed by a slower decline. This is because a larger θ implies a relatively smaller solution flow rate, a larger heat exchange area, and a stronger system reversibility. However, q_{min} and w_{min} will not decrease indefinitely. As θ approaches infinity, w_{min} approaches a critical value, rather than zero. This critical value should correspond to the minimum regeneration work for a reversible process. This is because an infinite θ implies an infinitely small solution flow rate and an infinitely large heat exchange area. From Fig. 5(b), it can be seen that at this point, the temperature difference for heat exchange gradually approaches zero, indicating that the regeneration process is fully reversible. Additionally, under the given regeneration requirements and environmental parameters, θ has a minimum boundary value. This means that a certain flow rate imposes a minimum requirement for the heat exchange capacity of the equipment, or a device with a certain heat exchange capacity can only accommodate a maximum solution flow rate. Under the basic parameters used in this study, the minimum value of θ is 1.15, corresponding to a q_{min} and w_{min} of 87.67 and 15.79 kWh/t, respectively. After θ reaches a certain value, further increases in θ will cause minimal changes in the minimum separation heat and work. If we define the thermodynamic perfection as:

$$\eta = \frac{W_{th}}{W_{min}} \tag{17}$$

Where w_{th} is the minimum separation work for a reversible process, i.e., the value of w_{min} when θ approaches infinity. Under the basic operating conditions of this study, when θ reaches 6, η reaches approximately 95%. The θ corresponding to η = 95% is referred to as the recommended θ_{rec} in this study.

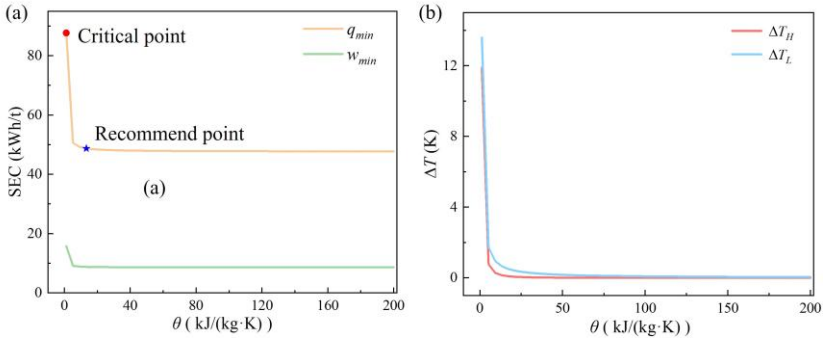

Figure 5. Influence of θ

3.5. Influence of θ_H/θ_L

Fig. 6 shows that as θ_H/θ_L increases, W_{min} first decreases and then increases. There exists an optimal ratio at which W_{min} reaches its minimum. In this study, the optimal ratio is 0.81, corresponding to a W_{min} of 8.84 kWh/t.

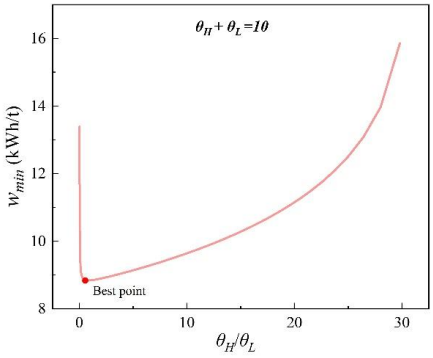

Figure 6. Influence of θ_H/θ_L

4. CONCLUSION

This study utilized finite-time thermodynamics to derive expressions for the minimum separation heat and work of an internally reversible heat-driven antifreeze regeneration process. The results show that the minimum specific regeneration heat and work are 87.67 and 15.79 kWh/t, respectively, under conditions where heat transfer capacity-to-mass flow coefficient reaches its minimum value. The recommended heat

transfer capacity-to-mass flow coefficient is 6. When the total heat transfer capacity-to-mass flow coefficient is 10, the best high temperature-low temperature heat transfer capacity ratio is 0.81, corresponding to a Wmin of 8.84 kWh/t.

Stochastic assessment requirements for unsteady ventilation flow patterns

Jelle Laverge [1], Merel Decleyre [1], Lisa Corneillie [1], Klaas De Jonge [1]

[1]*Ghent Univeristy, Gent, Belgium, jelle.laverge@ugent.be*

SUMMARY
The evolution of ventilation systems toward "smart" designs aims to enhance indoor air quality (IAQ) while minimizing energy consumption and costs. Traditional design standards use predefined airflow rates, but recent advancements advocate for performance-based approaches, as outlined in the proposed CEN standard prEN 15665. Smart ventilation systems dynamically adjust airflow based on factors like occupancy and environmental conditions. Advanced controllers with self-learning features, such as grey-box model predictive controllers (MPCs), outperform conventional proportional controls but necessitate the use of stochastic assessment methods and convergence-based performance indicators, which assess system behavior over time. In this paper, we propose the use of convergence based performance indicators the assessment of smart ventilation as a way to address this. This approach offers computational efficiency and addresses the complexities introduced by self-learning algorithms. For regulatory applications, convergence assessments must consider confidence intervals and sensitivity of the performance indicators to low frequencies in the input parameters. This approach can enhance the accuracy and neutrality of ventilation performance assessment while reducing simulation times by up to 90%.

Keywords: Ventilation, IAQ, Assessment, Criteria, Performance based design

1. INTRODUCTION

The primary goal of the ventilation system is to insure good IAQ through replacing indoor air with (hopefully) cleaner outdoor air. In currently applicable design standards, such the European EN 16798-1 and EN 16798-3, this is generally translated in requirements for applying a known supply or extraction flow rate in the individual rooms of the building or to the full building, with or without transfer between the rooms. Adding additional transfers is often called extended cascade ventilation (Rojas et al., 2015) and adds some complexity in estimating the exposure of the occupants, but does not fundamentally affect the design strategy of a known airflow directed through the building as if it were a duct system.

Only in recent years have efforts from the scientific community to define, implement and test ‘smart’ ventilation led to the adoption of more performance-based rating methods to assess ventilation design and performance (Guyot et al., 2019). The AIVC definition of smart ventilation (Durier et al., 2018) is relatively long, but starts as follows:

> *"Smart ventilation is a process to continually adjust the ventilation system in time, and optionally by location, to provide the desired IAQ benefits while minimizing energy consumption, utility bills and other non-IAQ costs (such as thermal discomfort or noise).*

A smart ventilation system adjusts ventilation rates in time or by location in a building to be responsive to one or more of the following: occupancy, outdoor thermal and air quality conditions, electricity grid needs, direct sensing of contaminants, operation of other air moving and air cleaning systems. "

Typical implementations of 'smart' ventilation only partially exploit the potential for 'smartness' put forward in this definition allows and only add proportional control to the predefined flow pattern from the design standards (Guyot et al., 2018).

In an effort to embrace more ambitious renderings of what smart ventilation could be, the proposal for a new CEN design standard for residential ventilation systems prEN 15665 defines 3 steps within the performance assessment method step of the performance-based design process: 1) Select a calculation level, 2) Describe the relevant features, and 3) Select an appropriate calculation method and run the calculations. This paper addresses the question of the appropriate calculation method and calculation level for systems with advanced controllers.

2. ASSESSMENT REQUIREMENTS

For the 'appropriate calculation method', the most advanced options in literature typically use multi-zone airflow simulation with 1 or more (using Monte-Carlo techniques) fixed weather and occupancy profiles (Laverge, 2011). Such simulations show that, in multi-zone ventilation systems typical for residential settings, the intended flow pattern regularly breaks down due to the impact of wind and thermal buoyancy. Advanced controllers, like grey-box MPCs, have been shown to have superior performance to typical proportional rule based controlers in such conditions (Merema al., 2022) and, provided the appropriate actuators are available, can change flow paths through the flow network in response to the changing ventilation needs.

The grey-box nature of existing optimal controllers and the increasing popularity of the inclusion of self-learning algorithms in control loops (eg. Zou et al., 2024), introduces fundamentally new features to the process and poses a challenge to the selection of the appropriate calculation method for regulatory purposes. A fundamental requirement for a regulatory assessment procedure is that it does not provide an advantage to a particular (type of) system that is not a reflection of a real feature of the system (avoiding bias or 'technological neutrality' of the assessment method). As the repetition of known boundary conditions (weather data) and excitations (occupancy patterns) in existing methods can easily be picked up by self-learning algorithms, the appropriate assessment methods needs to be inherently stochastic in nature. This, however, requires fundamentally rethinking the current *best practices* of performance assessment for smart ventilation and IAQ management more broadly. A fundamental step towards this is moving to stochastic assessment methods.

In addition to moving towards stochastic inputs, like stochastic user profiles (Verbruggen et al., 2019) and synthetic weather files (Jia et al., 2024), the checking of the satisfaction of the set IAQ criteria, required moving to a convergence based assessment rather than a deterministic threshold, because the obtained performance metrics will be affected by the stochastic variation in conditions. The simulation then needs to be run until the selected performance indicators have converged. In this paper, we analyse the feasibility of convergence based performance indicators.

3. ANALYSIS AND DISCUSSION

As shown in Figure 1, this is typically reached relatively soon in simulations ran over one year or heating season. The figure shows the convergence of the average exposure of 4 occupants to carbon dioxide in a single family apartment in Belgium in a simulation of 1 heating season spanning from September to April, at 477, 615, 407 and 439 ppm respectively. All modeling assumptions used can be found in report of the 'Freduc' study (Caillou et al. 2014).

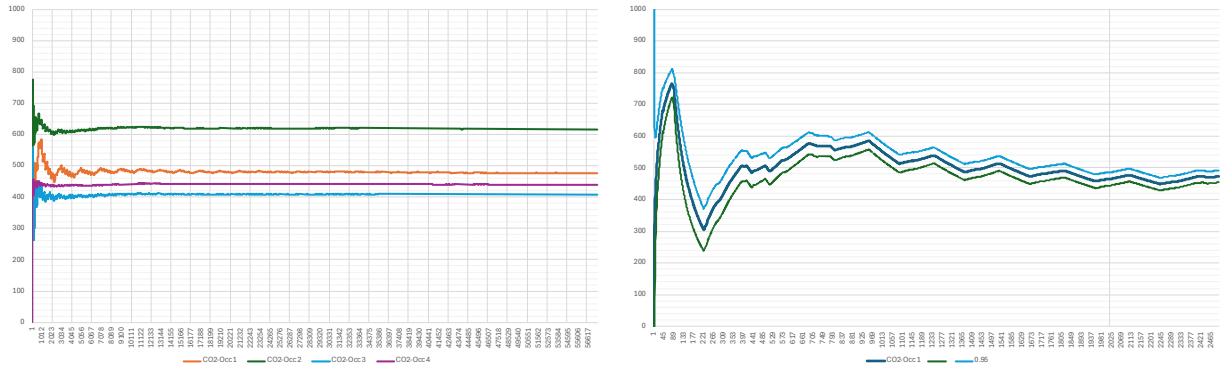

Figure 1. Convergence of average exposure to CO_2 (ppmvol) of 4 occupants in a traditional deterministic simulation over 1 heating season (left) and the confidence interval around the mean for occupant 1 over slightly more than 1 weeek (right).

It is clear that convergence of this particular performance indicator is reached relatively quick. After 6 weeks (grid lines in the graph), all values have effectively converged. If ranking of the occupants is the objective of the analysis (Sarrazin et al., 2016), then this is already the case after 2 weeks. This analysis shows that moving towards a convergence based assessment could not only provide an answer to the challenge of assessing self-learning controls, but could also provide substantial computational savings over traditional simulation methods, in this case by a factor of 8-20, depending on the selected performance indicator and convergence metric.

At the same time, the results also show that the average exposure of occupant 1 is strongly affected by weekly disturbance in the occupancy pattern, the regular occurrence of the weekend for a full-time working adult in the repeating fixed occupancy pattern as shown in Figure 2. (left), leading to an underestimation of the confidence interval around the mean early in the early stages of the convergence. Although several of the weather variable included in the analysis have frequence components with a much longer period than the occupancy pattern (think of temperatures that typically follow a one-year cycle and therefore will only converge after several years, see Figure 2.), these components do not seem to affect the convergence of the selected performance indicator. In this particular case, this means we need to use both the confidence interval and the value of the performance indicator when assessing convergence.

The sampling of the input parameters could be optimized to facilitate faster convergence provided that this does not affect the behavior of the system that is being assessed. A stochastic assessment framework for IAQ management systems should therefore include an analysis of the dominant frequencies in the input variables as well as a sensitivity analysis of the selected performance indicators to the input parameters.

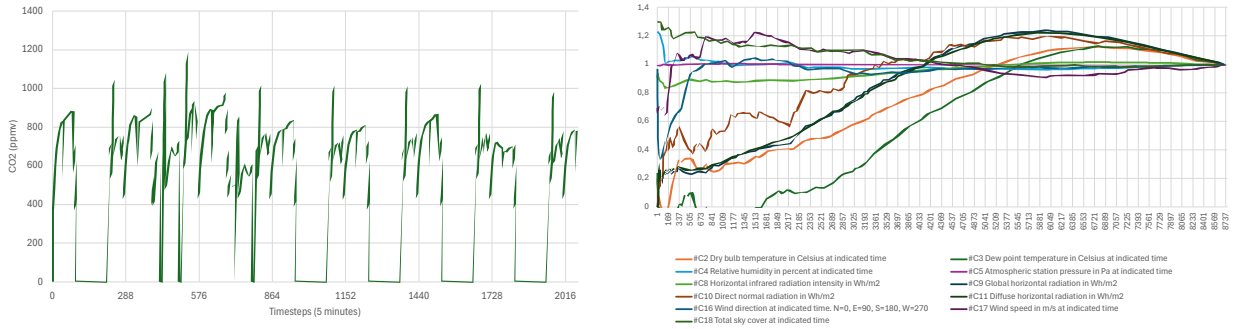

Figure 2. Time series of the exposure of occupant 1 to carbon dioxide (ppmvol) over 1 week (left). Convergence of normalised average values of the weather variables in the weather input file of the simulation over 1 year (right).

5. CONCLUSIONS

In this abstract, we have argued that the advent of MPC and self-learning controls in smart ventilation and other IAQ management applications introduces the need for stochastic simulation methods in a regulatory framework. We proposed the use of convergence based performance indicators and demonstrated that it is important to consider both the confidence interval and the value of the performance indicator when assessing convergence. Finally, our findings suggest that moving to stochastic assessment methods could reduce computation times by at least one order of magnitude.

SUMMARY
In urban development, buildings have a key influence on energy use and sustainability. Therefore, accurate building energy demand predictions are required to design climate neutral energy systems. GML models, common for city-scale energy simulations in Europe, often lack detailed building information about architecture and construction. This study addresses the challenge of predicting heat load profiles for buildings with limited available data, especially those characterized by multiple thermal zones and various use types. A Multizone Assignment Algorithm (MZA) is developed to improve load prediction by defining zoning strategies using the concept of Binary Space Partitioning (BSP). The MZA integrates an automated zoning approach, embedded into the TEASER-AixLib framework for seamless energy simulation. By incorporating adjacency relations and interzonal heat transfer, the methodology improves prediction accuracy while requiring minimal manual input. This novel approach accelerates and simplifies district-scale simulations, providing important insights into how different areas within buildings interact and improving the operation of energy systems with limited initial data.

Keywords: CityGML, heating demand simulation, zoning strategies

1. INTRODUCTION

Buildings account for up to 40 % of global energy demand, significantly contributing to climate change (Statista, 2022). Improving energy efficiency in buildings is crucial for sustainable development, with heat demand prediction playing a central role in optimizing design and operation. Thermal simulations often rely on public GML files, classified into Levels of Detail (LoD) that range from simple footprints (LoD0) to detailed volumetric models (LoD3) (Biljecki et al., 2016). However, most municipal data is typically limited to rudimentary information, resulting in reduced prediction accuracy and compromised thermal simulation quality.

Despite the frequent lack of information, there are approaches aimed at improving the accuracy of predictions. In addition to the estimation of material properties of the facade or the enrichment of building models with information from aerial images, the assumed structure within the building envelope also plays a decisive role. For example, unheated partial areas or heat transitions between neighboring zones influence the heat demand of a building. Through inadequate or inappropriate zoning techniques this results in deviations of up to 15 % for a single zone (Jansen et al., 2021; Kühn et al., 2024). In addition, the high diversity of occupancy profiles and, in this context, the behavior of the residents significantly influences energy consumption patterns. Not only do heat transitions into unheated neighboring zones affect the heat demand, but also heat exchanges between apartments and floors arise due to user-controlled setpoint temperatures. Hence, the decomposition of a single-zone model into a multi-zone model is suggested and has already been

addressed in other works. Some approaches address this challenge by focusing on the expansive generation and zoning of interior floor plans. For instance, Lopes et al. (2010) present a flexible method for generating procedural interior room layouts that accommodate various building types, including those with multiple floors. In contrast, Dogan et al. (2016) and Johari et al. (2022) concentrate on subdividing larger buildings into subzones, both recommending detailed zoning for varying usage profiles.

In contrast to these advancements, many existing approaches do not adequately address the complexities introduced by multiple thermal zones and diverse usage types on a larger scale for multi-family houses or apartment blocks. Due to the lack of information, a time-consuming multiple zone modeling is not considered, leading to inaccuracies in energy demand predictions. This work addresses these challenges by enhancing heat demand estimation through an automated zoning algorithm, even when detailed architectural information is lacking. The methodology focuses on an automated heuristic approach that can generate individual apartments within multi-family buildings while adhering to predefined constraints. Although manual zoning and perimeter-core zoning have been integrated into the framework, the emphasis in the present study is on the automated zoning method.

2. METHODOLOGY

2.1. Data aggregation and preprocessing

In this work, we combine geodata from OpenStreetMap (OSM) (2024) with CityGML data (Remmen et al., 2016) as input in order to obtain detailed information about the buildings. The integration of OSM data enables the supplementation of the information contained in CityGML, specifically by using attributes such as building and roof type in OSM or the address point of a building. In addition, we integrate further data (Blanco et al., 2023), enriching the dataset per building with additional information, such as the classification of buildings into construction year typologies. The systematic analysis and processing of these combined sources ensures a consistent and sufficient database for subsequent applications.

In order to reduce the computational effort and limit the number of possible solutions, a discretization of the building floor area is necessary. We carried out this reduction of the solution space using the Binary Space Partitioning (BSP) algorithm (H. Fuchs et al., 1980). This approach enables an automatic subdivision of the base surface up to a predefined granularity, efficiently dividing the solution space into smaller, manageable, and convex hyperplanes called leaves. The outcome is a recursive data structure in the form of a tree, as shown in Fig. 1.

Finally, further information is aggregated per leaf, such as direct neighboring leaves or connections to the outer edge of the building, which are essential for the functionality of the proposed methods and the placement of staircases. The latter is important for two reasons: Firstly, an unheated staircase influences the energy demand of a building and its individual zones, and secondly, the placement creates additional constraints that facilitate the automatic zoning. Consequently, the staircase for a building is aligned based on the address point and orthogonal to the nearest possible external wall. The dimensions of the staircase are currently determined by a proportion of the floor area and with respect to the standards (DIN 18065, 2011), but future iterations will adjust them according to the year of construction and building type.

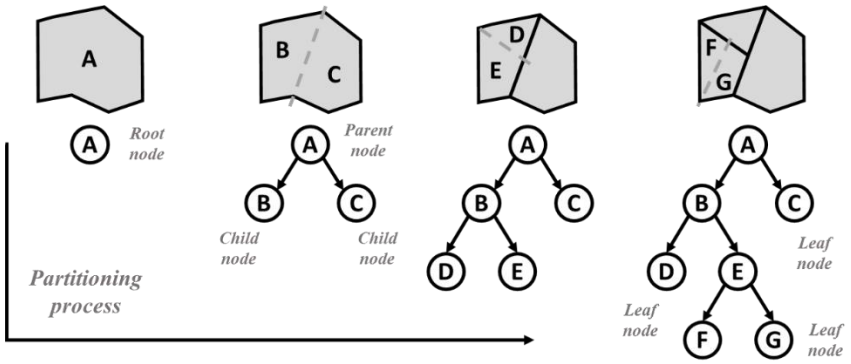

Figure 1. Partitioning process of a Binary Space Partitioning (BSP) tree with leaves as final partitions

2.2. Automatic zoning

The heuristic zoning algorithm presented here is based on a combination of random seed placement and subsequent regional allocation of areas, under adherence to predefined constraints. In the first step, the seeds — i.e., starting points — are generated along polygon boundaries. These boundaries correspond to the partition wall between the stairwell and the rest of the floor area along which the starting points are positioned. Each starting point represents a required zone per floor. The number of zones or apartments to be determined per building and per floor is derived from databases, using either the average apartment size or a predefined number of households per building volume (Census, 2011; Destatis, 2023). Subsequently, up to a defined iteration limit, a procedure with uniform spacing of the starting points is carried out. Beyond a certain threshold, random placements within or along the boundary line are allowed. For each iteration, all leaves are assigned to the nearest sub-area using a breadth-first search method, where multiple seeds act simultaneously in a queue. The subareas grow in parallel, assigning neighboring leaves (connected by an adjacency list) to the subarea that "captures" them first, which is comparable to the method described by Loga et al. (2016).

As soon as all leaves have been assigned, a constraints check is carried out to ensure minimum requirements are met. These relate to the number of leaves bordering the stairwell and an external facade in each sub-area or a maximum permissible deviation of the individual subarea areas from the specified average value. An assignment is only considered valid if these conditions are met.

$$Z = P_{\text{total}} + \alpha(\max(A_{\text{subarea}}) - \min(A_{\text{subarea}})) \quad (1)$$

The final step involves postprocessing to reduce local irregularities at the boundaries and smooth out potential "jagged patterns" in the subareas. For this purpose, each leaf is evaluated in the context of its neighborhood, where the majority subarea is determined based on the adjacent leaves. If flipping the respective leaf into this dominant subarea is feasible without violating global constraints, the adjustment is executed. Overall, this methodology combines a heuristic, random-based approach with multi-criteria evaluation and a local smoothing algorithm. It is primarily designed for an accelerated process and simpler building floor plans. However, for more complex geometries and additional boundary conditions, such as window positions specified in an LoD3 standard, a different algorithm is currently under development. This algorithm will employ graph partitioning to address the optimization problem.

2.3 Enrichment and simulation

For the thermal simulation of buildings, the methodology presented in 2.2 is embedded in the TEASER framework (Remmen et al., 2018) and the Modelica library AixLib (Müller et al., 2016). TEASER, a Python-based program, automates the parametrization of building models according to VDI 6007-1 (2015) and utilizes data such as construction type, year, and material properties derived from the German TABULA typology (Loga et al., 2016). Additionally, features such as the set temperature and the usage conditions of each zone are defined. Through its interface with AixLib, the model is converted into a Reduced-Order Model (ROM), which represents thermally conductive components using resistance-capacitance (RC) elements. To allow heat exchange between zones, we follow the approach of Groesdonk et al. (2023), which extends the ROM by adding an additional RC element per zone. This enables the simulation of interzonal heat transfer in cases of temperature differences or adjacent unheated zones. If the building model lacks window information, window areas are determined by considering wall-to-window ratios from the TABULA database and the available external walls, taking adjacent buildings into account. Furthermore, internal gains can be provided via an external model for residential energy consumption as an alternative to the standardized approach. The LoadProfileGenerator (LPG) (Pflugradt et al., 2022) determines profiles for occupants, machinery, or lighting based on Markov chains, allowing a more accurate representation of human behavior and the associated internal gains. The LPG simulates the activities of individual households, which we then distribute across the zones, allowing us to assign each household to a specific subarea. Fig. 2 provides an overview of the study's workflow.

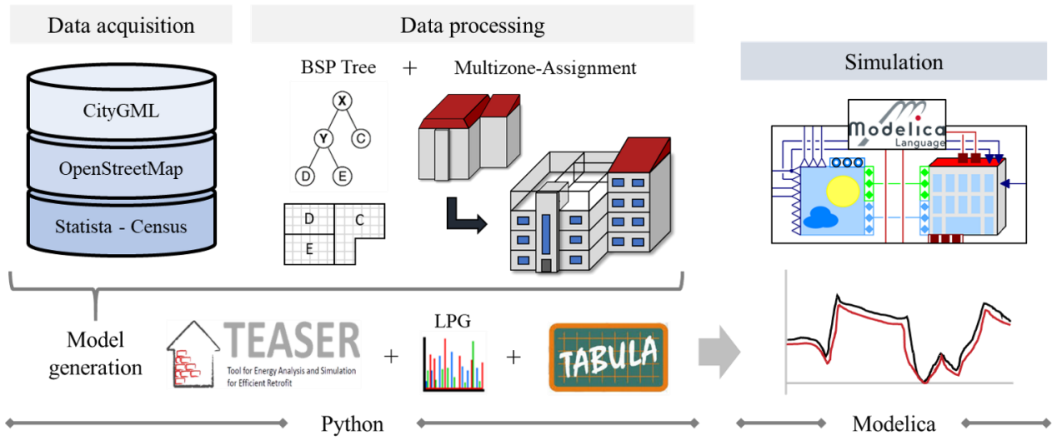

Figure 2. Schematic overview of the process.

3. FIRST RESULTS AND DISCUSSION

The partitions shown in Fig. 3 represent the results of applying the previously discussed sequence of methods for automatic zoning. We processed the GML models of three different apartment blocks (A-C) and three different apartment buildings (D-F). Additionally, a second version was created for each floor plan (specified as "-2"), either generating a predefined number of partial areas or applying a different weighting factor for the objective function. All samples were generated with a total of 200 iterations for the assignment of leaves, as determined through experiments. Increasing the number of iterations beyond this value does not generally improve results, while reducing it, for structures such as in example C, fails to produce sufficiently valid

results for satisfactory zoning (e.g., isolated inclusions). The algorithm demonstrates its ability to produce consistent zonings for most base areas. The equality of areas is preserved across all samples, although certain zone boundaries tend to exhibit irregularities. These include narrow elements, as observed in A-1 and B-1, as well as unsatisfactory handling of the "jagged pattern," as seen in F-1 and E-2. The postprocessing step requires further refinement to better identify and adapt these cases more effectively and accurately.

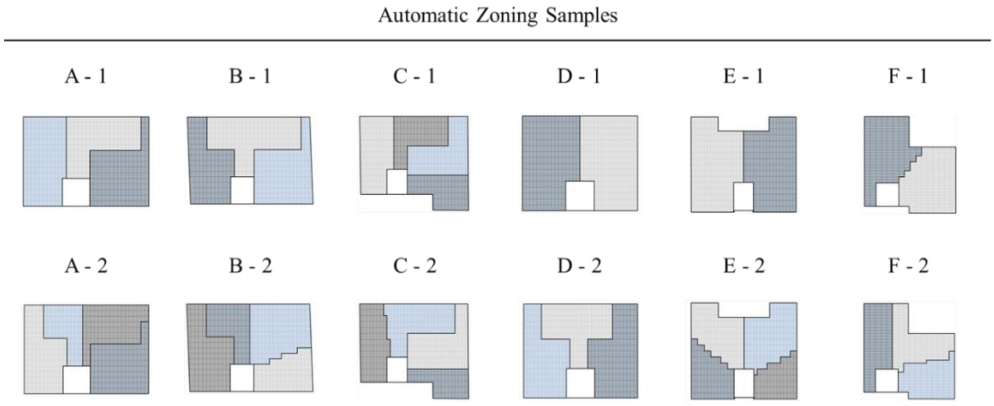

Figure 3. Results for the automatic zoning process for six different floor plans (staircase in white) with $\alpha = 2.0$ (except for C - 2 ($\alpha = 1.0$)) and predefined number of subareas for "-2".

Although the advantages of zoning with dynamic occupancy profiles and variable setpoints per dwelling have been extensively discussed in other studies (see, e.g., Kühn et al. (2024) for a detailed analysis of zoning effects and LoD variation), the results of a dynamic thermal simulation for the building depicted in Fig. 3 (E-1) are presented in Fig. 4-6. We simulated a total of four variants: Variant Multizone A corresponds to the partitioned building with an unheated stairwell, Multizone B includes a heated stairwell, Variant C incorporates usage profiles from the LPG with an unheated stairwell, and the final variant represents a single-zone model. For the weather data, a Test Reference Year (TRY) for the city of Aachen from 2015 was used. Unless otherwise specified, a setpoint temperature of 20 °C was assumed for all zones. An ideally operating heater was modeled for all variants, combined with a standard construction type from the Tabula database. An ideal cooler was not considered, since we primarily focus on the heating demand. The modeling (data acquisition and processing) as well as the simulation were executed on an i7-1370P CPU (1.90 GHz, RAM 16 GB). The figures show that the Multizone models exhibit a heat demand curve with an increased number of steep demand peaks. Notable peaks, particularly around midday, are clearly visible, whereas the single-zone model does not display these peaks to the same extent. It is evident that the single-zone model has the lowest annual heat demand of all versions. This may be attributed to the Reduced-Order Model for larger buildings, which tends to underestimate the internal mass of the building, thereby reducing the heat demand (see also Jansen et al., 2021). Additionally, significant differences in simulation time are apparent. While the modeling remains below 20 seconds for all models, the simulation time for the Multizone model, including heat transfer, increases substantially up to 750 %. This can pose challenges when simulating a large number of buildings. Nonetheless, considering the Multizone model offers advantages for scenarios with varying occupancy profiles and setpoints.

It accounts more accurately for demand peaks and provides a more precise representation of

dynamic processes (as demonstrated in variant C), both of which are critical for the design and operation of an energy system, such as ensuring sufficient capacity during high-demand periods in winter when heating requirements significantly increase. It is evident that the individual zones contribute not only differently to the peak demand during colder periods (see Fig. 5) but also, particularly on summer days (Fig. 6), to an increased overall heat demand. The zoning also indicates that cooling specific areas is becoming more important due to a spread in overheating zones. Temperatures exceeding 28 °C are reached for certain zones, while in the single-zone model, values above 25 °C are rarely found during the same period.

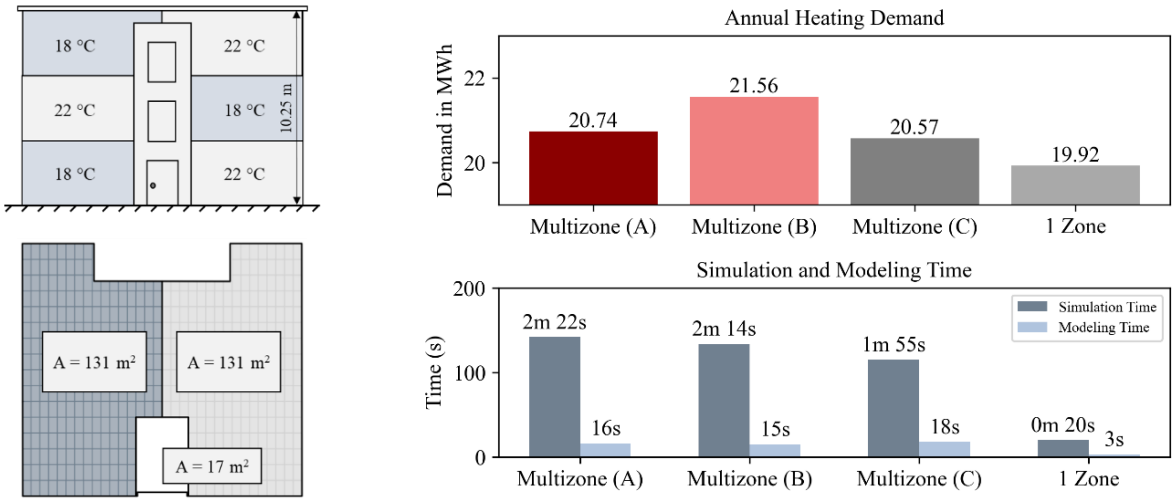

Figure 4. Front and top view of the building with varying set temperatures (left), annual heating demand, simulation and modeling time (right).

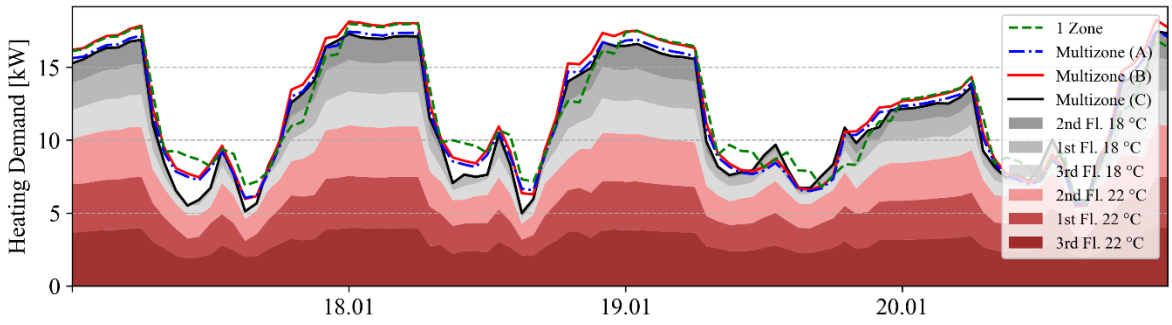

Figure 5. Heating demand comparison over a four-day time span for four different variants and stacked heating demand for the Multizone (C). Multizone (C) demand contributions are ordered from highest (dark red) to lowest (dark gray).

Regarding the zoning methodology and its functionality, some additional points require discussion. There are regional and age-related differences in the layout and construction of apartment buildings, including variations in staircase and corridor dimensions, as well as differences in apartment size and orientation. These assumptions must be carefully considered, as they significantly influence the simulation results. Furthermore, the most advantageous granularity of the zones must be considered in terms of the trade-off between accuracy and effort. While

Jansen et al. have already analyzed this for an office building, they, like Kühn et al., refer only to more complex models as a reference. However, a comprehensive examination and validation of this aspect for residential buildings using real measurement data remains open and should be pursued in the future. Moreover, the location of the stairwell can vary, potentially being positioned away from the street-facing side or located in a corner of the building.

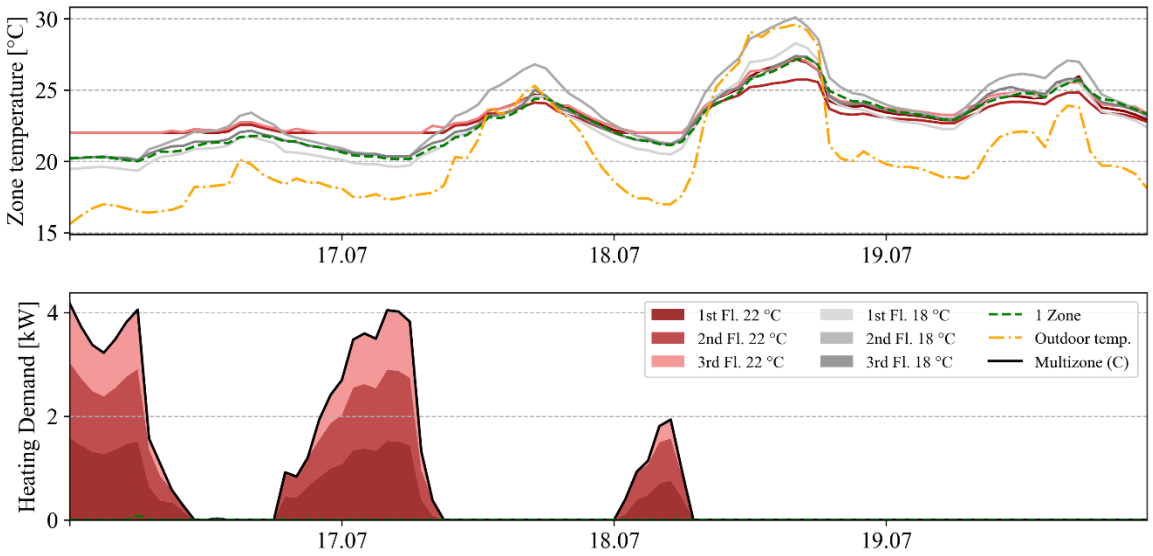

Figure 6. Zone temperature curves (above) and heating demand comparison over a four-day time span Multizone (C) and single zone (below).

These variations affect the zoning configuration and may distort heat demand results. Large apartment blocks present a significant challenge due to the increased number of apartments, which substantially raises simulation effort. Additionally, LoD2 models lack window areas in their GML data, leading to inaccuracies when assigning windows to walls that do not actually have them. Addressing this issue without image evaluations is not feasible.

4. CONCLUSION AND FUTURE WORK

This study focuses on the automatic partitioning of building models into individual residential units to improve heat load calculations. The Multizone Assignment Algorithm utilizes open-source data to enhance building models and is integrated into a thermal simulation environment within the TEASER-AixLib framework. The methodology is primarily designed for analyzing heat demand in smaller areas or specific applications, rather than large districts or entire cities. From a computational perspective, the single-zone model is the most resource-efficient option for large-scale observations. In contrast, the zoning approach targets small to medium-sized districts emphasizing dynamic factors like varying temperature setpoints and diverse occupancy profiles. This methodology aims to simplify building partitioning, especially when architectural data is limited, allowing users to model and parameterize buildings more easily. Future enhancements could include synergies with other algorithms, such as refurbishment status recognition or weather-related factors. Application scenarios may involve energy efficiency assessments for retrofitting buildings or demand response strategies for managing peak loads in urban planning. Further work

will primarily focus on refining the methodology's structure and conducting extensive validation using real buildings. Additionally, an export function for the generated models is planned, enabling not only the preservation of model configurations but also ensuring applicability beyond the scope presented in this study.

SUMMARY
Polycyclic aromatic hydrocarbons (PAHs) are known for their high toxicity and pose significant threats to human health, with vehicular traffic being a prominent source. Between October 2021 and September 2022, a comprehensive study was carried out along Beijing's roadside. The findings indicated that during winter, the concentration of PAHs in $PM_{2.1}$ peaked at 35.3 ng m^{-3}. Moreover, the leaves of 20 plant species exhibited diverse PAH levels, and it was observed that low-molecular-weight PAHs were more abundantly present in plant leaves of *Rosa chinensis* Jacq. Leaves were exposed to 0.1 μg $L^{-1}$and 5 μg L^{-1} PAHs for seven days, with de-ionized water serving as the control. The results demonstrated that the 5 μg L^{-1} treatment led to pronounced gene expression changes across seven pathways. In contrast, the environmentally relevant concentrations of PAHs had minimal effects on the leaves of *R. chinensis*. Collectively, these findings provide strong evidence in support of leveraging terrestrial trees to mitigate PAH pollution.
Keywords: ambient PAHs; roadside environment; phytoremediation mechanism

1. INTRODUCTION

Polycyclic aromatic hydrocarbons (PAHs), characterized by their teratogenic, carcinogenic, and mutagenic properties as recognized by the World Health Organization (WHO)(Cave et al. 2016), primarily emanate from the incomplete combustion of fossil fuels and hydrogen-containing materials such as wood, crop residues, and tobacco. Mobile sources, biomass combustion, and coal burning constitute the principal emission pathways(Wang et al. 2017). Notably, China's PAHs emissions account for approximately 20% of the global total. In North China, the mean annual particulate BaP (a paradigmatic PAHs) concentrations range from 1.1 to 14.3 ng m^{-3}, surpassing the WHO-recommended threshold of 1.0 ng m^{-3}(Shen 2019), thereby posing significant risks to public health and eliciting ecological toxicological impacts on the ecosystem.

The ecological remediation approach, leveraging trees and plant leaves, has emerged as a cost-effective and sustainable means to attenuate the high-toxicity PAHs in the ambient milieu. Trees function as sieves for PAHs, while plant leaves can be regarded as reactors for their removal. Prior investigations have demonstrated substantial air pollutant removal capacities. For instance, in 55 cities across the United States, trees were estimated to eliminate approximately 710,000 tons of air pollutants, inclusive of NO_2, SO_2, and particulate-bound contaminants(Nowak, Ellis and Greenfield 2022). Based on 150 field studies spanning 15 countries from 1960 to 2016, plant leaves were found to absorb around 1.71 ± 0.05 g m^{-2} of particulate air pollutants per week(Corada et al. 2020). Research on PAHs accumulation in species such as *Quercus palustris* and *Pinus nigra* has

elucidated correlations between leaf PAHs concentrations and ambient air, with discernible variations in PAHs levels contingent upon tree age and seasonal fluctuations(Fellet et al. 2016). The epicuticular waxes of leaves are deemed pivotal in PAHs sequestration.
The majority of PAHs ingress plant leaves via stomatal openings, wherein lipid constituents within the waxes engage in adsorptive interactions with ambient PAHs. Subsequently, the adsorbed PAHs traverse the leaf surface through the stomata and translocate to the internal leaf tissues. Previous studies have also documented the PAHs-mitigating capabilities of trees and the mechanisms underlying PAHs entry into leaf tissues(De Nicola et al. 2017). However, the toxicological ramifications of PAHs on plant leaves during their migration from the ambient environment to the internal tissues remain relatively understudied. The present study endeavors to bridge this knowledge gap by employing whole-transcriptome analysis to scrutinize the responses of plant leaves upon exposure to environmentally relevant and elevated levels of PAHs. By doing so, this research will amass evidence regarding the physiological and pathological responses of plants to ambient PAHs, thereby augmenting our comprehension of the plant-PAHs interplay and the potential of ecological remediation strategies.

2. MATERIALS AND METHODS

2.1. Sampling collection

Samples were collected from October 1, 2021, to September 30, 2022. The sampler was placed 1.5 m above the ground on the side road of the West Third Ring Road, within a commercial and cultural area. There were many roads in the vicinity, but no significant primary PAHs sources like industrial ones within several kilometers. Its proximity to the main urban highways made it suitable for representing a roadside environment.
An 8-stage sampler (Andersen Series 20-800, Cleves, USA) with cutoff points from 0.43 to 9.0 μm was operated at a flow rate of 28.3 L^{-1} min for 48 hours to collect size-resolved particles. Over 70% of the samples could detect the target PAHs compounds within 48 hours. A total of 35 sets of samples were collected on quartz fiber filters. Before sampling, the filters were preheated at 450°C for 2 hours to remove organic substances.
In July 2022, leaves of 20 tree species were collected along Beijing's West Third Ring Highway. For each species, three similar-sized and aged healthy trees were chosen. Around 100 leaves per set were gathered from the highway-facing side, placed in polyethylene bags, and transported to a 4°C laboratory for further study.

2.2 Chemical analyses

Mixed standards of 24 PAHs at 500 mg L^{-1} were used for a stock standard solution for PAHs quantification in leaves and particles, which includes naphthalene, acenaphthylene, acenaphthene, fluorine, phenanthrene, anthracene, fluoranthene, pyrene, benzo(a)anthracene, chrysene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(e)pyrene, indeno(1,2,3-cd)pyrene, dibenzo(a,h)anthracene, benzo(g,h,i)perylene, benzo(c)phenanthrene, 7,12-dimethylbenz(a)anthracene, benzo(j)fluoranthene, benzo(e)pyrene, 3-methylcholanthrene, picene, dibenzo(a,l)pyrene, and dibenzo(a,i)pyrene. Two substitutes including 2-fluorophenyl and terphenyl-d14 concentrated at 4000 mg L^{-1} were adopted to evaluate the efficiencies of extraction

processes. A solution of five compounds including naphthalene-d8, acenaphthene-d10, phenanthrened10, chrysene-d12, and perylene-d12 at 4000 mg L^{-1} was selected as the internal standard.

2.3 Exposure experiments

One-year-old healthy *Rosa chinensis* Jacq. were selected and planted in 15-cm pots with a 12L:12D photoperiod. Three groups were set: control, low ($0.1 \mu g L^{-1}$), and high ($5\ \mu g L^{-1}$) concentration exposure groups. The exposure reagent was a mixture of 16 commonly detected PAHs. Different concentration solutions were prepared. Considering leaves contain methanol (10-26.8 $\mu g\ g^{-1}$), the methanol levels in the exposure groups (about $25 \mu L\ L^{-1}$ and $0.5\ \mu L\ L^{-1}$ respectively) had negligible impacts on leaf physiology. Each group had 4 replicates. Leaves were washed with de-ionized water before the experiment. The exposure groups were sprayed with corresponding PAHs concentrations daily, while the control group used de-ionized water on similar leaves. Daily measurements of chlorophyll, water content, and nitrogen in leaves were averaged. Given the PAHs half-life on leaves, the experiment was conducted at 18-20°C and 40%-50% humidity for 7 days. Then, 5 g of leaves from each low and high-concentration group were collected and stored at -80°C for transcriptomic sequencing.

2.4 Transcriptome sequencing and bioinformatic analyses

The RNA Nano 6000 Kit was used to assess the quantity and integrity of leaf RNA. Starting with total RNA, through steps like mRNA purification, fragmentation, cDNA synthesis, end treatment, adapter ligation, fragment screening, PCR, and product purification, 150 bp paired-end reads were generated on the Illumina Novaseq platform.
Raw data were processed by fastp software to obtain high-quality data for subsequent analyses. The reference genome files were downloaded, and Hisat2 was used for alignment. StringTie assembled the reads, Counts counted, and FPKM was calculated to evaluate gene expression. DESeq2 analyzed differential genes, and the p-values were corrected. Genes with an adjusted $p \leq 0.05$ were considered differentially expressed. The cluster Profiler R package was used to test the enrichment of differential genes in KEGG pathways.

3. RESULTS AND DISCUSSION

3.1. Seasonal variation in PAHs

The mean levels of 24 species of PAHs in fine particles ($PM_{2.1}$) exhibited obvious seasonal variations (Fig. 1), with the greatest found in winter (35.3 ± 14.6 ng m^{-3}), followed by autumn (16.0 ± 6.1 ng m^{-3}), spring (15.3 ± 4.6 ng m^{-3}), and summer (6.5 ± 1.8 ng m^{-3}). The seasonal trends of average PAHs concentrations in coarse particles ($PM_{2.1-9}$) differ from those of $PM_{2.1}$ slightly. The highest concentration of PAHs was detected in winter (20.5 ± 10.3 ng m^{-3}), followed by spring (16.5 ± 7.4 ng m^{-3}), autumn (7.1 ± 5.2 ng m^{-3}), and summer (6.8 ± 4.5 ng m^{-3}). The high concentrations of PAHs in coarse particles in spring may be related to the high concentration of dust in spring. The seasonal trends in PAHs mainly resulted from variations in emission sources and changes in meteorological conditions. Compared to previous studies in Beijing, the

concentrations of PAHs in fine particles in winter were lower relative to the results reported during the periods from 2013 and 2018(Li et al. 2022). The reduction in concentrations of PAHs implied the effectiveness of pollution prevention strategies in Beijing.

From the perspective of PAHs with different benzene rings, concentrations of low molecular-weight PAHs (2–3 ring, LMW PAHs) and middle molecular-weight (4 ring, MMW PAHs) PAHs in fine particles followed the order of winter > spring > autumn > summer, while concentrations of high molecular-weight PAHs (5–6 ring, HMW PAHs) were higher in autumn and winter compared to those in spring and summer. HMW PAHs (29.0–45.7%) and MMW PAHs (22.0–36.3%) were the main PAHs compounds during the cold period, while LMW PAHs (47.9–57.5%) dominated the PAHs mixture during the warm period. LMW PAHs in coarse particles exhibited the highest concentrations in spring, followed by winter, summer, and autumn. However, MMW PAHs showed the highest concentration in winter, followed by spring, summer, and autumn. Notably, the levels of HMW PAHs were found to be greater in autumn and winter than in spring and summer. The contributions of LMW PAHs (36.9–71.9%) to total PAHs in coarse particles were higher than that of MMW and HMW PAHs in all seasons.

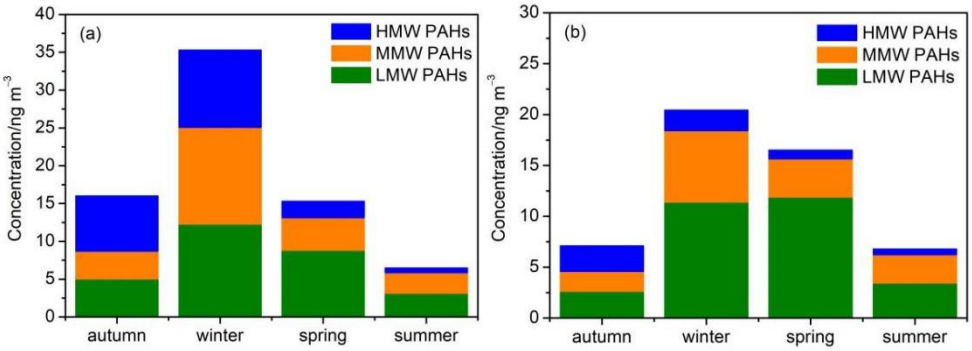

Figure 1. Concentrations of PAHs in $PM_{2.1}$ (a) and $PM_{2.1–9}$ (b)
(Note: originated from Tian *et al.*, Atmosphere, 2024, 15, 346, Figure 1)

3.2. Differences in the accumulation of PAHs across plant species

The highest concentration of total PAHs was found to be 68.4 ng g^{-1} in the leaves of *Ginkgo biloba* L., followed by *Viburnum sargentii* (67.1 ng g^{-1}), *Robinia pseudoacacia* (65.9 ng g^{-1}), *Platanus* × *acerifolia* (58.1 ng g^{-1}), *Sophora japonica* (54.1 ng g^{-1}), *Populus tomentosa* (53.1 ng g^{-1}), *Salix matsudana* (48.4 ng g^{-1}), *Salix babylonica* (47.8 ng g^{-1}), *Ailanthus altissima* (43.7 ng g^{-1}), *Broussonetia papyrifera* (43.2 ng g^{-1}), *Lonicera maackii* (42.1 ng $g^{-}1$), *Paulownia fortune* (40.9 ng g^{-1}), *Fraxinus chinensis* (40.7 ng g^{-1}), *Acer mono* (38.6 ng g^{-1}), *Ulmus pumila* (36.7 ng g^{-1}), *Prunus triloba* (35.7 ng g^{-1}), *Prunus cerasifera* (32.7 ng g^{-1}), *Chaenomeles speciosa* (26.7 ng g^{-1}), *Jasminum nudiflorum* (23 ng g^{-1}), and *Prunus persica* (12.4 ng g^{-1}) (Fig. 2).

The adsorption amounts of PAHs on leaves are associated with several environmental factors (Klingberg et al. 2022). Among 20 trees, the occurrences of naphthalene, fluorene, fluoranthene, and pyrene were detected in the leaves of 20 trees with an average concentration in the range of 2.0–7.8 ng g^{-1}, while most PAHs congeners, including acenaphthylene, acenaphthene, anthracene, benzo(g,h,i)perylene, benzo(c)phenanthrene, benz(a)anthracene, benzo(k)fluoranthene, 7,12-dimethylbenz(a)anthracene, benzo(j)fluoranthene, benz(e)pyrene, perylene, 3-methylcholanthrene, dibenz(a,h)anthracene, picene, benzo(g,h,i)pery, dibenz(a,l) pyrene, dibenz(a,e)pyrene, coronene, dibenz(a,i)pyrene, and dibenz(a,h)pyrene, were not detected (<0.5

ng g^{-1}) in the leaves of 20 trees. The highest number of detected species of PAHs congeners was eleven in an individual tree among 20 species of trees, while the lowest number of detected species of PAHs congeners was five in the leaves of *Prunus persica*. The contribution of low-ring (i.e., the sum of two-ring and three-ring) PAHs accounted for the total PAHs in the range from 37% to 71%, while medium-ring (i.e., four-ring) and high-ring PAHs (i.e., the sum of five-ring and six-ring) contributed to the total PAHs ranging from 20% to 47% and from 5% to 13%, respectively (Fig. 2).

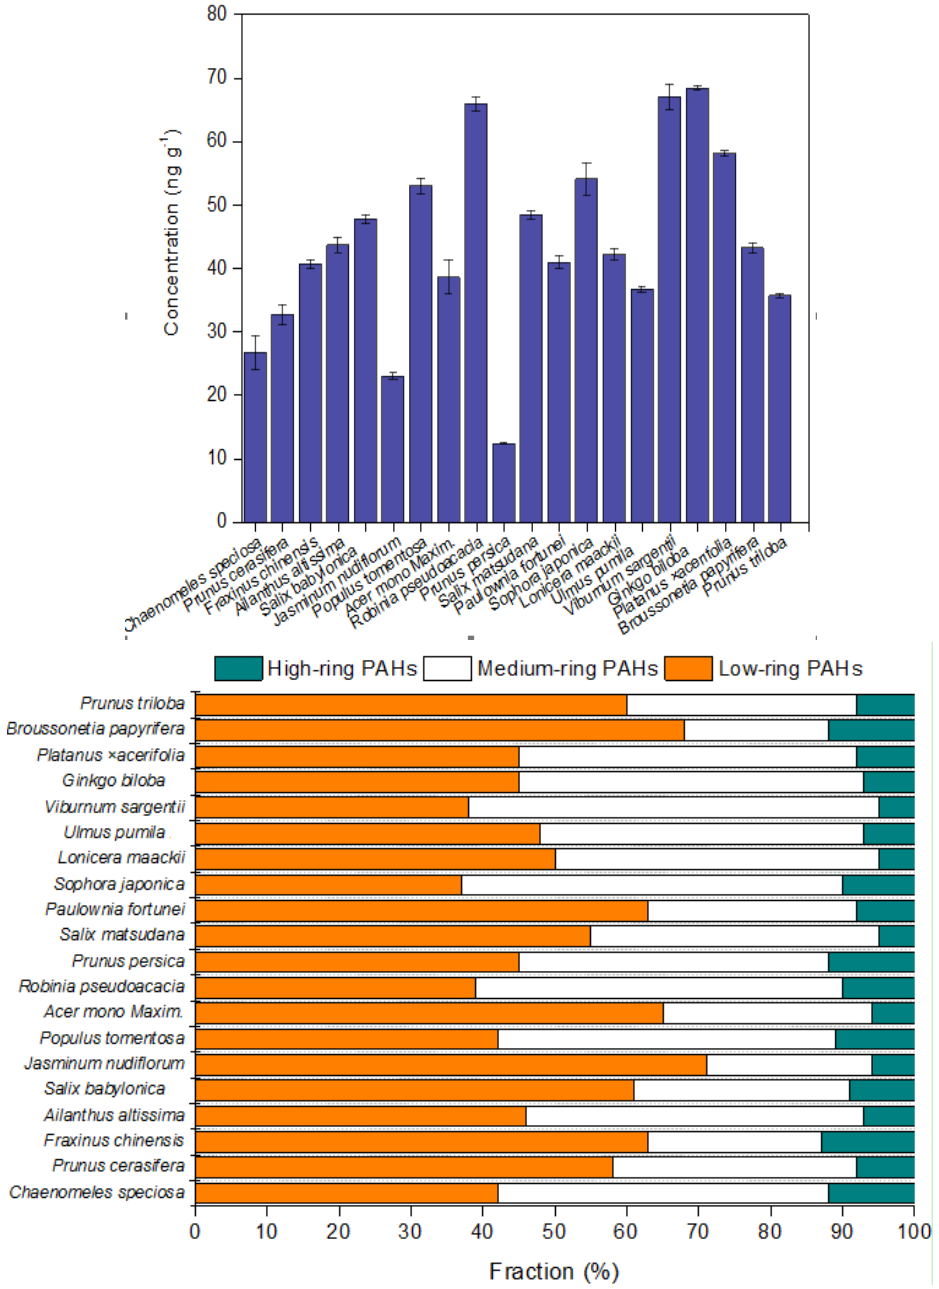

Figure 2. Concentrations of PAHs in 20 tree leaves

(Note: originated from Yang *et al.*, Atmosphere, 2024, 15, 1165, Figure 1 and Figure 2)

3.3. Differentially expressed genes

We used the concentrations of individual PAHs at 5 μg L^{-1} to investigate the responses of leaves under exposure to PAHs at a high concentration. As shown in Fig.3, significant differences in expressed genes were observed after 7 days of exposure between the high-concentration exposure group and the control group. The numbers of upregulated and downregulated genes of the high-concentration exposure group relative to the control group were 1150 and 5502, respectively. It is noteworthy that the concentrations of individual PAHs in the exposure group were much higher than the levels of individual PAHs at the environmentally relevant concentration in this study(Tian et al. 2019). After exposure to individual PAHs at 0.1 μg L^{-1} for seven days, differences in expressed genes between the low-concentration exposure group and the control group were found to be insignificant. The numbers of upregulated and downregulated genes were 112 and 195, respectively.

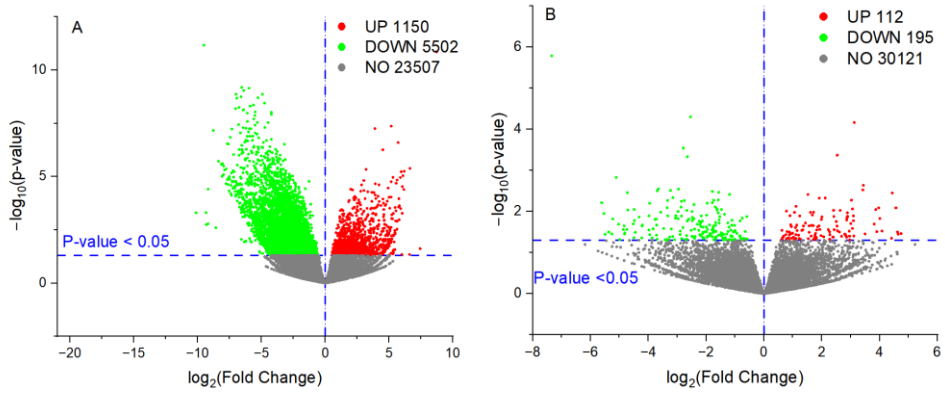

Figure 3. Number of upregulated and downregulated genes for high-concentration exposure group relative to the control (**A**) and low-concentration exposure group relative to the control (**B**)
(Note: originated from Tian *et al.*, Toxics, 2023, 11, 610, Figure 2)

3.4. KEGG enrichment analysis

Subsequently, we performed KEGG enrichment analysis to show which genes or pathways that the differentially expressed gene cluster was in. KEGG is a comprehensive database that integrates genome, chemistry and system function information(Sangwan et al. 2013). A padj of less than 0.05 was used as the threshold for significant enrichment. For the comparison between the high-concentration exposure and the control group, significant differentially expressed genes were assigned into seven main pathways, which included flavone and flavonol biosynthesis, glyoxylate and dicarboxylate metabolism, RNA polymerase, ribosome biogenesis in eukaryotes, porphyrin metabolism, photosynthesis-antenna proteins and photosynthesis (Fig.4).
In contrast, there were no significant differentially expressed genes in the KEGG enrichment analysis between the low-concentration exposure group and the control group (Fig. 4). In general, the gene transcription levels obtained from the KEGG enrichment analysis exhibited a similar pattern and degree of alterations in comparison to the physiological results, thereby demonstrating that the responses of leaves to exposure to PAHs at environmentally relevant concentrations were negligible.

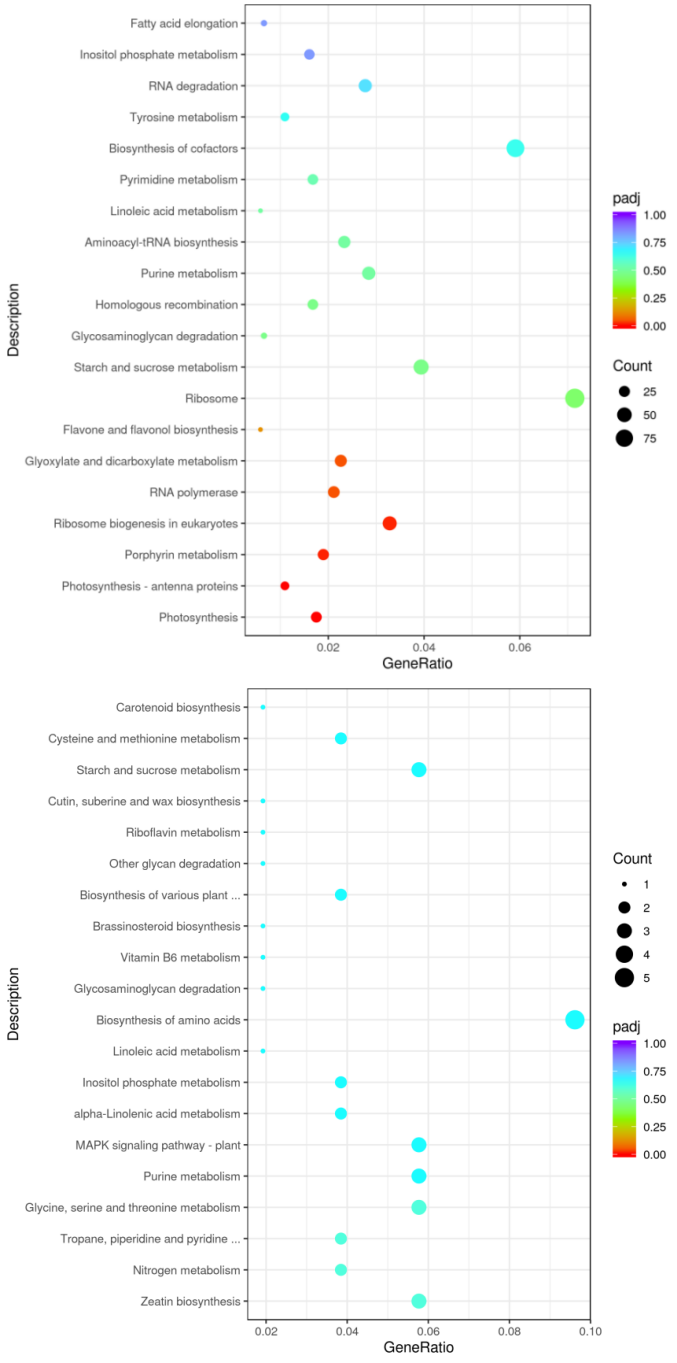

Figure 4. KEGG enrichment analysis of high and low-concentration exposure group relative to the control group. Scatter plot of KEGG enrichment, showing all pathways significantly enriched ($p < 0.05$) in each module （Note: originated from Tian *et al.*, Toxics, 2023, 11, 610, Figure 3 and Figure 4）

4. CONCLUSIONS

In this study, 24 species of PAHs in size-segregated particles and 20 species of plant leaves at the roadside environment of Beijing were observed. The levels of total PAHs across 20 tree species ranged from 12.4 ng g^{-1} to 68.4 ng g^{-1}. After exposure to PAHs at 5 μg L^{-1}, significant differences in the gene transcription levels of the leaves of *Rosa chinensis* Jacq. were observed relative to the

control group. These significant differentially expressed genes pertain to seven main pathways, which are flavone and flavonol biosynthesis, glyoxylate and dicarboxylate metabolism, RNA polymerase, ribosome biogenesis in eukaryotes, porphyrin metabolism, photosynthesis-antenna proteins, and photosynthesis. On the contrary, environmentally relevant concentrations of PAHs had no significant effect on the physiological parameters and gene transcription levels of the leaves of *Rosa chinensis* Jacq. during the 7-day exposure period in this study. Our results illustrate that exposure to ambient PAHs may have a negligible impact on the leaves of terrestrial plants at gene transcription levels. The findings of our study highlight the important roles of terrestrial plants in regulating ambient PAHs.

SUMMARY
Climate change and rapid urbanization have increased the risk of urban flooding, creating challenges for cities such as Rotterdam and Chennai. To address these flood threats and improve urban resilience, this study focusses on the construction of an urban digital twin under the Resilient Hydro Twin (RHT) project. RHT is designed to support decision-makers and urban planners in enhancing flood preparedness and response strategies. The platform features interactive visualizations and a web-based dashboard, enabling users to analyse flood scenarios, assess blue-green infrastructure strategies and soft adaptation measures, and contribute to data-driven policy decisions. Initial results indicate that the system may improve collaboration, enhances data accessibility, and facilitates participatory flood risk management. This work-in-progress research highlights the potential of digital twins in fostering interdisciplinary flood resilience strategies.

Keywords: digital twin, flood simulation, urban resilience, stakeholder participation

1. INTRODUCTION

Urban flooding is an increasingly critical challenge as climate change accelerates the frequency and intensity of extreme weather events (Pour et al., 2020). This challenge is particularly critical for vulnerable cities such as Rotterdam and Chennai, where flood control has been a vital concern for centuries due to their geographic and climatic conditions. Rotterdam, as a low-lying delta city, has historically relied on advanced flood management systems such as the Delta Works to mitigate risks (Klijn et al., 2015), while Chennai faces recurrent urban flooding exacerbated by rapid urbanization and monsoon variability, necessitating improved drainage and water governance (Singh et al., 2023). With rapid urbanization, cities face growing exposure to flood risks, highlighting the need for more advanced flood management strategies that integrate real-time data, predictive modelling, and stakeholder engagement.

Traditional flood risk assessment methods rely heavily on hydrological models and static flood maps, often lacking the dynamic capabilities required for proactive decision-making (Ward et al., 2015). Recent advancements in digital twin technology offer an opportunity to transform urban flood resilience by providing a data-driven, interactive, and continuously updating representation of flood risk scenarios (Batty, 2018; Dembski et al., 2019). Digital twins allow the integration

of multi-source data, such as hydrological models, GIS, BIM, and real-time IoT sensor networks, facilitating real-time monitoring and improved collaboration between stakeholders.

Despite the potential of digital twins in flood risk management, significant challenges remain in ensuring effective stakeholder participation, data integration, and system scalability (Ge and Qin, 2025). Many existing flood models are designed primarily for hydrologists and engineers, often requiring specialised knowledge that limits accessibility for policymakers, urban planners, emergency responders, and the general public (Gralepois, 2020). In addition, integrating heterogeneous data sets, including real-time hydrological monitoring, urban infrastructure data, and behavioural flood models, remains a complex technical challenge (Yan et al., 2025). Addressing these challenges requires a system that not only improves predictive accuracy but also enhances multi-stakeholder engagement by making flood risk data more transparent, interactive, and actionable.

In these contexts, the Resilient Hydro Twin (RHT) project aims to explore how the implementation of a digital twin in water disaster management can enhance the overall urban resilience of a city. This will be achieved through the development and integration of a digital twin, stakeholder cooperation, and resilience building strategies. This paper presents RHT, which is designed to bridge the gap between data-driven flood modelling and stakeholder-driven decision making. Built on a modular architecture, the system will induce hydrological simulations, GIS-based flood mapping, and infrastructure analysis. This approach enables different user groups to interact with flood risk data according to their specific needs. The platform aims to facilitate collaborative decision making by allowing stakeholders to visualise flood scenarios, run predictive simulations, and explore alternative mitigation strategies based on blue-green infrastructure, soft adaptation measures, and adaptive planning solutions.

This study focusses primarily on the role of stakeholder participation in the development and deployment of the RHT platform. In particular, it emphasises the identification of relevant stakeholders involved in urban flood resilience and the systemic listing of their user and software requirements. By engaging multiple stakeholders from the outset, the platform aims to provide a more inclusive and accessible decision support system that extends beyond technical experts to include policymaker and urban planners.

The early results of the implementation suggest that the system facilitates improved collaboration by reducing disciplinary silos, enhancing data accessibility, and providing interactive tools for flood risk assessment. The following sections detail the methodology used to define stakeholder requirements and develop the system architecture, discuss preliminary results on user engagement, and outline future directions. By addressing both the technical and participatory challenges of digital twin applications in flood resilience, this study aims to advance the role of data-driven decision making in urban flood risk management.

2. METHODOLOGY

This study adopts a multi-phased methodological approach to guide the development of the Resilient Hydro Twin (RHT) platform. The process begins with the identification of relevant stakeholders engaged in urban flood resilience, followed by the gathering of user and software require-

ments, the design of a modular system architecture, and iterative co-design activities for platform refinement. The methodology emphasizes stakeholder-centered design, technical feasibility, and system scalability to ensure the platform's adaptability in real-world contexts.

2.1. Stakeholder identification

The identification of stakeholders formed the foundational step in the development of the Resilient Hydro Twin (RHT) platform. Recognising that flood resilience involves a wide array of actors with varying roles and responsibilities, the research adopted a structured approach to stakeholder mapping. The stakeholders were initially identified through a series of collaborative workshops involving consortium partners and domain experts. These sessions aimed to determine the actors involved in flood resilience efforts. To complement this, brainstorming sessions were held to refine and categorise stakeholders based on thematic areas such as planning, hydrological modelling, infrastructure management, and governance. Then a dedicated stakeholder mapping document was developed in collaboration with the project partners. This document systematically linked stakeholder groups to specific components and activities of the RHT project, enabling a clear understanding of their relevance and expected interactions with the platform.

2.2. Determining the User and Software Requirements

Following stakeholder identification, the next phase involved the systematic gathering of user requirements and the finding out the corresponding software requirements. User needs were gathered through workshops conducted during the early stages of the project. To ensure that the platform met the real-world expectations of its users, user stories were collected during these workshops. These user stories captured narrative scenarios describing how different actors intended to interact with the system, what problems they aimed to solve, and what kinds of outcomes they expected. These needs were classified into functional domains relevant to the core aims of the RHT platform, including traffic modelling, semantic city modelling, hydrological simulations, blue-green infrastructure planning, and stakeholder engagement.

The translation of user needs into concrete software requirements was guided by participatory design principles. Functional requirements were defined to describe specific capabilities the platform must offer to support each stakeholder group. Concurrently, non-functional requirements were identified to address broader system qualities such as interoperability, scalability, usability, and security. The MoSCoW prioritization method (Must-have, Should-have, Could-have, Won't-have) was employed to evaluate the relative importance of each requirement, ensuring that platform development was aligned with stakeholder priorities and constraints (Clegg and Barker, 1994).

2.3. System architecture

A modular system architecture (Figure 1) was designed to ensure flexibility, scalability, and maintainability within the RHT platform. The system is built using Django, a Python-based framework widely used for developing scalable and maintainable web applications. Django follows the Model-View-Template (MVT) architecture, organising the platform's logic into distinct layers to improve data management, request handling, and user interaction.

At the core of Django's architecture, the model represents the data structure and business logic, defining the entities and relationships stored in the database. The view layer is responsible for pro-

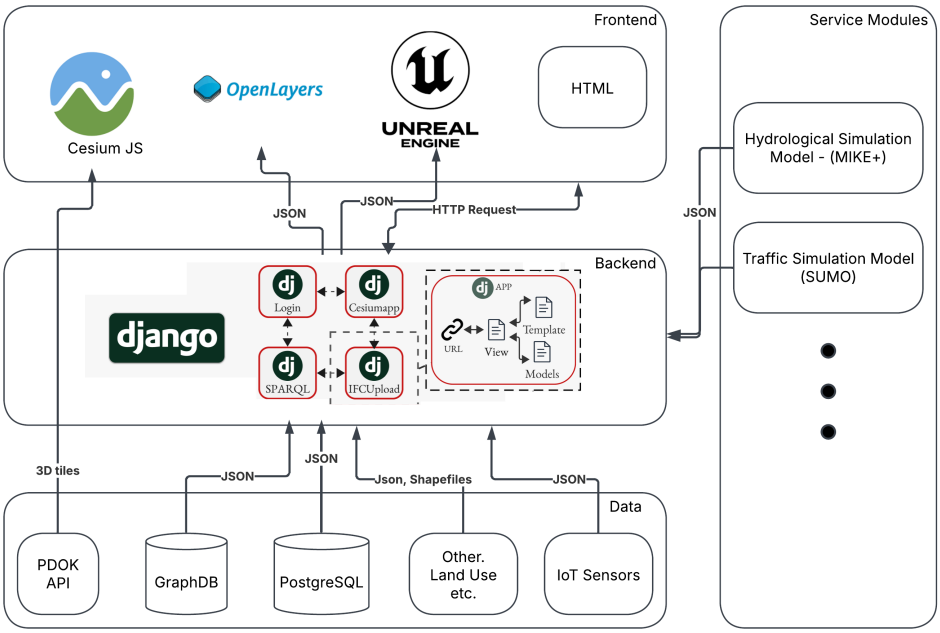

Figure 1. System Architecture.

cessing user requests, interacting with models, and generating appropriate responses. Views are defined as Python functions or classes, managing data retrieval, computation, and user authentication. The template layer is used for rendering dynamic HTML content, ensuring that users receive real-time updates and interactive visualisations. In Django-based applications, when a user makes a request, Django's URL resolver matches the request to the correct view function, which then queries the database, processes the logic, and renders the appropriate template. This structured flow ensures that the platform remains efficient and user-friendly, catering to multiple stakeholders with varying levels of technical expertise.

To ensure scalability, the platform follows a modular structure, where different applications are developed as independent units, each handling a specific functionality. Within the RHT, these modules correspond to key functional areas, such as traffic modelling, hydrological simulations, semantic city modelling, and blue-green infrastructure planning. Each module contains its own models, views, templates, and APIs, allowing for independent development, testing, and integration.

A PostgreSQL database stores foundational data, including login credentials, land use information, and GIS datasets. A graph database manages semantic relationships, enabling advanced data integration and querying. In addition, the system is designed to connect with various external APIs, such as PDOK which is an open data API of the Netherlands for geospatial data and IoT sensor networks, ensuring seamless data retrieval and dynamic flood prediction capabilities.

For front-end visualisation, Django integrates with CesiumJS to provide 3D geospatial mapping and with openlayers for 2D maps with GIS features, allowing urban planners, researchers, and

policymakers to interact with real-time flood scenarios. Additionally, RESTful APIs are implemented using Django REST Framework (DRF) to enable external system integration, allowing data exchange with hydrological modelling tools, GIS platforms, and urban planning dashboards.

3. RESULTS AND DISCUSSION

3.1. Stakeholder Groups and Platform Interaction

A key outcome of the early development phase of the RHT platform was the systematic identification and classification of stakeholders engaged in urban flood resilience. Stakeholders were grouped into five major categories: infrastructure engineers, water management agencies, urban planners, policymakers, and the general public. Each group demonstrated distinct functional needs and varying levels of technical expertise, necessitating tailored interfaces and access levels within the platform. Table 1 summarizes the functional focus and expected platform interactions for each group.

Table 1. Overview of RHT Stakeholders and their Platform Needs

Stakeholder Group	Functional Focus	Platform Needs and Interactions
Infrastructure Engineers	Traffic modelling during flood events	Simulate traffic disruptions, test evacuation scenarios, modify network parameters
Water Management Agencies	Hydrological modeling and drainage performance	Integrate and calibrate hydrological models, process real-time sensor data, run flood simulations
Urban Planner	Blue-green infrastructure and spatial planning	Evaluate nature-based adaptation strategies, conduct spatial analysis, integrate planning scenarios
Policymakers	Governance, regulation, and stakeholder coordination	Access regulatory scenarios, visualize historical and projected flood data, facilitate public engagement
General Public	Risk awareness and emergency readiness	View simple dashboards, receive flood alerts, understand neighborhood-specific flood risk

Functional requirements are collected after the review of user stories and they are structured around the core domains of the platform, including traffic modelling, semantic city modelling, hydrological simulations, blue-green infrastructure planning, and stakeholder engagement. These requirements are summarized in Table 2. In parallel, a comprehensive set of non-functional requirements was established to address system-level performance, data integration standards, and user experience criteria. These include aspects such as interoperability, scalability, usability, and security—essential for ensuring the platform's long-term adaptability and accessibility for users with varying technical backgrounds. These are presented in Table 3.

The resulting stakeholder-system relationships were also visualized through a platform use case diagram (Figure 2), which illustrates the key interactions between each stakeholder group and the functional modules they access. By aligning technical development with clearly articulated stakeholder narratives and requirements, the RHT platform advances a participatory and user-informed approach to digital twin system design. This ensures that the resulting tool remains relevant, functional, and inclusive for a broad spectrum of end users engaged in urban flood resilience planning and response.

3.2. Initial Results

The initial implementation of the platform has focused on stakeholder engagement workflows and collaborative data sharing. A preliminary version of the system has been deployed for internal

Table 2. Functional Requirements

Functional Area	Requirement Description	MoSCoW Priority
Traffic Modelling	The system shall integrate real-time traffic models to calculate the impact of flood events to road network.	Must have
	The system shall allow engineers to modify parameters and simulate different traffic scenarios.	Should-have
Semantic City Modelling	The platform shall integrate GIS and BIM data to create a structured urban flood risk model.	Must-have
	Users shall be able to query semantic city models.	Should-have
	Users shall be able to visualize flood defences in 3D.	Could-have
Hydrological Model Integration	The system shall integrate existing hydrological and hydraulic simulation models.	Must -have
	The system shall support real-time hydrological data input and processing from IoT sensors.	Could-have
	The platform shall allow users to run flood simulations and visualize projected inundation.	Could-have
Blue-Green Infrastructure Planning	The system shall allow urban planners to analyse flood mitigation strategies using blue-green infrastructure models.	Should-have
	Users shall be able to compare different nature-based flood adaptation strategies.	Should-have
Governance & Stakeholder Collaboration	The platform shall support multi-user collaboration, allowing different stakeholders to contribute to the Resilient Hydro Twin application.	Must-have
	The system shall include a stakeholder feedback module for collecting public insights on flood resilience measures.	Could-have

Table 3. Non-functional Requirements

Category	Requirement Description	MoSCoW Priority
Interoperability	The platform shall support open standards (e.g., IFC, CityGML) to ensure compatibility with external GIS and BIM systems.	Must-have
	The system shall allow exporting flood simulation results in commonly used formats such as GeoJSON.	Must-have
Scalability	The system shall be scalable to accommodate change in the scale of flood-prone areas without major architectural changes.	Should-have
	The system shall support integration with additional data sources, including external hydrological models and real-time APIs.	Must-have
Usability	The platform shall provide an intuitive, user-friendly interface for stakeholders with varying levels of technical expertise.	Must-have
Security	The system shall enforce role-based access control to prevent unauthorized access to sensitive data.	Must-have

testing. The early results indicate that the system has the potential to improve interdisciplinary collaboration by allowing stakeholders to work with a shared data environment. In addition to improving cross collaboration, the platform has enhanced stakeholder interaction and accessibility. The use of web-based interactive dashboards will make it easier for non-technical users, such as policymakers and community representatives, to engage with flood risk data. Public stakeholders can check flood risks and increase their awareness and readiness for an emergency.

Although the system provides a robust framework for stakeholder collaboration, several challenges remain in data integration and user adoption. Integrating heterogeneous datasets, including hydrological models, GIS layers, and sensor data, has proven complex. Furthermore, the need for increased automation in data preprocessing and scenario-based decision support was highlighted. The early findings suggest that the Resilient Hydro Twin has the potential to improve cross-sector collaboration and decision-making in urban flood resilience. However, several areas require further refinement. Expanding stakeholder participation will be a priority in future iterations of the platform, involving broader engagement workshops to gather more diverse feedback from local governments, environmental agencies and the private sector. Efforts are also underway enhance-

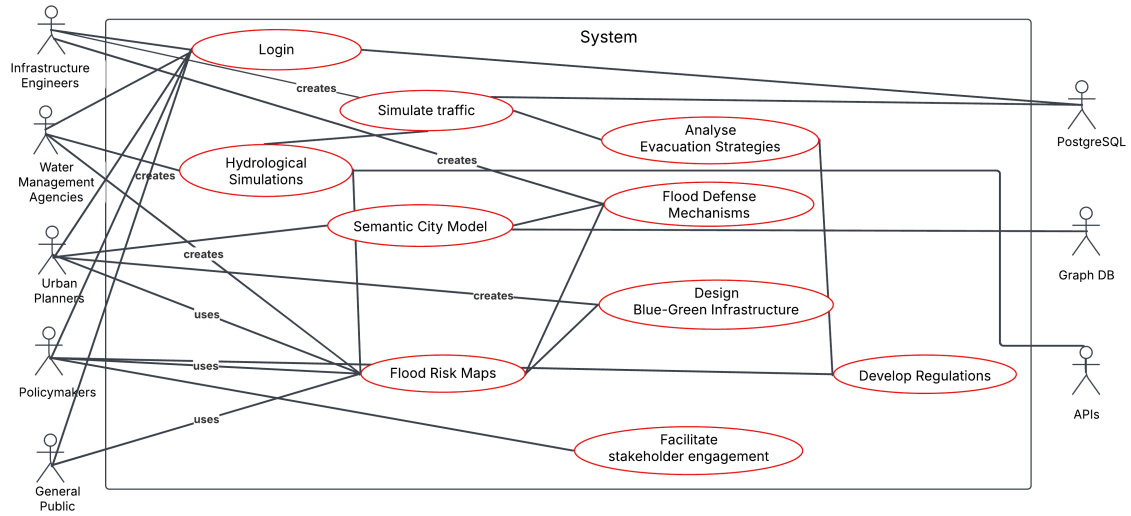

Figure 2. Use case diagram.

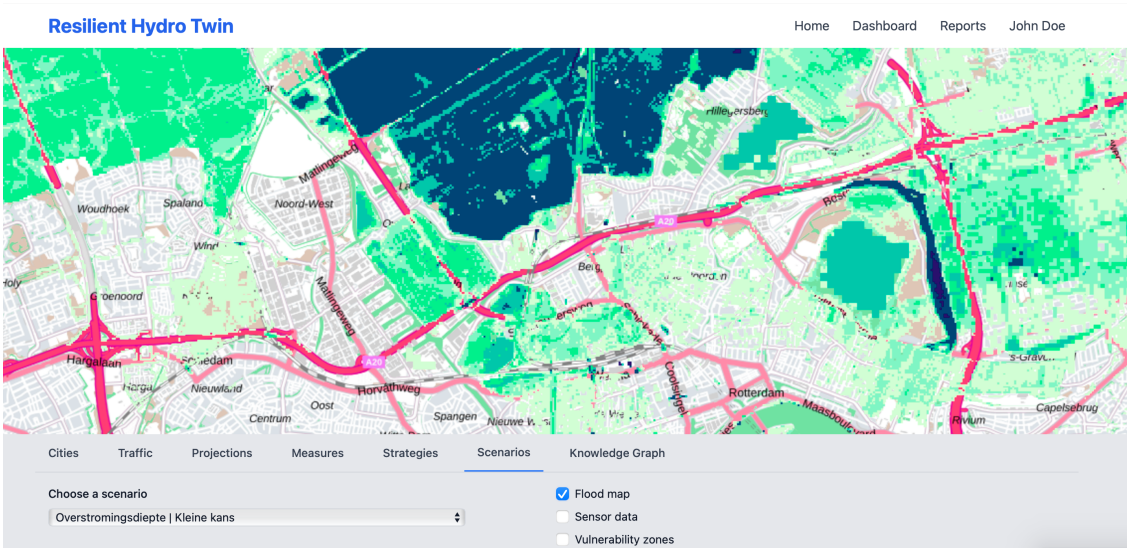

Figure 3. Screenshot of the Resilient Hydro Twin (RHT) platform interface.

ments in decision-support features will allow policymakers to evaluate different flood mitigation strategies and assess the long-term implications of policy decisions.

Overall, RHT can serve as a valuable tool for collaborative flood risk assessment and has the potential to transform stakeholder engagement in urban flood resilience planning. Future work will focus on refining system usability and improving data integration pipelines.

4. CONCLUSIONS

This paper presented the ongoing development of a Resilient Hydro Twin platform designed to enhance urban flood resilience through improved stakeholder engagement and data integration.

The system architecture was developed with a modular approach, allowing various stakeholders to interact with flood risk data through a shared and accessible platform. The integration of GIS, BIM, hydrological models, and sensor networks has demonstrated potential in fostering interdisciplinary collaboration and supporting data-driven decision-making in flood risk management.

The preliminary results suggest that the platform facilitates more effective collaboration by providing a centralized system where different user groups can access, analyze, and contribute to flood-related data. However, challenges remain, particularly in ensuring seamless integration of heterogeneous datasets, hydrological and hydraulic simulation capabilities, and making the system more user-friendly for a diverse set of users.

As this is an ongoing study, future work will focus on completing the functional and non-functional requirements as discussed previously. In addition, more engagement with stakeholders will be conducted through participatory workshops and pilot studies to assess the usability and effectiveness of the platform in real-world scenarios. The expansion of decision-support functionalities will be a priority, ensuring that policymakers can effectively evaluate the impact of different flood mitigation strategies. By addressing these challenges, the RHT aims to become a comprehensive decision-support tool that enhances flood resilience through interdisciplinary collaboration, and stakeholder-driven decision-making.

Improved data preprocessing for secondary network heating load prediction

Bingyang Zhang [1], Tianle Chen [1], Xuesong Hu [1], Yuanyuan Liu [1], Naiping Gao [1,*]

[1] *Tongji University, Shanghai, China, gaonaiping@tongji.edu.cn*

SUMMARY
Accurate heating load prediction is crucial for the meticulous management of heating station. Data-driven heating load prediction techniques have garnered significant attention due to its promising application prospects. High-quality historical input data is the key prerequisites for improving model prediction accuracy. Taking a floor radiant heating system as the case, this paper applies Singular Spectrum Analysis to decompose the original heating load, removing noise components with the cumulative feature contribution rate of less than 9.2%. Then the improved quartile method is employed to identify outliers in the denoised reconstructed time series. Finally, the back propagation neural network (BPNN) is adopted to establish an hourly heating load prediction model. The results show that compared with the original data processed using the traditional quartile method, the load prediction accuracy can be significantly improved by Singular Spectrum Analysis and the improved quartile method, with the root mean square error (RMSE) reduced by 51.0%.

Keywords: Secondary heating load prediction, Singular spectrum analysis, Improved quartile method.

1. INTRODUCTION

District heating system is an important part of the urban energy infrastructure. According to statistics (Center TUBE, 2021), the total urban heating area in China reaches 15.2 billion m^2, and the heating energy consumption is 213 million tons of standard coal, accounting for 30% of the total building energy consumption. With the application of building management systems, the large amount of data obtained from the management platform helps to build data-driven models for load prediction (Fan et al., 2020). The accurate load prediction technique can realize personalized and meticulous regulation of the district heating system, and reduce the system energy consumption by improving the energy efficiency. High-quality historical input data can ensure the load prediction accuracy of the data-driven model. To improve the quality of the input data, the data decomposition and outlier identification of the original data have been investigated by many researchers. The Empirical Mode Decomposition (EMD), proposed in 1998, can decompose the signal with the intrinsic mode function (Huang et al., 1998). Deng and Jin used EMD to decompose the electric load into the stochastic, periodic, and trend components, removing the redundant components by analyzing the characteristics of each sub-signal (Deng & Jin, 2018). Then the Variational Mode Decomposition (VMD) was proposed to in 2014, and it was found that using this algorithm to decompose the data can effectively improve the prediction accuracy. (Dragomiretskiy, 2014; Sun et al., 2019). However, these decomposition methods typically require manually setting the number of components or modes, and an excessive or insufficient number will affect the decomposition accuracy. Recently, Singular Spectrum Analysis（SSA）has been widely applied to time series as it does not require the assumption of parametric models and stationarity conditions. While most current research focuses on power load decomposition, there

are relatively few studies on the secondary heating load (Stratigakos et al., 2021). In terms of outlier identification, various methods have currently been proposed such as the quartile method, 3σ criterion, and t-test criterion, etc. (Frigge et al., 1989; Xue et al., 2017). However, these traditional methods usually focus on the mathematical level and lack integration with domain-specific knowledge for more effective identification. Based on the research gaps, this paper applies Singular Spectrum Analysis to decompose the original heating load time series, and then proposes a novel improved quartile method incorporating the professional background knowledge for more precise outlier identification. Finally, taking the secondary heating system of Tianjin, China as an example, an hourly heating load prediction model is built based on the back propagation neural network (BPNN) algorithm to validate the effectiveness of the adopted load decomposition and outlier identification methods.

2. METHOD

2.1 Singular Spectrum Analysis

Singular Spectrum Analysis (SSA) is a decomposition method with simple operation and excellent decomposition effect. It can extract trend items, period items and residual items from time series. Since it does not require the assumption of parametric models and stationarity conditions, it has been well applied to time series. SSA embeds, decomposes, groups, and diagonally averages the studied time series.

2.1.1. Embedding

The original time series $X = (x_1, x_2, \dots, x_N)$ is transformed into a K-dimensional vector matrix, where each vector has a length of L. N is the length of the one-dimensional time series, and the transformed matrix is shown in Eq. (1).

$$X = [x_1, x_2, \dots, x_K] = (x_{ij})_{i,j=1}^{L,K} = \begin{bmatrix} x_1 & \cdots & x_K \\ \vdots & \ddots & \vdots \\ x_L & \cdots & x_N \end{bmatrix} \quad (1)$$

Here, L represents the window length, with a range of $2 \leq L \leq N/2$, $L \leq K$, $L = N - K + 1$

2.1.2. Decomposition

The transformed matrix is processed using Singular Value Decomposition (SVD). Due to the difficulty of direct matrix manipulation, covariance matrix S is constructed according to Eq. (2) and Eq. (3).

$$S = XX^T \quad (2)$$

$$X = X_1 + X_1 + \cdots + X_L \quad (3)$$

Here, $X_i = \sqrt{\lambda_i} U_i V_i^T$, $\lambda_i, \lambda_i, \dots, \lambda_L$ is the eigenvalue of S, the corresponding orthogonal vector is $u_1, u_2, \dots, u_L$, and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_L \geq 0$.

2.1.3. Grouping

Divide all L components into m mutually exclusive groups $I_1, I_2, \dots I_m$, let $I = \{i_1, i_2, \dots, i_p\}$, corresponding to the composite matrix $X_I = X_{i1} + X_{i2} + \cdots + X_{ip}$, then the matrix X is expressed as Eq. (4)

$$X = X_{I1} + X_{I1} + \cdots + X_{Im} \tag{4}$$

2.1.4. Diagonal averaging

Transforming X_{ij} in Eq. (4) into a sequence of length N. Define Y as a matrix with L rows and K columns, where the elements are represented by y_{ij} for $1 \le i \le K$ and $1 \le j \le K$. The diagonal averaging can be expressed through Eq. (5).

$$y = \begin{cases} \frac{1}{k}\sum_{m=1}^{k} y_{m,k-m+1}, & 1 \le k \le L^* \\ \frac{1}{L^*}\sum_{m=1}^{L^*} y_{m,k-m+1}, & L^* \le k \le K^* \\ \frac{1}{N-k+1}\sum_{m=k-K^*+1}^{N-K^*+1} y_{m,k-m+1}, & K^* \le k \le N \end{cases} \tag{5}$$

For singular spectrum analysis, the trend term, period term, and residual term are determined based on the finally calculated eigenvalues of each signal component. Generally speaking, trend items and period items include more than 80% of the main information of the original load series.

2.2 The Quartile Method

Identifying and eliminating outlier data is an important means to improve the quality of sample data. The traditional quartile method usually identifies the outlier data from the whole dataset and performs well in small to medium-sized sample datasets with a lower percentage of outliers. The relevant calculation formulas are shown in Eq. (6), Eq. (7) and Eq. (8).

$$IQR = Q_3 - Q_1 \tag{6}$$
$$P_L = Q_1 - 1.5IQR \tag{7}$$
$$P_U = Q_3 + 1.5IQR \tag{8}$$

Where Q_1 and Q_3 represent the lower and the upper quartile, respectively; *IQR* represents the interquartile range; P_L and P_U represent the lower and the upper boundary, respectively.

The heating system monitoring data spans an entire season and exhibits high volatility and seasonal variability. It typically contains tens of thousands of records, which can be considered a medium to large-sized dataset. In such cases, the traditional quartile method may fail to accurately identify outliers. Given that there is a strong negative correlation between the heating load and the outdoor temperature, this paper proposes an improved quartile method for fine-cleaning of the heating data. The heating load data is divided into several intervals based on the outdoor temperature with 1°C increments, and each interval is calculated individually in quartile method.

2.3 Machine Learning Algorithm and Evaluation Indices

The BPNN algorithm is often used in heating demand prediction and have good performance. The learning process of the BPNN model can be mainly divided into two stages: information forward propagation and error back propagation, which can realize highly nonlinear mapping. The basic learning principle of BPNN model is the gradient descent method, and its core idea is to minimize the total error by adjusting the weights and thresholds of the network connection. In this paper the mean absolute error (MAE), the root mean square error (RMSE), and the determination coefficient (R^2) are used to evaluate the performance of the prediction model. MAE, RMSE, and R^2 are calculated according to Eq. (9), Eq. (10), and Eq. (11).

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \quad (9)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)} \quad (10)$$

$$R^2 = \frac{\sum_{i=1}^{n}(\hat{y}_i - y_i)^2}{\sum_{i=1}^{n}(\bar{y}_i - y_i)^2} \quad (11)$$

Where n represents the sample size, $\hat{y}_i$ represents the true value, y_i represents the predicted value, $\bar{y}_i$ represents the average value of the true value.

3. DATA PREPROCESSING RESULTS

3.1 Case Information and Data

In this study, a secondary heating system in Tianjin, China is selected as the case. The system is for residential customers, with a heating area of about 80,000 square meters. The heating system operates in a quality-regulated mode, maintaining a nearly constant flow rate. The heating terminal adopts floor radiant. The design outdoor temperature in winter is -7℃, and the design secondary supply/return temperature is 50/40℃. By the smart heating platform and meteorological stations, this paper collected secondary heating system operation data and outdoor meteorological parameter data from November 10, 2022 to March 9, 2023. The collected data include secondary heating load, secondary supply/return temperature, indoor temperature, outdoor air temperature, air velocity, and solar radiation intensity.

3.2 Decomposition of Heating Load

Affected by the monitoring devices and the variation of the outdoor parameters, the heating load is characterized by high volatility and strong instability. This paper adopts the singular spectrum analysis to decompose the heating load, and a total of 27 days from February 2, 2023 to February 28, 2023 (with a large variation in heating load) were selected for analysis. The embedding window length is 12, resulting in 12 sub-signals. Fig. 1 illustrates the sub-signals of the heating load after SSA decomposition. Table 1 presents the specific feature values for each sub-signal.

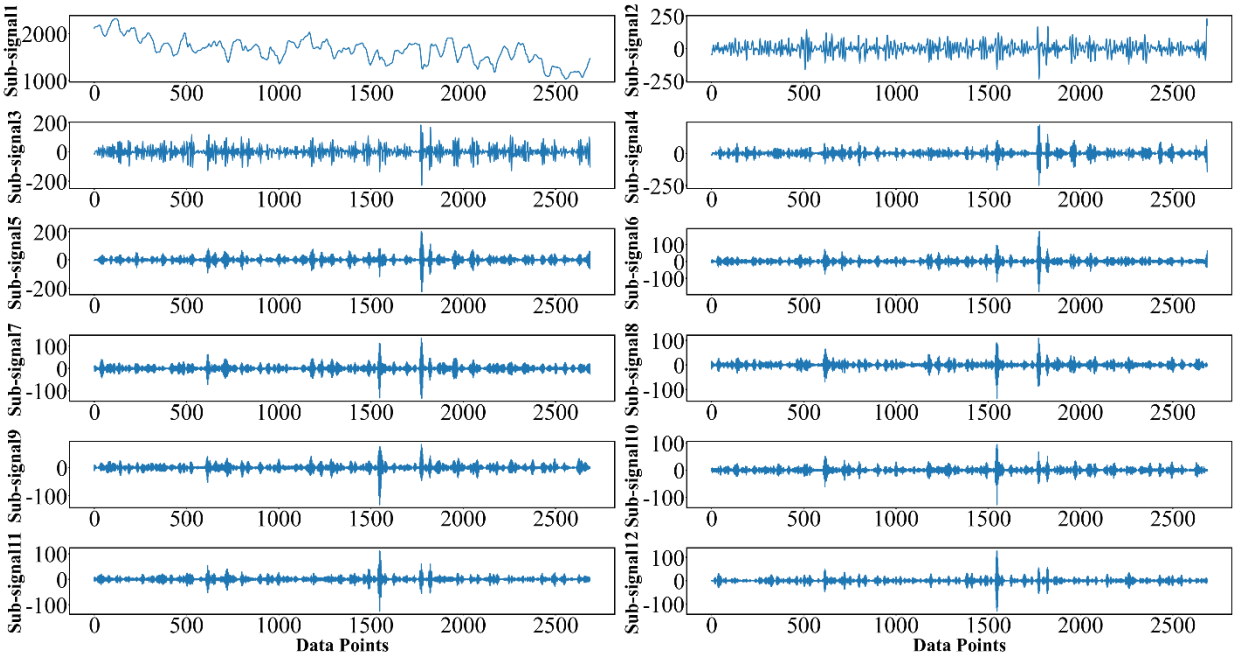

Figure 1. Sub-signals of heating load decomposed by SSA.

Table 1. Feature values and variance contribution rates of sub-signals

Number	Feature Value	Variance Contribution Rate	Cumulative Variance Contribution Rate
1	298085.73	82.72	82.72
2	11552.82	3.21	85.93
3	9880.12	2.74	88.67
4	7880.46	2.19	90.86
5	6498.52	1.80	92.66
6	5197.62	1.44	94.11
7	4506.02	1.25	95.36
8	3970.93	1.10	96.46
9	3494.38	0.97	97.43
10	3266.29	0.91	98.33
11	3031.61	0.84	99.18
12	2968.91	0.82	100.00

According to the Table 1 and Fig. 1, the sub-signal 1 is considered a trend component, which has the highest variance contribution rate of 82.72%, providing a reasonably accurate reflection of the original load trend. The sub-signals 2 to 4 are considered periodic components, with the range of 3. 21% to 2.19%. From the 5th sub-signal, the contribution rate of features begins to level off, indicating a slow change in feature values. Consequently, sub-signals 5 to 12 are considered residual components.

This paper selects the top 4 sub-signals as the reconstruction time series with the cumulative feature contribution greater than 90%, while eliminates the noisy data with the cumulative feature contributions less than 9.2%. The comparison of the heating load time series before and after processing is shown in Fig. 2. It can be found that the reconstructed time series presents clear non-linearity and smoothness, which can better reflect the trend and periodicity of data.

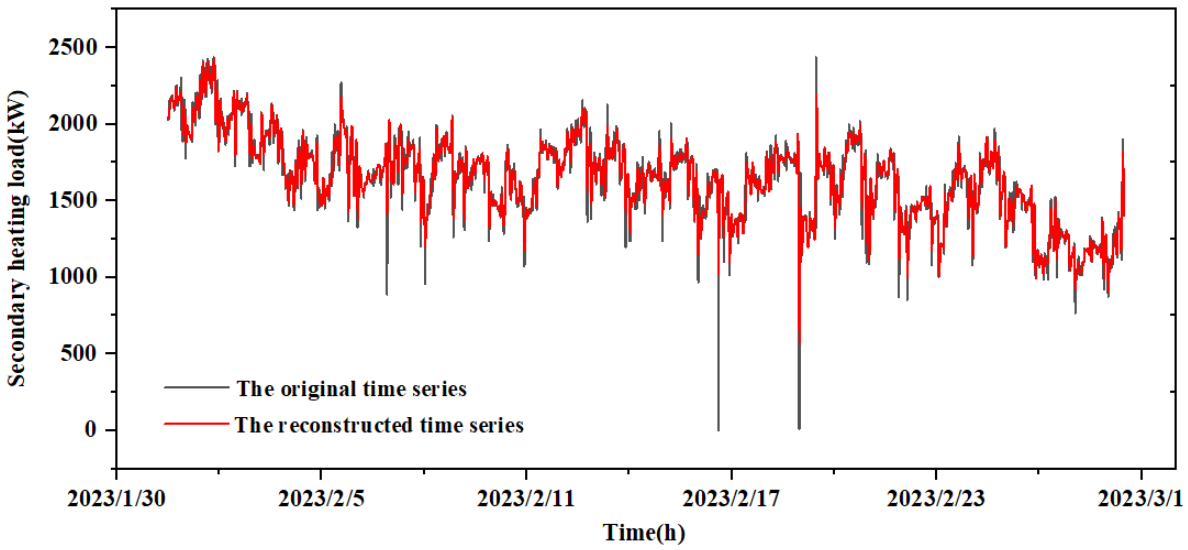

Figure 2. Comparison of the heating load time series before and after processing.

3.3 Identification of Outlier Data

This section focuses on identifying outliers in the hourly heating load data using the two quartile

methods mentioned in Section 2.2. A total of 2735 records from the whole heating season were selected for analysis. Fig. 3 and Fig. 4 show the identification results under the traditional quartile and improved quartile method, respectively.

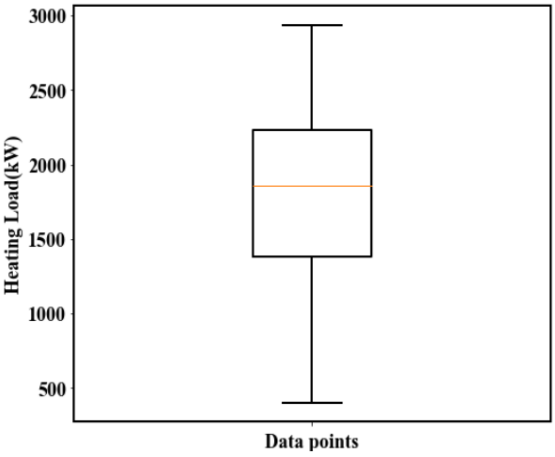

Figure 3. Identification result of traditional quartile.

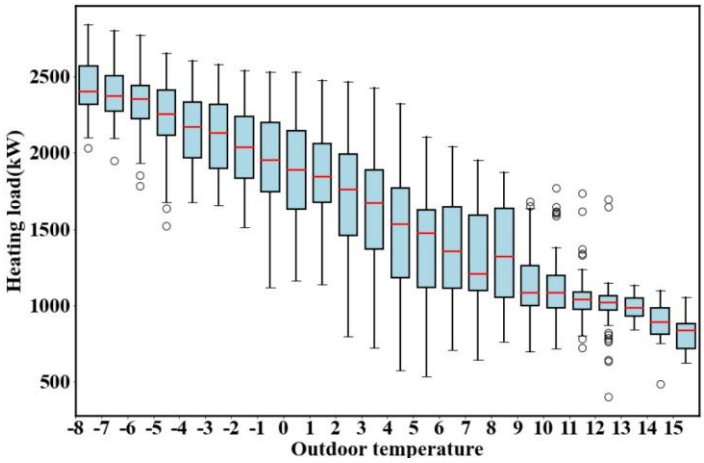

Figure 4. Identification result of improved quartile.

As shown in Fig. 3, there are no outliers identified by the traditional quartile method. A possible explanation is that the selected dataset is a medium to large-sized dataset with the high volatility and seasonal variability, where the traditional quartile method fails to identify the outliers.

For the improved quartile method, the heating load is divided into 23 intervals based on the outdoor temperature with 1°C increments, and each interval belongs to small and medium-sized sample datasets. Fig. 4 shows that the median of the boxplot overall presents a decreasing trend as the outdoor temperature increases, which indicates there is a negative correlation between the outdoor temperature and the heating load. The outliers exceeding the upper and lower boundaries of the boxplot are indicated by black circles in Fig. 4. It can be evidently observed that there are a few outliers in the heating load below the lower boundary when the outdoor temperature is lower than -3°C, and a larger number of outliers exceeding the upper and lower boundaries when the outdoor temperature is higher than 9°C. Further analysis reveals that most of these outliers are distributed at the end of the heating season, a period when the outdoor temperature fluctuations greatly, leading to an increased instability of the heating system, making it susceptible to outliers. In conclusion, the outliers can be effectively identified by using improved quartile method.

4. MODEL VALIDATION AND RESULTS

4.1 Selection of Input Feature Variables

For a defined building, the secondary heating load is influenced by both heating parameters and indoor and outdoor air parameters, specifically the secondary supply temperature (T_g), secondary return temperature (T_h), indoor temperature (T_{in}), outdoor air temperature (T_{air}), solar radiation (S), and wind speed (V_w). Due to the thermal inertia of the building and the thermal delay of the radiant floor heating system, heat dissipation from the heating system to the room is influenced not only by the current heating load but also by the historical load. Moreover, this paper selects the historical supply/return temperatures to reflect the heating system thermal delay, and the historical indoor and outdoor parameters to consider the influence of building thermal inertia. Further considering

that the delay time of ground heat transfer is generally longer than that of building envelope heat transfer, the heating load prediction also needs to consider the outdoor parameters of multiple future moments, which can be obtained from meteorological forecasts. In this paper, L^t is the predicted heating load at the moment t. L^{t-i} and L^{t+i} represent the moment of i hour ahead and after moment t, respectively, and the other variables are expressed in the same way. Finally, this paper uses the Spearman rank correlation coefficient to calculate the correlation between the heating load and various variables, the 47 variables with strong correlation are input feature variables, as shown in Table 2.

Table 2. The input feature variables

Feature categories	Feature variable symbols	Range of i values
Secondary heating load	L^{t-i}	$i = 1 \ldots 6$
Secondary supply temperature	T_g^{t-i}	$i = 1 \ldots 6$
Secondary return temperature	T_h^{t-i}	$i = 1 \ldots 6$
Indoor temperature	T_{in}^{t-i}	$i = 0 \ldots 1$
Outdoor air temperature	$T_{air}^{t\pm i}$	$i = 0 \ldots 4$
Solar radiation intensity	$S^{t\pm i}$	$i = 0 \ldots 4$
Wind speed	$V_w^{t\pm i}$	$i = 0 \ldots 4$

4.2 Comparison of Load Prediction Results

This section uses the BPNN algorithm to compare the load prediction results under the two different inputs. Input_1 is the original data processed by the traditional quartile method, and input_2 is the original data processed by the singular spectrum analysis and improved quartile method. The data from February 22 to February 28, 2023 is selected as the test set, while the rest as the training set. Fig. 5 shows the prediction results of the 2 groups inputs under the BPNN model, respectively. And the performance of the models is summarized in Table 3.

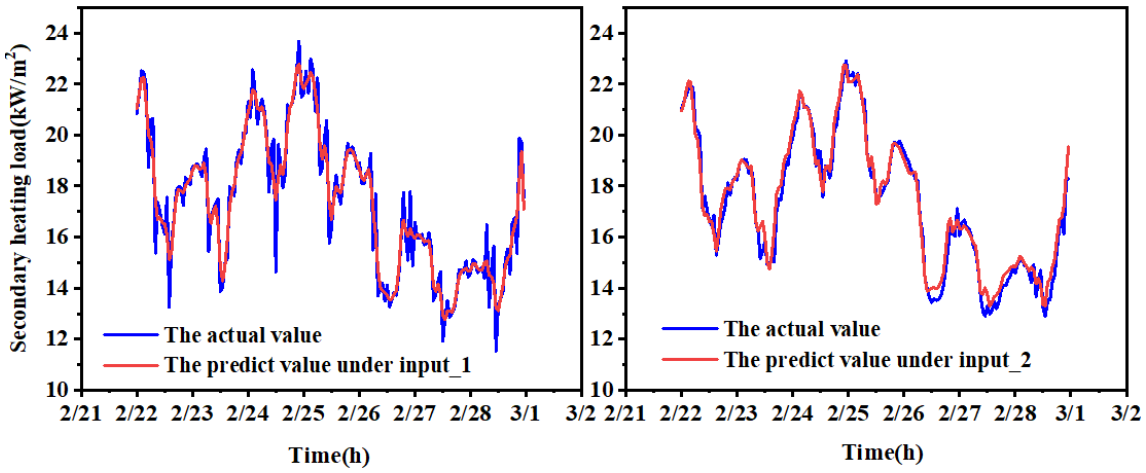

Figure 5. Prediction results of BPNN models.

Table 3. The performance of the models

Input data	MAE (℃)	RMSE (℃)	R^2
Input_1	0.930	1.301	0.792
Input_2	0.456	0.588	0.960

Fig. 5 and Table 3 show that the model based on the input_2 achieves higher prediction accuracy with an RMSE of 0.456℃. Compared to the model based on input_1, the MAE value decreased by 54.8% and the R^2 value increased by 21.2%. This indicates that the noise and outliers of the original data will affect the model prediction performance, and the prediction accuracy can be significantly improved through singular spectrum analysis and improved quartile method.

5. Conclusions

The energy saving of urban heating systems is crucial to achieving the dual-carbon goals, and secondary network heating load prediction plays a key role in the operation and regulation of heating systems. This study focuses on the hourly heating load prediction based on the improved data preprocessing method, mainly includes Singular Spectrum Analysis and an improved quartile method. The specific conclusions are as follows:

The Singular Spectrum Analysis algorithm is applied to decompose the secondary network heating system monitoring load data, removing noisy data with the cumulative feature contributions less than 9.2%. The comparison results show that the reconstructed time series presents clear non-linearity and smoothness, which can better reflect the trend and periodicity of the load data. In terms of outlier identification, compared with the traditional quartile method, the improved quartile method can effectively identify outliers and improve the quality of the data. Further comparison shows that the accuracy of heating load prediction can be significantly improved through Singular Spectrum Analysis and the improved quartile method, with the RMSE reduced by 51.0% for the BPNN model. In conclusion, data preprocessing is essential for building high-precision data-driven models. The results of this paper can guide the fine operation of heating system, promoting the development of green buildings and energy-saving technologies.

SUMMARY
To meet global climate goals by 2050, policies such as the European Energy Performance of Buildings Directive focus on enhancing building energy performance. Traditionally, this involved improving building envelopes and technical systems. Recently, smart building technologies, such as Building Automation and Control Systems (BACS), have gained attention for optimizing energy performance and occupant comfort. However, BACS adoption faces challenges, including high initial investment, uncertain returns, and concerns about component reliability and vendor lock-in. The B•CLIC project aimed to bring data-driven scientific insights on the benefits of BACS in office buildings, enabling stakeholders to make well informed investment decisions beforehand. This is done through the development of a novel proof-of-concept tool that allows stakeholders to compare the life cycle cost of different BACS scenarios in early design stages. Although the current version of the tool has some important limitations, the results look promising and the feedback from stakeholders shows its usefulness.

Keywords: Building Automation, Life Cycle Cost Assessment, Energy simulations, office buildings

1. INTRODUCTION

To meet global climate goals by 2050, national and international policies, such as the European Energy Performance of Buildings Directive, are increasingly focusing on enhancing the energy performance of buildings by reducing energy usage and subsequent emissions (The European Parliament and the Council of the European Union, 2024). Traditionally, this has involved improving the envelope and increasing the efficiency of technical building systems. More recently, there has been growing awareness of the potential of smart building technologies, such as Building Automation and Control Systems (BACS), to optimize energy performance and occupant comfort. This shift is supported by the revised European Directive on Performance of Buildings (The European Parliament and the Council of the European Union, 2024).

Despite their potential, the adoption of BACS is hindered by perceived drawbacks. The initial investment can be substantial, and the return on investment is often uncertain. Additionally, there is a lack of information on the service life of components, reliability, and the risk of vendor lock-in, which increases the investment risk (Sophie van Roosmale et al., 2024). The B•CLIC project aimed to bring data-driven scientific insights on the benefits of BACS in office buildings, enabling stakeholders to make well informed investment decisions in early design stages. This was achieved through the development of a novel life cycle cost assessment tool that includes innovative energy

simulation data and a probabilistic approach to maintenance costs. This article describes the methodology behind this novel tool and shares preliminary results.

2. STATE OF THE ART

2.1 Building Automation and Control systems

BACS are defined as systems that comprise products, software and engineering services for automatic controls, monitoring, optimization, operation, human intervention and management integrated in buildings with the aim of ensuring energy efficient, safe and cost-effective building operations and services (European Commission et al., 2021; Van Thillo et al., 2022; L. Vandenbogaerde et al., 2023). According to the EN ISO 52120-1:2022 standard, BACS can be classified in seven main control functions: Heating control, cooling control, ventilation and air conditioning control, lighting control, blind control, domestic hot water (DHW) control and technical home and building management (Bureau for standardisation, 2022). In this study, only five of these functions will be considered: heating, cooling, ventilation, lighting and blind control.

2.2 Life cycle cost assessment

Investments in BACS can be very substantial due to the inherent complexity of these systems (S. van Roosmale et al., 2024). Therefore, it is crucial for investors and other stakeholders to have a comprehensive understanding of initial investments, expected costs, and anticipated returns. A widely used methodology for assessing these aspects is Life Cycle Cost Analysis (LCCA), which evaluates all costs associated with constructing, owning, operating, maintaining, and disposing of a building or asset (Fuller & Petersen, 1996).). The specific LCCA methodology for the assessment of buildings and construction is established in several standards such as the ISO 15686-5:2021 standard (International Standards Organisation, 2021), NIST (Fuller, 2016) or the ASTM standard (ASTM, 2011). These standards are often generic to accommodate a wide range of building and construction project types.

The LCCA methodology framework includes costs related to initial investment (IC), operations (OP), maintenance (MC), and end-of-life (EoL) (Fuller & Petersen, 1996; Islam et al., 2015). Initial investment costs encompass all expenses related to design, planning, permits, construction, acquisition, and installation of BACS. Operational costs include day-to-day expenses such as energy and other consumables. Maintenance costs, which can be periodic (e.g., daily, weekly, monthly, yearly) or ad-hoc, cover all expenses necessary to keep the system operational, including both scheduled and unscheduled maintenance actions. EoL costs pertain to disassembly, demolition, and disposal, including labour, transport, and waste disposal. Depending on the system boundaries, EoL costs may also include recycling, reconditioning, or refurbishing. Future costs must be discounted to present value (PV) to account for the time value of money. An overview of the LCCA formula is provided:

$$LCCA = IC + OP_{PV} + MC_{PV} + EoL_{PV} \quad (1)$$

3. METHODOLOGY

The objective of the B•CLIC project was to develop an enhanced methodology for assessing the life cycle cost of Building Automation and Control Systems (BACS) in office buildings, allowing

investors to make well informed investment decisions early on in the design stage. This methodology integrates two innovative approaches: the creation of a toolchain to evaluate the energy savings potential of BACS in office buildings, and a novel Life Cycle Cost Analysis (LCCA) methodology that addresses specific challenges and pitfalls of BACS applications, such as component service life, reliability, and uncertain return on investment. These approaches were combined into a preliminary tool that enables stakeholders to evaluate BACS investments ex ante. The tool was implemented using Python. In the following sections, the general functioning of the tool will be addressed, and both the novel tool chain for energy simulations and the novel LCCA methodology will be explained.

3.1 Preliminary tool to assess BACS investments

The tool allows stakeholders to simulate and compare different BACS scenario's, based on different sets of predefined characteristics. In a first step, stakeholders determine the case parameters: a building typology is specified, and case-specific parameters are determined. In total the impact of ±27.000 different combinations can effortlessly be studied, with for each set of combinations a specific energy profile that is simulated through the novel toolchain discussed in section 3.2. Based on the selected case and simulated energy profile, a specific LCCA is performed following the newly developed probabilistic method, which is elaborated on in section 3.3.
In the B•CLIC project, four distinct base building typologies were identified to represent typical office building configurations. Figure 1 provides an overview of these four typologies, highlighting their most distinguishable characteristics. All typologies are situated within the climate zone of Brussels, Belgium.

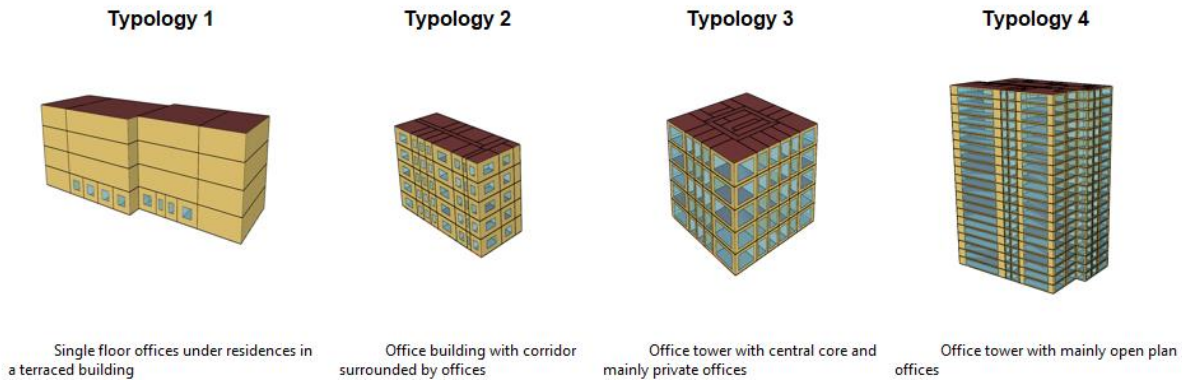

Figure 1. Overview of office building typologies as included in the B•CLIC project

In addition to selecting the building typology, it is necessary to specify several general characteristics of the office building that influence its energy performance. This can be done for selected characteristic through a dropdown menu, which is included in parentheses: Window-to-wall ratio (20%-50%-80%), Building envelope characteristics (Passive Building, EPB 2006 demands[1], Pre-EPB demands), internal gains (LED lighting and energy-efficiency equipment vs. non-LED and low energy-efficiency equipment), Main heating generator (Fuel, Boiler-non-condensing, Boiler-condensing, heath pump air to water, heath pump ground to water) and main cooling generator (Chiller-air cooled, Chiller-water cooled, heath pump air to water, heat pump

[1] The Flemish government imposed a maximum K-Value of K45 for office buildings between 2006 and 2009

ground to water).

After specifying its general characteristics, it is necessary to specify the current and desired status of BACS in the studied office building, in order to compare a business-as-usual LCCA scenario and a future BACS LCCA scenario. This comparison allows for the calculation of savings and return on investment. For these scenarios, the following parameters have to be specified: heating and cooling system automation (Central thermostat with fixed or setback temperature, Room thermostat with fixed or setback temperature), free cooling system automation (manual window control – no heat recovery, Free cooling – heat recovery), ventilation system automation level (High constant flow, time control flow, CO2 level based flow), lighting system automation level (manual – no dimming, manual – no dimming-sweeping signal, Occupancy on/off - Off with sufficient daylight, Occupancy on/off - Daylight dimming) and sun shading system automation (no shading, Manual Control, Automated based on irradiance, Automated considering lighting and cooling loads). After specifying all characteristics, energy requirements for both business-as-usual and BACS scenarios are simulated and LCCA is calculated. In the following sections both the novel toolchain for the energy savings assessment and the novel LCCA methodology is explained.

3.2 Novel toolchain for energy savings assessment

EnergyPlus[2] is used as simulation engine to assess the potential of the aforementioned BACS functionalities in 4 typologies. Python is used to implement the behavioural impact of occupants in operating windows, shades and lights, and to implement the functions of BACS. This resulted in ±27,000 unique cases where the electricity, heating and cooling demand is simulated in a multizone dynamic thermal simulation for a full year at a subhourly timestep. Due to the time-consuming simulation process, the simulations are not carried out live, but processed prior and fed into the database of the B•CLIC tool. As a further elaboration of the novel toolchain does not fall within the scope of this paper, readers are encouraged to consult L. Vandenbogaerde et al. (2025).

3.3 Novel Life Cycle Cost Assessment methodology

In this section, an overview of the LCCA methodology is given based on the different components of the assessment-methodology. A lifespan of 20 years was considered and a discount rate of five percent (European Commission, 2024) was included in all future cost calculations.

3.2.1 Initial costs

The initial costs of Building Automation and Control Systems (BACS) can vary significantly between buildings, primarily depending on the level of automation and the types of BACS implemented. To estimate the initial investment costs for both current and desired BACS systems, a comprehensive inventory of the required BACS components was created. This inventory includes, but is not limited to, sensors, switches, cables, valves, and actuators. These components are considered brand-independent, meaning no specific brand names are included. For each component type, an average cost was determined based on the building material cost indexes for the Flanders region in 2024 (ASPEN Architecten & Ingenieurs, 2024). Additionally, a statistical lifespan for each component was established based on regulations, academic literature, and technical sheets from manufacturers (i.a. Belany et al., 2021; European Parliament & Council of the European Union, 2024; Richter et al., 2019; Verhelst et al., 2017; Zhang & Cai, 2014)

[2] https://energyplus.net/

Using the case characteristics outlined in Section 3.1, a list of components (including both types and quantities) was compiled from the inventory, allowing for the calculation of the initial cost.

3.2.2 Operational costs

Operational costs are those costs that occur to ensure the operation of BAC-systems on a daily basis. In this model, the main operational costs are energy costs considered to run the different BACS. In the current version these are limited to electricity costs only. For the proof-of-concept version of this tool, electricity costs are set on an arbitrary fixed rate of €0.15/kWh (Eurostat, 2024), with energy consumption derived from the energy simulations presented in section 3.2. To account for potential increases in energy prices, an annual escalation rate of two percent (Eurostat, 2024) has been incorporated into the model

3.2.3 Maintenance costs

Maintenance costs comprise all costs pertaining to the maintenance of BACS, whether it is considered reactive, proactive or preventive, planned or unplanned. The main cost of maintenance is considered to be the replacement cost of hardware. In traditional LCCA of buildings, the expected lifespan is typically well known because of ample records of historic performance data. Many components of BACS however have a much shorter expected life time compares to other construction products, and empirical data is scarce and scattered. Furthermore, as BACS can be very complex systems, consisting of hundreds of components, it is likely that some components will fail before their predicted functional life expectancy. For some critical subsystems, failure of one component can affect the operation of the BACS system as a whole. Therefore, the B•CLIC project introduces a probabilistic method to estimate life span of BAC systems. The current version of the tool incorporates Monte Carlo simulations in order to predict the life span of individual components in the business-as-usual and future scenarios. For each component type, a specific probability distribution was developed based on the statistical lifespans described in section 3.2.1. These probability distributions are used as input for the Monte Carlo simulations that simulate the life spans of each component in the simulated system, resulting in a more scattered cost profile than in LCCAs of conventional building materials, which represents a real life scenario for BACS more closely.

3.2.4 End-of-life costs

In the current model, no end-of-life-costs are included. Determining end-of-life costs of BACS can be quite challenging, as of the components are integrated in the building in such a way that removal would require drastic actions. Conversely, some components such as copper wire or electronic waste can generate a positive cashflow at the end of life. Given this complexity and expected limited net impact on the discounted life cycle costs, end-of-life costs (or profits) are currently not included in the proof-of-concept model.

4. RESULTS

The results from the LCCA methodology explained in section 3.3 entail both an overview of life cycle costs for a business-as-usual scenario, where no changes to BACS are made in the next 20 years except for maintenance replacements of components, and a desired future BACS scenario, under the same conditions. This allows stakeholders to compare the life cycle costs of the two BACS scenarios, in order to determine the potential benefits and costs of both scenarios in an early

stage. This would enable stakeholders to test different future BACS scenarios and, compared to their current BACS status, determine which BACS investments could result in the highest return on investment, before major design decisions and commitments have to be made.
The tool returns a set of different graphical overviews, as can be seen in figure 2. On the left diagram, an overview is given for both scenarios based on cost category. This allows stakeholders to visualise investment estimates and simulated operational costs to evaluate the potential return on investment. In the right diagram, the cumulative life cycle costs over the 20-year life span are shown. This gives stakeholders a clear idea of when an investment in BACS will start paying off, and whether this payback time is acceptable or not.

Figure 2 displays the results of a case pertaining an office building following Typology 4, studying the impact of lighting automation on life cycle costs under ceteris paribus conditions. In the business-as-usual scenario, lights are manually controlled, and no dimming function is present. In the desired BACS scenario, lights are automatically controlled based on zone occupancy and daylight dimming is active. In this example, the investment in the smart lighting system pays of in the operational phase: the electricity consumption is significantly lower than in the business-as-usual scenario, and after approximately seven years, the life cycle cost of the desired BACS scenario is already lower than the business-as-usual scenario. Given the limitations to the current methodology (as discussed in section 5), the absolute numbers should be interpreted with caution. Nevertheless, this example shows the potential and usefulness of the tool for different stakeholders.

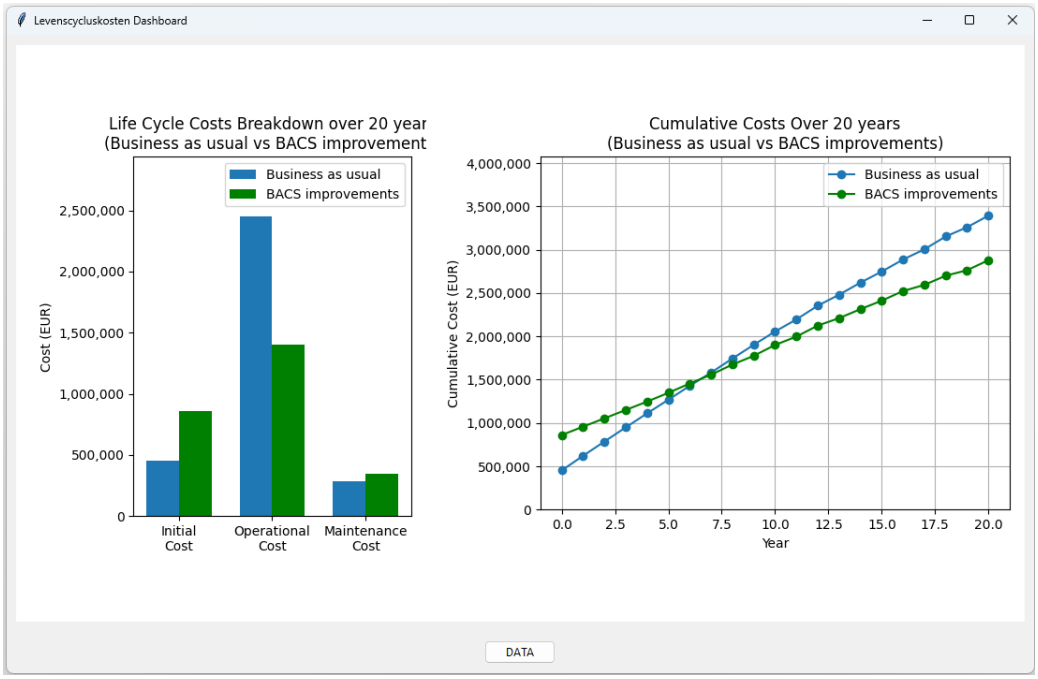

Figure 2. The B•CLIC tool returns different graphical interfaces

5. LIMITATIONS, DISCUSSION AND FUTURE RESEARCH

The current tool, still in its proof-of-concept phase, has several limitations, including the exclusion

of energy consumption from heating and cooling, which would enhance model accuracy. It also lacks labor cost data for installation, operation, and maintenance of BACS, and uses fixed economic parameters over a 20-year period, which should be adjustable for relevance. These issues are currently being worked on, to increase the overall accuracy and usefulness. The maintenance cost calculation in the Life Cycle Cost Analysis (LCCA) methodology relies on limited theoretical data for Monte Carlo simulations, needing more real-life data for accuracy. Additionally, data protection by producers and high costs of data extraction pose challenges.

Early feedback from stakeholders on the proof-of-concept tool was promising, as its usefulness is very apparent. However, the tool's accuracy heavily depends on the quantity and quality of the included data. Therefore, developing a robust data-gathering strategy for these systems in the long term is crucial to benefit from data-based models.

To tackle this last problem, a new research project is planned, in cooperation with different stakeholders within the building automatization ecosystem: Building owners, BACS producers, integrators, etc. with the aim of developing said robust data gathering strategy and including more real-life data into the current model. Furthermore, this research project will allow for more insight into the needs of stakeholders when it comes to BACS project evaluation, improving the usability of the current tool.

6. CONCLUSIONS

The aim of the B•CLIC project was to develop a novel LCCA tool including innovative energy simulation data and a probabilistic approach to maintenance costs, to enable stakeholders to make well informed decisions on BACS investments in early design stages. While the current tool is only a proof-of-concept, it shows great promise for various stakeholders. It allows different stakeholders to evaluate the life cycle costs of BACS in office buildings for current business-as-usual and future desired scenarios. However, currently there are still important limitations to the model, that influence the accuracy of the results, that must be addressed in the further development of the tool. This includes but is not limited to the further integration of real-life data in the probability distributions for life spans of components. To conclude, this methodology and tool not only provide a robust framework for evaluating BACS but also pave the way for future innovations in the field. By addressing different cost categories comprehensively, this work ensures informed decision-making and promotes the efficient use of resources, ultimately contributing to the advancement of sustainable office building.

SUMMARY
High performing buildings are a consequence of an integrated design approach with a good understanding of the building science domain coupled with the ability to quantitatively evaluate performance at various stages of the design process. This paper aims to share the pedagogy of such a graduate course of our MSc (Building Performance and Sustainability) program, focusing on Green Building Integration and Evaluation Studio. It is offered as a two-semester studio-based course that synthesizes the theoretical and practical aspects of building performance and detailed design development, bringing sustainable design concepts and elements to the forefront. The students are exposed to performance evaluation and simulation tools such as SpaceCLAIM, ANSYS Meshing, ANSYS-FLUENT, Rhino, Design Builder and EnergyPlus. The need for sustainable design and its integration into a holistic performing building will be a key principle of studio learning. Design decision support using simulation tools will be brought to life in a studio environment in the realization of holistic sustainable buildings. Simulation tools will be used for thermal, ventilation, IAQ, daylighting and building energy analysis. Current sustainable building assessment techniques will be applied. During semester 1 (13 weeks), students work on two individual assignments, namely application of CFD in Natural Ventilation Modelling and familiarization with BES tool. In Semester 2, students work in small groups on the design and development of an actual project on a site in Singapore. It involves the evolution of the design to lead to a high performing building using Building Performance & Simulation (BPS) tools to guide the design development process. Since its inception in 2010 and as envisioned then, this course has been pivotal in strengthening our graduates' future career path to become qualified Environmental Sustainable Design (ESD) consultants in the built environment profession.

Keywords: Building Performance and Simulation, CFD Applications in Built Environment, Green Development, Building Energy Analysis and Simulation

1. INTRODUCTION

The global urgency to address climate change and promote environmental sustainability has significantly transformed the priorities of the built environment sector. In response, academic institutions have a pivotal role in cultivating a new generation of building professionals who are equipped with the interdisciplinary skills and knowledge to design, evaluate, and deliver high-performance sustainable buildings. While conventional design education often emphasizes aesthetic and functional aspects, there remains a critical need to integrate building performance evaluation and sustainability principles into the architectural and engineering design pedagogy. The challenge lies in effectively bridging the gap between theoretical learning and practical application, especially through simulation-based design processes that reflect real-world complexities.

A growing body of literature advocates for the incorporation of performance-based design education into architectural and engineering curricula. Studies highlight the importance of

embedding Building Performance Simulation (BPS) tools in design studios to enable students to evaluate energy efficiency, thermal comfort, natural ventilation, indoor air quality (IAQ), and daylighting performance (Hansen and Lambert, 2019; Zhai, 2020; Mirzaei, 2022). However, existing pedagogical approaches often fall short in ensuring students develop a deep, iterative understanding of how to use simulation data to inform design decisions in a holistic and integrated manner. Furthermore, most reported case studies are limited to singular aspects of performance—typically building energy or daylighting—rather than demonstrating a comprehensive, multi-domain evaluation across the building lifecycle.

In the context of Southeast Asia's tropical climate and the policy direction set by national green building certification schemes such as Singapore's BCA Green Mark, there is a pressing demand for graduates who are not only familiar with sustainability frameworks, but also competent in using advanced digital tools to support performance-driven design. Despite this, limited academic publications have documented how postgraduate design studios in this region are responding to this need through innovative pedagogical strategies.

To address this knowledge gap, this paper presents the pedagogy and studio-based learning structure of the National University of Singapore (NUS) *Master of Science in Building Performance and Sustainability* (MSc BPS), specifically focusing on the course BPS5112 – *Green Building Integration and Evaluation Studio*. This two-semester course exemplifies how a performance-driven studio can serve as an effective educational platform to merge sustainable design principles with simulation-informed decision making. The course exposes students to a suite of performance evaluation tools—such as SpaceCLAIM, ANSYS Meshing, ANSYS Fluent, Rhino, DesignBuilder, and EnergyPlus, - and guides them through a structured progression from individual analytical tasks to collaborative real-site design development projects.

The primary objective of this paper is to share the methodology, structure, and learning outcomes of BPS5112, emphasizing how simulation tools are applied across multiple sustainability dimensions. It aims to demonstrate how this pedagogical model fosters critical thinking, technical competence, and professional readiness among students aspiring to become Environmental Sustainable Design (ESD) consultants. In doing so, the paper contributes to the discourse on effective pedagogy for sustainable building education and provides a reference model for other academic institutions seeking to enhance their curricula in the face of growing sustainability imperatives.

2. METHODOLOGY

The BPS5112 course adopts a studio-based learning methodology structured over two semesters, combining individual analytical tasks with collaborative project-based learning. The first semester emphasizes foundational skills through targeted assignments focused on computational modelling and performance evaluation. The second semester transitions into integrative group work on an actual project site in Singapore, enabling students to apply simulation tools in iterative design development. Students are guided through a design-thinking process grounded in sustainability principles, where feedback loops between design intent, simulation results, and performance goals are emphasized. This hands-on approach fosters critical inquiry, teamwork, and professional-level competency in sustainable building design.

Further description about student's training on BPS tools and Design Brief of the studio project are illustrated as below.

2.1. Training on Computational Fluid Dynamics (CFD) tool

Students are trained to use CFD simulation tool (ANSYS-FLUENT) in order to perform ventilation simulation modelling and analysis and ensure good natural ventilation within the functional unit. They must complete the individual assignment. The Intended Learning Outcomes (ILO) of this CFD assignment are 1) To ensure CFD quality control and fulfil check list for the building aerodynamics and natural ventilation study, 2) To analyze the CFD result and perform a series of modified/improved design iteration for GM building natural ventilation design. The assignment comprises two work scopes as listed below.

Firstly, students should ensure good wind flow simulation can be obtained from CFD modelling work through benchmarking studies. They can choose any two (2) of the following test cases for their benchmarking study. The literature data of the test case are given to students.

1. Wind flow around single buildings
2. Wind Flow Over 2 Buildings; with one smaller building in front of the big building
3. Urban Street Canyon Flow; with wind flow regime at three different H/W
4. Urban Like Flow Around Building Blocks
5. Venturi Effect In Between Buildings; Wind Flow Over V Shape channel between two buildings

Secondly, students are expected to use the established CFD methodology from the first part to perform CFD Natural Ventilation studies for the actual building, either residential or non-residential unit type. The Non-Residential Building type includes *hospitals, industrial facilities, hawker centres, sports facilities, commercial atriums and schools.* They should follow the Green Building certification criteria (e.g. Singapore BCA Green Mark Platinum GM Version 2021 or equivalent standard) to assist the natural ventilation analysis for their project. The project work scopes should include firstly baseline design case (1 geometry); and followed by improved design cases (another geometry is required). Each simulation case is subjected to one (1) prevailing wind condition (either Northerly or Southerly wind). Students can plan for computational domain with maximum site development area of 100m x 100m, subjected to computer resource availability. Plot ratio can be approximated necessarily. Existing building layout can be obtained from google map and on-site observation (for building height). Building geometry entities can be imported from SketchUp, AutoCAD 2D/3D, 3D Studio Max or BIM-REVIT. Alternatively, students can also plan for the new building with their own drawing or derive the necessary info from work experience or literature paper. In this CFD assignment, students are also encouraged to follow the CFD quality control checklist adopted in Singapore BCA CFD Guidelines Green Mark Platinum GM Version 2021 (Poh et. al, 2019) to ensure the CFD Natural Ventilation results fulfill the modelling fidelity and accuracy standard.

2.2. Training on Building Energy Simulation (BES) tool

The aim of the BES assignment is to familiarize student with building performance modelling and simulation. The Intended Learning Outcomes (ILO) of this BES assignment is to evaluate student's ability to quantify building performance using simulation tools. The proposed location for the assignment is the current building at Department of the Built Environment (DBE) on NUS campus. The building shall have a floor area of approximately 6,000m2 ± 5%. Student must use perimeter/core zoning where the depth of the perimeter zone does not exceed 1.5 times the floor-to-floor height. The submission requirement for this BES assignment is listed below.

1. Perform a climate analysis by reviewing the local climate information. The climate analysis should include the following:

a. Dry-bulb temperature
b. Relative humidity or wet-bulb temperature
c. Wind speed and direction
d. Insolation

2. Analyse and discuss the effects of the following on building energy use and peak cooling load:
    a. Building geometry and orientation.
    b. Window-to-wall ratio (by orientation) and shading options.
    c. Envelope thermal performance.
    d. Effects of the above three parametric variations on the subsequent cooling energy consumption. Student can assume a generic cooling system using the DesignBuilder simple HVAC template.

The ETTV does not need to be considered in this assignment. However, internal loads and their corresponding schedules, and ACMV schedule (On/Off) should follow the baseline standards specified in Green Mark 2021 Energy Modelling Guideline.

3. Provide a clear and concise report of BES study. The report should include Study objectives, Model inputs (including assumptions) and the corresponding sources/references, Results and discussion.

2.3. Design Brief of Studio Project

The proposed location is the empty land located at typical site in Singapore, which is assumed to be developed as **a mixed-use district comprising educational institute, commercial and business park uses**. The maximum allowable GFA for the development is limited to 80,000 sqm (+/- 10%). Students are required to develop a design for a mixed-use development comprising the following components:

- Offices (40% of NFA)
- Retail, food & beverage shops (20% of NFA)
- Educational & childcare centre (40% of NFA)

Students must consider the following attributes while developing the design of the above building:

a. Passive design principles and system solutions that achieve a minimum of 20% reduction in cooling load compared to baseline building that is based on the Singapore Green Mark 2021 Energy Modelling Guideline.
b. At least 25% and not more than 40% of the total GFA to be naturally and/or hybrid ventilated (without cooling). The remaining GFA is to be air-conditioned.
c. Achieve 80% energy savings based on SLE criteria compared to 2005 codes.
d. There is no cap on the overall building energy use derived from renewable sources.

In support of Singapore Green Building Masterplan's (SGBMP) 80-80-80 by 2030 targets, the project shall aim to achieve the following objective:

1. Super Low Energy (SLE) Certification: Demonstrate compliance with the SLE certification under Green Mark 2021, specifically through Pathway 3 as detailed in the Green Mark 2021 energy efficiency standard,
2. Explore innovative technologies and solutions to exceed the minimum 60% energy savings threshold (compared to 2005 codes) required for SLE certification to achieve 80% energy savings. Student can consider both passive and active strategies. Building performance simulation should be used to evaluate the feasibility of the proposed solution, ensuring that additional energy savings do not compromise thermal comfort or other total building performance mandates.

The environmental building analysis shall include but not limited to bioclimatic analysis, sun-path analysis, wind analysis, solar radiation and insolation analysis, daylight and glare analysis, energy modelling, weather protection, rain penetration, building orientation, natural and mechanical ventilation strategies, etc.

CFD indoor environmental modelling should also be carried out to exploit the innovative component on both active and passive design. Students are required to develop a design solution through an integrated design and engineering approach using performance evaluation tools (such as CFD and energy simulation tools), which shows a holistic appreciation on sustainability issues. Every individual in the group should make a specific contribution towards one or more aspects of the studio project. The design shall demonstrate adequate considerations for the latest version of Singapore BCA GM2021 in terms of Energy Efficiency, Resilience, Health and Wellbeing and Intelligence.

All groups are expected to carry out a thorough solar modelling including daylighting evaluation of the office spaces, CFD simulation and studies for habitable naturally ventilated spaces, complete energy modelling that includes detailed ACMV modelling with appropriate thermal zoning, and a Green Mark score card evaluation for the project.

There are three main stages of evaluation for the project:

1. Concept design stage – During this stage, each group is expected to develop a design idea identifying the key performance mandates that they want to achieve through their design and set targets for spatial, thermal, acoustic, indoor air quality, visual & building integrity.
2. Design evaluation stage – During this stage, the group is required to demonstrate a thorough simulation of the concept taken through evaluation of parameters to demonstrate that their design achieves the set targets during the earlier stage. A refinement of the targets is allowed at this stage.
3. Final design stage – This would be a consolidated outcome of the entire semester's work and for this final design submission, students are required to submit a group report. One A1 e-poster can be used to explain the design supported with simulation images and graphics.

<u>Deliverables for 3 stages:</u>

Stage 1 – Design Target & Concept design which includes Preliminary massing, Site level studies – wind analysis, solar modelling and over shadowing by adjacent buildings, Preliminary evaluation of energy end uses and demand characteristics that affect building conceptual design that are tied to the form and architecture of the building, Sustainability thrust area – case studies or examples to demonstrate key ideas or concepts, Conceptual idea for the active systems proposed for the project and Targets and performance matrix

Stage 2 – Design evaluation stage which includes Site plan, Ground floor plan, typical office, retail, childcare centre plan, Massing level studies – floor plate daylighting, massing and heat gain performance, 3D model for simulation, Massing studies for wind flow and CFD, Indoor environmental modelling for both active and passive designs, Develop and evaluate load reduction strategies, Estimate annual energy and demand impacts of active system options, Design integration and optimisation, CFD and energy simulations (where available), Green Mark evaluation with recommended ideas and Relevant Green Mark calculations.

Stage 3 – Final design stage to include 1 x A1 e-poster, Rendered perspective of design, Floor plans, Site plan, Roof plan, Final simulation results of energy modelling, daylighting, facade study, CFD study and Final Green Mark score card

3. RESULTS

The selective results from student's studio project are shown below. For brevity, they are presented here without further illustration. More details to be shared during the COBEE 2025 symposium.

3.1. Design Targets & Concept Design

Figure 1 shows the design target comprise the spatial, thermal, acoustic, IAQ, visual and building integrity aspects of total building performance.

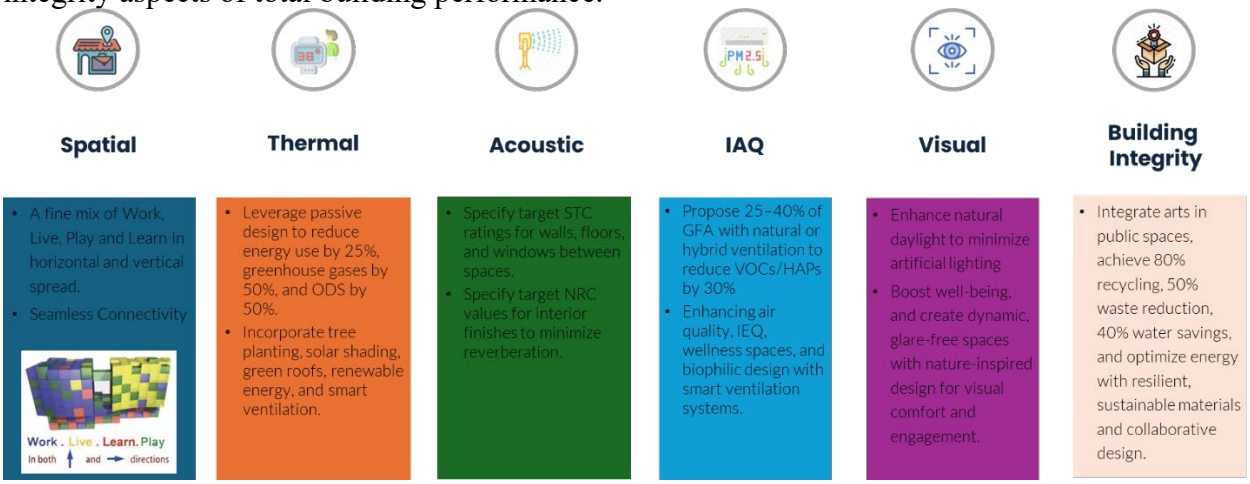

Figure 1. Total Building Performance Target.

Figure 2 shows the massing concept with three design options, namely 1) 4 isolated blocks with podium, 2) 5 isolated blocks with low level connectivity and 3) 4 isolated blocks with high level connectivity.

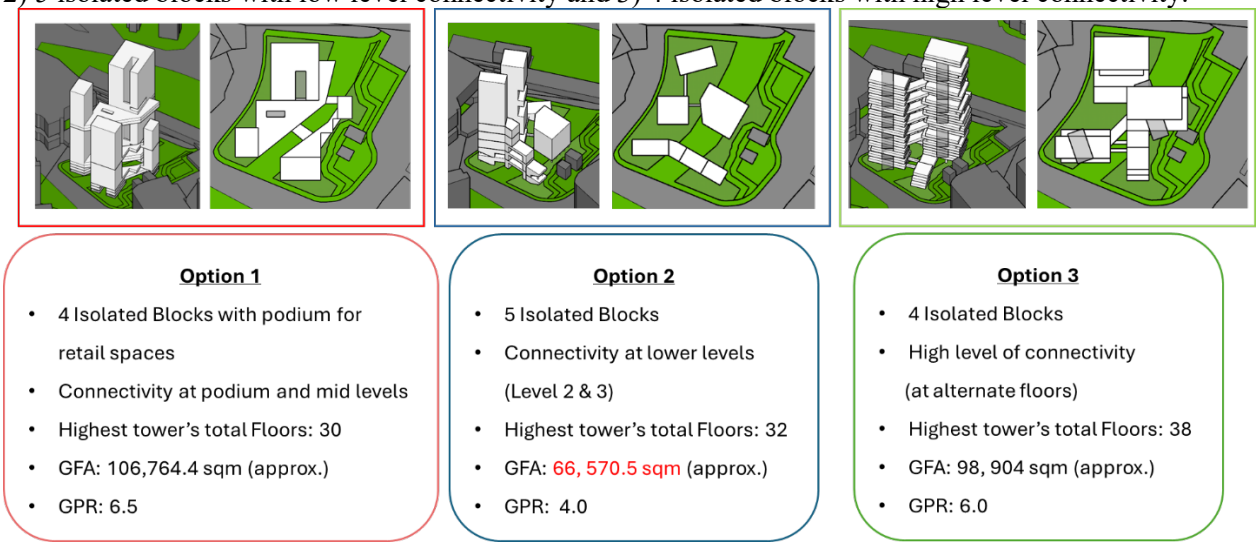

Figure 2. Massing Concept with Three Design Options.

3.2. Design Evaluation

After the concept design, the studio team proceed to the design evaluation stage with the key refinement indicators as illustrated in Figure 3.

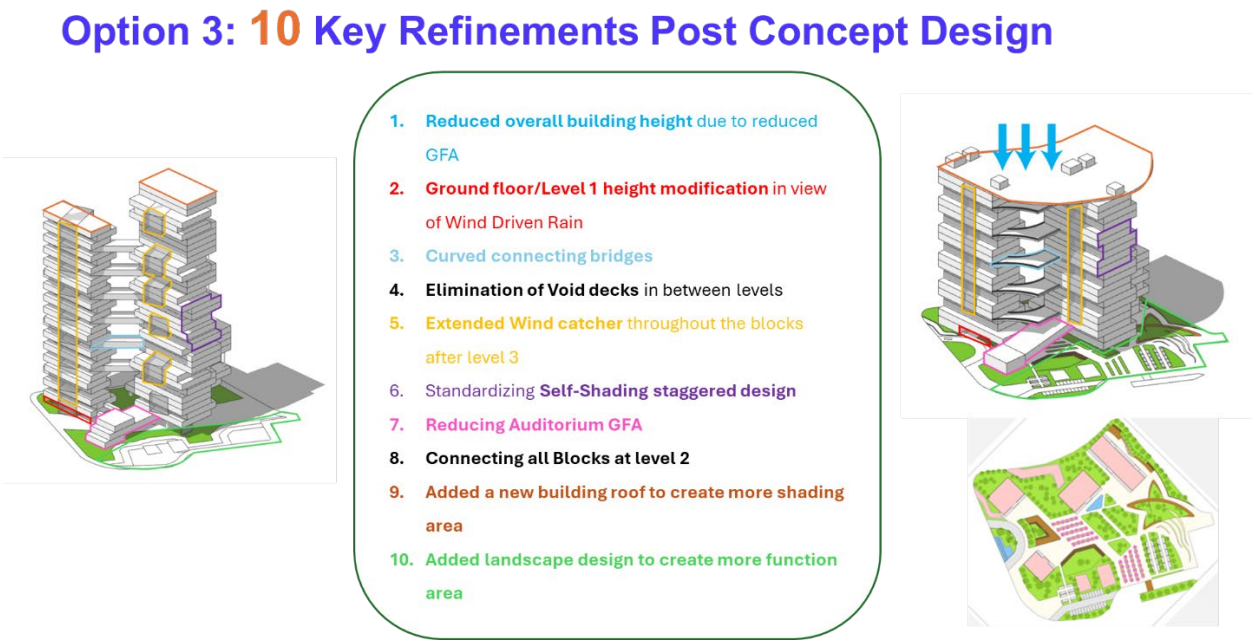

Figure 3. Key Refinements Post Concept Design.

3.3. Final Design

4. CONCLUSIONS

Since August 2010, the BPS5112 Green Building Integration and Evaluation Studio has been a compulsory course in the NUS Master of Science in Building Performance and Sustainability programme, providing comprehensive training to nearly 500 graduate students. It serves as a pedagogical model that effectively integrates sustainable design principles with performance-based simulation tools. By combining theoretical knowledge with real-world application, the course empowers students to make informed design decisions that align with environmental performance goals. Through iterative learning, hands-on simulation training, and collaboration on actual projects, students gain the technical proficiency and critical thinking skills necessary for future roles as Environmental Sustainable Design (ESD) consultants. This studio experience underscores the value of simulation-driven education in shaping the next generation of built environment professionals committed to sustainability and performance excellence.

ACKNOWLEDGEMENTS

Authors would like to acknowledge BPS5112 students' contribution, in particular Mr. Ng Jing Xian and Mr. Ang Kok Kiong, along with Mr. Ian Tan Eng Kiong, Ms. Lyu Jiachen, Mr. Ng Jing Xian, Ms. Patil Tanaya Amar, Ms. Patnala Reena Sri, Ms. Si Wenqing, Mr. Wilfred Leung Wei Lit. These students are part of this course in AY24/25 and are sharing their results in the paper. We are also grateful to our Teaching Assistants (TAs), namely Xiang Yeyu, Liu Puyang, Lin Subin, Ting Shi An, Sicheng Zhan, Siyu Cheng, Yue Lei, Kazuki Horikoshi and Zhang Yiting for their invaluable support to the students during the coursework.

SUMMARY
Duct network with multiple branch ducts is widely used to distribute conditioned air to some indoor spaces. Reducing flow resistance while assuring the identical flow rate to each branch duct is needed. However, these dual objectives may conflict between each other. This investigation proposed to adopt a two-stage shape optimization to realize the both objectives: in the first stage the flow resistance is minimized by optimizing the geometric shapes without addressing the requirement of identical airflow rate in each duct; in the second stage, the airflow rate in each duct is adjusted. A duct network containing one main duct and four arc-shaped branch ducts are optimally designed. The designed duct network was manufactured by the 3D printing for measurement. The obtained results reveal that the flow resistance was reduced by at least 30% after the design while achieving the nearly identical airflow rate in each branch duct.

Keywords: Duct network, adjoint shape optimization, flow resistance, identical flow rate distribution, energy saving

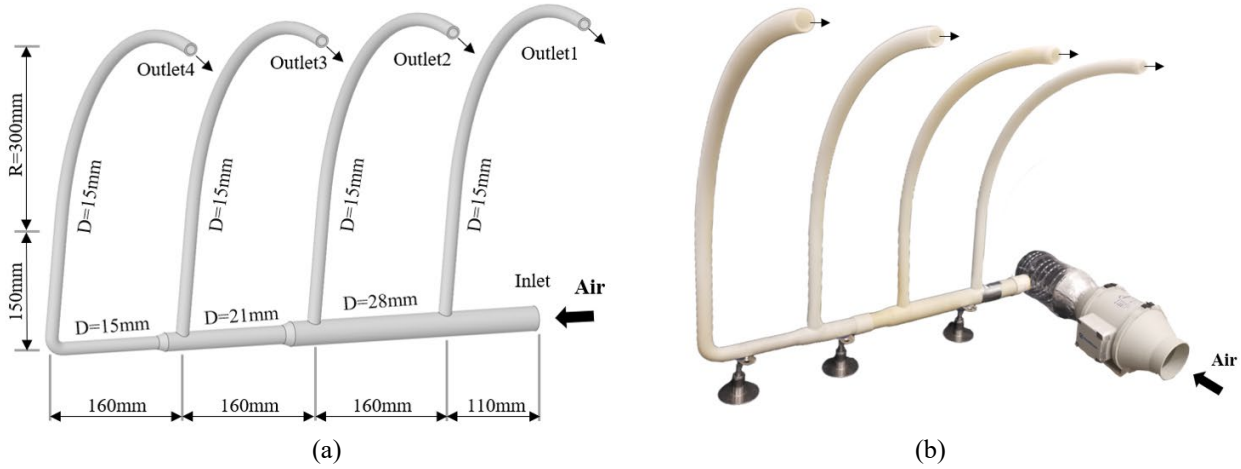
1. INTRODUCTION

For long enclosed space like an aircraft cabin, train compartment, and coach, the conditioned air is commonly supplied into the internal space by a ductwork with many branch ducts. Commonly the airflow rate in each branch duct shall be nearly identical to minimize the undesired longitudinal airflow. The current practice adds some flow resistances, such as baffles or restrictors, to hydraulically balance the airflow rate in each branch duct. This inevitably leads the increased energy consumption and louder noise. It is viable to adopt the guide vanes (Yin et al., 2021) or shape optimization (Tian et al., 2024) to reduce the flow resistance. The optimization algorithms, such as genetic algorithms (Simpson et al., 1994; Dandy et al., 1996), simulated annealing method (Cunha et al., 1999), harmonic search (Geem et al., 2002), and Dijkstra's algorithm (Gunawan, et al., 2021), etc., have been proposed to improve the ductwork design. These practices concentrate to the sole goal to reduce the flow resistance. So far, no research optimizes the duct geometry to reduce flow resistance while assuring the identical airflow rate to each branch duct. This research proposes a two-stage adjoint-shape optimization to achieve the dual goals. Note that these dual goals may contradict with each other during the design.

2. METHODS

A simplified network with multi-branch ducts as shown in Fig. 1(a) is investigated. This duct network contains a main duct with two transitions in the duct diameter and four arc-shaped branch

ducts. The main duct has a total length of 59 cm. Each branch duct has an inner diameter of 15 mm and is separated from the adjacent duct(s) with 160 mm. The inner diameter of the entrance section of the main duct is 28 mm. The diameter is reduced to 21 mm between the two middle branch ducts. The main duct is finally narrowed to 15 mm, as the same size of the branch ducts. The rated total airflow rate through the main duct is 25.31 m³/h. When optimizing the geometric design, the total airflow rate, the inner diameter of the main duct at the entrance, and the inner diameter of the branch duct exits are fixed, while the remaining geometry is adjustable.



(a) (b)

Figure 1. A duct network for optimal geometric design: (a) initial geometric model, (b) picture of the optimally designed duct network for measurement.

A two-stage optimization strategy is utilized: in the first stage the flow resistance is minimized without considering the requirement of identical airflow rate in each duct; in the second stage, the airflow rate in each duct is adjusted to approach identity with the optimized geometry in the first stage as the input. The two design objectives are defined as:

$$J_1 = \frac{P_{\text{Outlet}-i}}{P_{\text{Inlet}}} = \frac{\int p_{\text{Outlet}-i} dS}{\int dS} \Big/ \frac{\int p_{\text{Inlet}} dS}{\int dS} \tag{1}$$

$$J_2 = \frac{\sum_{i=1}^{n} \left| Q_{\text{Outlet}-i} - Q_{\text{Average}} \right|^2}{n} = \frac{\sum_{i=1}^{n} \left| \int q_{\text{Outlet}-i} dS - \frac{\sum_{i=1}^{n} \int q_{\text{Outlet}-i} dS}{n} \right|^2}{n} \tag{2}$$

where J_1 and J_2 are the design objective in the first and second stage, respectively, P represents the surface-average total pressure (relative pressure), p is the local total pressure (relative pressure) per unit area, S denotes the cross-sectional area, Q is the airflow rate, q is the airflow rate per unit surface, n represents the total number of branch ducts, and i denotes the branch duct index. The design tries to minimize both J_1 and J_2.

The steady-state flow in the duct network was resolved by the Reynolds-averaged Navier-Stokes (RANS) modeling with the Realizable k-ε turbulence model and the Menter-Lechor wall treatment in Ansys Fluent. All of the physical variables were discretized by the second-order upwind scheme. The pressure and velocity were coupled by the SIMPLE algorithm. The discrete adjoint method

(Liu et al., 2023) was employed to guide the duct geometry adjustment based on the sensitivity of the objective functions. The convergence criterion for adjoint equations was defined as the adjoint residuals below 10^{-3}. A total of $200 \times 100 \times 50$ control points were adopted and the geometric modifications were implemented using the mesh morphing technique based on the Bernstein polynomials and B-spline function. The design was continued until the residuals of both J_1 and J_2 are below 10^{-3}.

The optimally designed prototype was manufactured by the 3D printing with the interior surfaces polished for measurement of the performance, as shown in Fig. 1 (b). A fan pumped the outside air into the plenum connecting to the main duct. The airflow rate in each branch duct and the total flow resistance through the whole duct network were measured by a Pitot tube (model: LPT-03-300; Yiou, China). The fan energy consumption was recorded by a power meter (model: DL333501C; Deli, China) to examine the energy saving. The noise was measured by a sound level meter (model: HS6288B; Hongsheng, China). In addition to the designed airflow rate of 25.20 m³/h, other total airflow rates were also tested, including 8.25, 12.52, 19.24, and 33.89 m³/h, respectively. This was to evaluate the robustness of the optimal design.

3. RESULTS AND DISCUSSION

Fig. 2(a) presents the optimally designed geometric shape of the duct network. After the optimal design, the transitions in the diameter of the main duct along the flow direction were still maintained. The major geometric shape adjustment lied in the Tee ducts and the elbow, which were evolved into irregular shapes. Fig. 2(b) presents distribution of the total pressure across the middle cross-section in surrounding of the main duct. The maximum total pressure inside the main duct has been reduced from 193.0 Pa in the initial design to 111.9 Pa in the optimal design. The pressures near the Tee ducts have been minimized significantly.

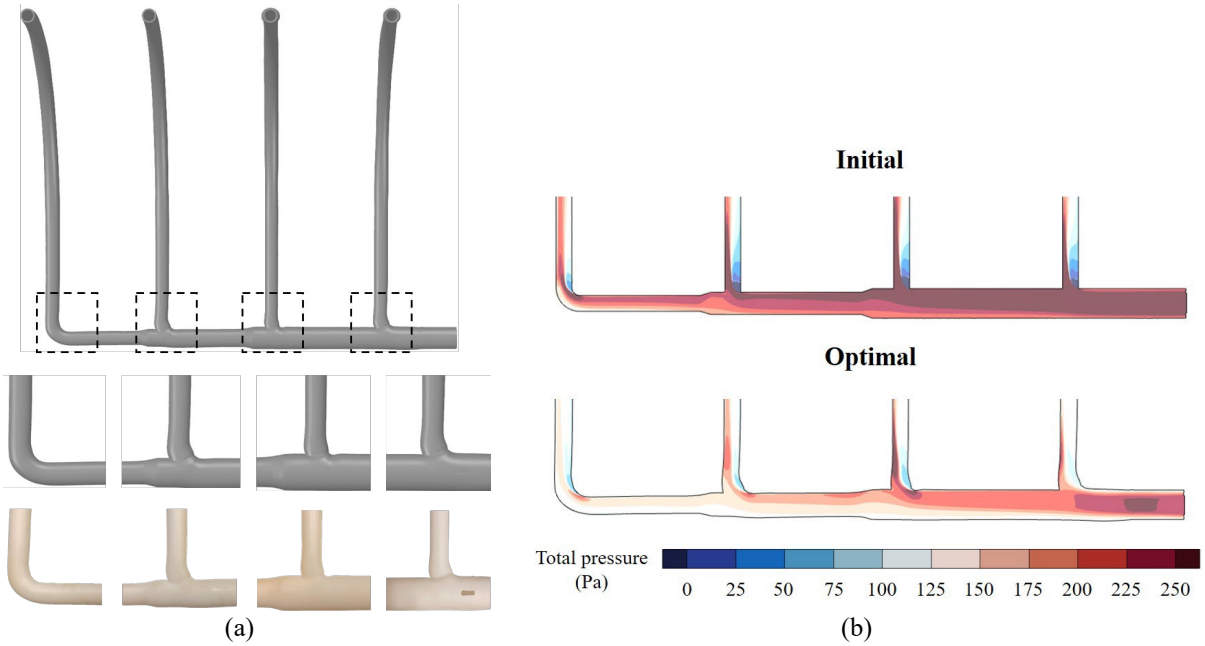


Figure 2. Optimally designed duct network: (a) geometric shape of the final optimal design, (b) comparison of the total pressure distribution across the middle cross-section in surrounding to the main duct between the initial design

and the final optimal design.

Fig. 3(a) shows comparison of the measured total pressure difference between the initial design and the final optimal design under different total ventilation rates. Under the ventilation rate of 25.31 m³/h, the total pressure was reduced by 75.2 Pa after the optimal design and the pressure reduction rate was 41.02%. Fig. 3(a) also shows the total pressure reduction ratio increases with the ventilation rate for the ventilation rates between 8.25 and 19.24 m³/h. The pressure reduction ratio is nearly identical for the ventilation rates between 19.24 and 33.89 m³/h. The total pressure reduction ratio ranges from 30.81% to 41.02%. Fig. 3(b) shows that the standard deviation of the airflow rate in each branch duct is reduced from 0.28 m³/h to 0.11 m³/h under the rated ventilation rate of 25.31 m³/h. The flow homogeneity has been increased by 18.68% to 61.93% among the tested ventilation rates. The varying trend of the fan energy consumption resembles the total pressure difference as shown in Fig. 3(c). The fan power consumption reduction ranges from 15.04% to 31.72%. Fig. 3(d) shows the design can also reduce the noise level by 3.4-4.8 dB, mainly because the rotational speed of the fan is slowed down with the reduced flow resistance.

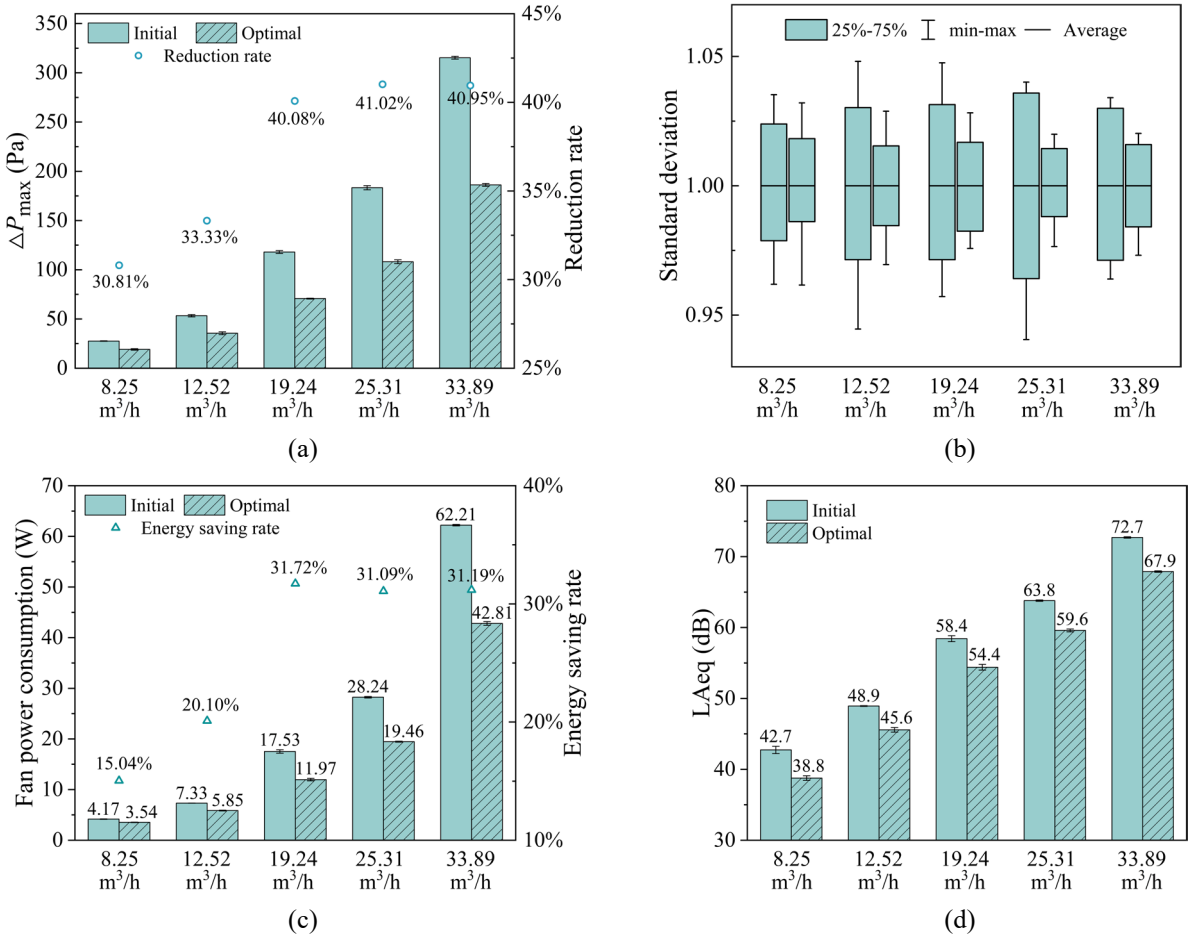

Figure 3. Performance of the final optimized ductwork under different total ventilation rates: (a) total flow resistance and the total resistance reduction rate, (b) homogeneity of the flow rate distribution evaluated by standard deviation of the ratio of the flow rate in each branch duct to the average flow rate, (c) fan power consumption and the energy saving rate, (d) noise level (LAeq).

These improvements are primarily attributed to the geometric optimization that refrain the vortex

development mainly in the Tee ducts and elbow. However, the optimal design also results in 4% increase of the total surface area, which requires slightly more investment in the materials.

4. CONCLUSIONS

As compared with the conventional duct network without carrying out the optimal geometric design, the optimally designed duct network improves the airflow rate homogeneity by at least 18.68%, while lowering the total flow resistance by no less than 30.81%. The monitored fan energy consumption of the new design was at least 15.04% less. Although the geometric design is carried out under the rated total ventilation rate, the optimally designed duct network performs robustly well in other smaller or larger ventilation rates. This justified that the proposed two-stage adjoint-shape design is very promising to enhance the duct network performance.

SUMMARY
Buildings are responsible for one-third of global energy consumption and greenhouse gas emissions. A major part of building energy consumption is related to HVAC systems which aim to provide thermal comfort. Hence, improving the efficiency of HVAC systems using optimization and fault detection techniques is crucial not only to mitigate climate change but also to satisfy occupant needs. To achieve the best performance, an accurate model is often required. Previous studies have highlighted potential limitations focusing on error minimization for model evaluation. This study (i) introduces the concept of reliability as a complementary criterion and (ii) analyzes its importance in building energy modeling using the concept of k-fold cross validation. To this end, models of a water-cooled chiller are developed and compared considering reliability. The results suggest that in addition to training accuracy, reliability is another important factor to consider in model selection and evaluation processes.

Keywords: Digital twin, Data-driven modelling, Model evaluation, Building energy system

1. INTRODUCTION

Buildings are major energy consumers and greenhouse gas emitters, with these issues worsening due to climate change, urbanization, and population growth (International Energy Agency (IEA), 2018). A positive feedback loop exists where increased energy use worsens climate change, further driving energy demand (UNEP, 2023). Breaking this cycle while satisfying occupant comfort needs requires improving HVAC efficiency, as these systems are a major energy consumer in buildings (Zhao et al., 2013)(Borja-Conde et al., 2024). The concept of digital twins, the creation of models for synchronized simulation with their target systems (Huang et al., 2022), provides opportunities to enable advanced optimization and fault detection strategies for improved HVAC efficiency(Pau et al., 2019). However, model evaluation and selection for digital twinning is still an active area of research (Mihai et al., 2022).

The majority of the previous studies in building system modeling primarily focus on minimizing prediction error (i.e., improving accuracy). Previous literature suggests that reliability could be another criterion besides accuracy (Newrzella et al., 2022). Reliability refers to a model's ability to produce consistent and stable outputs when deployed in real-world scenarios. A reliable model performs with low variability when encountering new but similar data to what it was trained on. (Cordeiro-Costas et al., 2023). Reliability is not necessarily aligned with accuracy. For instance, a model might achieve high overall accuracy but generate highly variable predictions for different operating conditions which shows low reliability. Reliability is used in fields such as finance (Ata & Hazim, 2020), medicine (Wang et al., 2023), and Chemistry (Naef, 2015), where it is quantified by measuring the variability of validation error metrics in K-fold cross-validation (KFCV) (Edgar Ceh-Varela et al., 2024).

This study highlights an opportunity to enhance model selection and evaluation processes in the

field of building energy modeling. By analyzing the impact of reliability, the study demonstrates that it is a crucial factor in determining which model should be implemented.

2. METHODOLOGY

Previous studies have often used the standard deviation of K number of validation errors from KFCV to evaluate reliability. A reliable model, which performs with low variability and high stability, exhibits a low standard deviation. This indicates that no matter which part of the dataset the model is exposed to, it provides consistent performance (Vorotyntsev et al., 2021).

To assess the importance of quantifying model reliability in the field of building energy modelling, a water-cooled chiller dataset (Zhang et al., 2022) is used. The aim is to predict the chiller's COP using condenser and evaporator inlet and outlet temperatures, along with water flow rates as input variables. To achieve the goal, 500 single-layer neural networks with random hyperparameters are constructed. Random hyperparameters and their range are shown in Table 1.

Table 1. Range of random hyperparameter values

	number of first layer neurons	activation function	L_2 regularization	Initial Learning rate	β_1	β_2
Range of random value	[10,100]	Logistic – Relu - Tanh	$[10^{-6}, 10^{-2}]$	$[10^{-6}, 10^{-2}]$	[0.85,0.99]	[0.85,0.999]

Models are then trained and validated using 10-fold cross validation. One fold is considered as the test and is not observed during the CV process. Nine folds entered the CV process and the means and standard deviations of the RMSE of the validation folds are obtained. Next, these values are compared and analysed to determine whether they affect the model's performance on the test data.

3. RESULTS AND DISCUSSION

Following the methodology results in 500 trained models, each with different mean and standard deviation for the RMSE of the validation folds as shown in Figure 1.

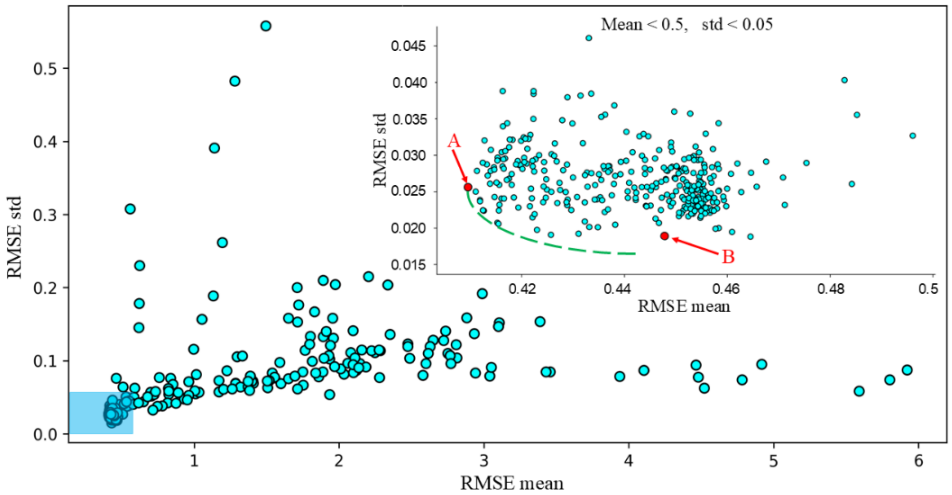

Figure 1. Mean and std of validation RMSEs (inner Figure shows the sky-blue area with mean < 0.5 and std < 0.05)

As Figure 1 shows, the relationship between the mean and standard deviation is not linear meaning that minimizing the mean does not result in the minimum standard deviation. In some cases, models have a close mean value but different standard deviations. In addition, the green line in the

inner figure resembles the Pareto frontier that can be obtained using bi-objective optimization. To analyse whether there is a difference in test performance between these models, points A, which has the minimum mean, and B, which has the minimum standard deviation, are selected for further investigation. The parameters of these models are shown in Table 2.

Table 2. Hyperparameters of model A and B

	number of first layer neurons	activation function	L_2 regularization	Initial Learning rate	β_1	β_2
Model A	47	Relu	0.0062689	0.00934	0.9496	0.9591
Model B	74	Tanh	0.0022579	0.00932	0.9619	0.9034

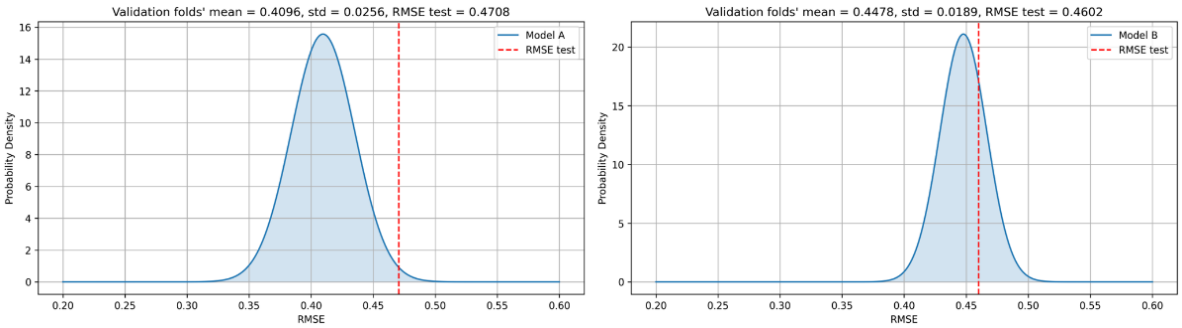

Figure 2. Comparing the test performance of models A and B with their validation error distribution

Figure 2 compares the test performance of these two models with validation error distribution. As can be seen, model B has a considerably lower bias, and the test error is closer to the expectation. Also, model A underestimated the error and provided an optimistically biased result which is aligned with the findings of previous studies in other fields (Pohjankukka et al., 2017)(Leinonen et al., 2024). In addition, absolute RMSE is also lower (0.46 vs. 0.47). Although the results do not guarantee that lower bias is always observed when minimizing standard deviation, it provides evidence indicating that ignoring reliability in model evaluation and selection process results in losing valuable information.

4. CONCLUSION

The present study investigated whether reliability is an effective criterion in model selection and evaluation. For this purpose, 500 single-layer neural networks with random hyperparameters are constructed to predict the COP of a real-world water-cooled chiller. Next, the models' performance is evaluated using KFCV, and the mean and standard deviation of the validation RMSE for each model are obtained. The results show that the mean and standard deviation do not always align, so minimizing the mean does not minimize the standard deviation. Thus, ignoring reliability and focusing only on average performance leads to the loss of useful information. For future research, a bi-objective hyperparameter tuning algorithm will be developed to find Pareto optimal solutions and evaluate test performance across these solutions. In addition, the performance of other machine learning algorithms will be analysed.

Fast building performance simulation method for evaluating renovation strategies of terraced houses in the Netherlands

Chaobo Zhang*, Pieter-Jan Hoes, Ruqian Zhang

Department of the Built Environment, Eindhoven University of Technology, Eindhoven, the Netherlands
**Corresponding author. E-mail address: c.zhang5@tue.nl*

SUMMARY
A fast building performance simulation method is proposed for evaluating renovation strategies of Dutch terraced houses. It utilizes limited EnergyPlus simulation data generated by data sampling to train surrogate models. Two data sampling approaches (simple random sampling (SRS) and Latin hypercube sampling (LHS)) and three data-driven models (multiple linear regression, extreme gradient boosting, and artificial neural network (ANN)) are investigated. A Dutch terraced house is applied for performance verification. The results show that surrogate models trained with simulation samples from LHS achieve accuracy similar to those trained with samples from SRS. Furthermore, it is found that limited simulation data (400 samples) are sufficient to train an accurate surrogate model. ANN is the most accurate model in simulating indoor air temperatures (R^2 = 0.99, *MAE* = 0.12 ºC) and thermal loads (R^2 = 0.95, *MAE* = 700 W). The computational time of ANN accounts for only 0.03% of that of EnergyPlus.

Keywords: machine learning, surrogate model, building performance simulation, building renovation.

1. INTRODUCTION

Building performance simulation (BPS) offers a cost-effective mean to evaluate building renovation strategies. There are two main modeling approaches: data-driven and physics-based. Data-driven models depend on high-resolution measured data from buildings (e.g., indoor air temperatures and energy consumption). However, the availability of such data is often limited, restricting the application of these models. Physics-based models, on the other hand, can simulate high-resolution dynamic performance of individual buildings without relying on measured data. They can provide reliable simulation outcomes based on general building information (e.g., location, geometry, and construction details), making them powerful tools for decision-making. Nevertheless, physics-based models typically result in high computational loads (Hong et al., 2020). When assessing renovation strategies for large neighborhoods (e.g., in the Netherlands, a typical neighborhood could encompass 1,500 houses with a variety of building typologies, building shapes and construction years), this computational demand becomes impractical. The challenge increases when investigating a wide range of renovation strategies per house, including the performance robustness of each strategy under different occupant behavior and climate change scenarios. The computational load becomes even more pressing when also evaluating neighborhood-scale energy system strategies, such as district heating or local energy communities that involve sharing and matching of electricity production and demand. Consequently, developing efficient methods to accelerate BPS is both necessary and important.

A promising solution is developing data-driven surrogate models based on physics-based models. These surrogate models are trained using a limited set of simulation data generated by the physics-

based models. Once trained, they can rapidly estimate the simulation results of physics-based models with acceptable accuracy. Surrogate models have been successfully applied in various areas, including urban building energy simulation, building energy model calibration, and optimization studies for building design and renovation. For instance, Pan et al. (2024) developed a long short-term memory-based surrogate model for hourly electricity consumption simulation of urban-scale buildings. This model reduced the simulation time by 90% while maintaining an accuracy of over 90%. Herbinger et al. (2023) used a limited set of simulation data from physics-based models to train artificial neural network (ANN) models. These trained ANN models were then utilized to calibrate unknown building model parameters, providing accurate parameter calibration with short calibration times. Yigit (2021) proposed a surrogate model based on gradient boosting machine to optimize envelope insulation retrofit strategies for residential buildings, revealing optimal design strategies with fast optimization speeds. Lu et al. (2024) developed a graph convolutional networks-based surrogate model to quantify the uncertainty of building design loads, reducing the computational time from 331 hours to 30 seconds compared to physics-based models. Sharif and Hammad (2019) trained an ANN model as a surrogate model to optimize building renovation strategies, reducing the optimization time by 99% compared to physics-based models while achieving similar optimization results.

Surrogate models thus show great potential for accelerating BPS. In the context of neighborhood-scale building and energy system renovation strategies, the surrogate models must reliably generate hourly simulation results based on the physics-based models. These hourly results are needed for calculating several relevant performance indicators. For instance, the hourly indoor air temperatures are needed to calculate summer overheating risks and the hourly energy demand is required for evaluating local energy matching and sharing strategies. However, few studies have explored the effectiveness of surrogate models in this context. Key questions that need to be addressed are: What are the most suitable data-driven surrogate models for this purpose? What data sampling approaches are appropriate for training the models? What is the appropriate sample size for physics-based models to ensure the accuracy of surrogate models? How much computational time can surrogate models save in practice?

This paper aims to address these questions through a case study of a Dutch terraced house using EnergyPlus simulation data. Specifically, it compares the performance of three widely used data-driven models: multiple linear regression (MLR), extreme gradient boosting (XGBoost), and ANN. Additionally, this study evaluates two common data sampling approaches: simple random sampling (SRS) and Latin hypercube sampling (LHS). This paper also provides valuable insights into generating simulation samples and training surrogate models to support fast and accurate performance evaluations.

2. METHODOLOGY

Figure 1 illustrates the surrogate model development process. The process consists of two steps: physics-based model sampling and surrogate model training. The first step aims to generate a limited set of EnergyPlus simulation samples. The second step focuses on training a surrogate model based on these samples. Further details on these steps are provided in Sections 2.1 and 2.2.

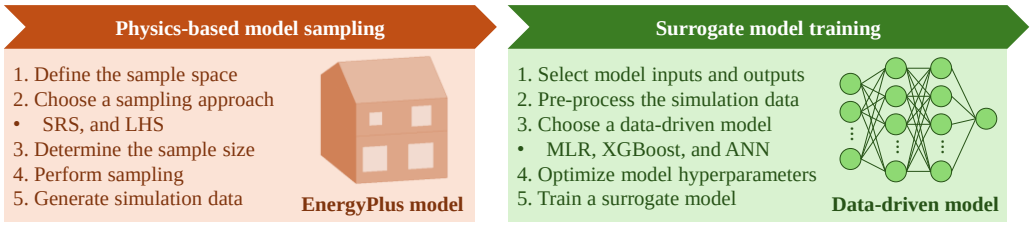

Figure 1. Flowchart of the surrogate model development process.

2.1 Physics-based model sampling

The first sub-step is to define the sample space. In this study, the sample space for variables influencing building renovation performance is defined. Key variables should be related to, but are not limited to, building geometry, occupant behavior, building insulation, and space heating.

Then, it is necessary to select a suitable sampling approach. SRS and LHS are two commonly used approaches for the surrogate models of BPS (Zhang, 2021). SRS is a basic approach where each variable value is chosen independently and has an equal chance of being selected. This approach is easy to implement. However, it might require a large sample size to fully capture the variability of multiple variables. LHS is a stratified sampling approach designed to ensure that each variable is sampled efficiently within its space. It maintains good coverage of the multi-variable space.

After that, the sample size is determined, and the selected sampling approach is used to generate the required number of samples. Finally, EnergyPlus is used to generate the data for the samples.

2.2 Surrogate model training

The first sub-step is to determine the model inputs and outputs. Relevant key performance indicators (KPIs) for evaluating building renovation strategies include thermal comfort, overheating/underheating hours, peak thermal loads, operational CO_2 emissions and operational costs. Hourly indoor air temperatures and thermal loads are needed to calculate these KPIs. Therefore, the outputs of the surrogate model in this study focus on those variables. The inputs are factors related to building geometry, occupant behavior, building insulation, and space heating.

Then, the simulation data of the inputs and outputs should be pre-processed to enhance the accuracy of the surrogate models. Max-min normalization is applied to scale both the inputs and outputs to the same range of 0 to 1. This reduces the impact of varying magnitudes between them.

Next, a suitable data-driven model should be selected for developing a surrogate model. MLR, XGBoost, and ANN are three commonly used data-driven models for building energy modeling (Zhao et al., 2022). MLR is used to learn the linear relationship between inputs and outputs. It is easy to implement and interpret, while it usually shows low accuracy. XGBoost is one of the most powerful ensemble learning models, known for its high accuracy and fast computation speed. As for ANN, it is a widely used machine learning model in this domain. This model excels at capturing non-linear relationships between inputs and outputs, resulting in high accuracy.

After that, the hyperparameters of the data-driven models are optimized, which plays a crucial role in enhancing the model accuracy. Grid search is applied for hyperparameter optimization. It involves systematically searching through a manually specified subset of hyperparameters to find

the best combination that maximizes the model accuracy on the validation datasets. Finally, the surrogate models with the best hyperparameters are trained using the EnergyPlus simulation data.

3. RESULTS

3.1 Case study overview

This case study focusses on a terraced house located in Eindhoven, the Netherlands. Space heating is provided on the first and second floors, while the attic is not heated. DesignBuilder is used to define the geometry and zoning of this house (see Figure 2). Subsequently, an EnergyPlus model is created using DesignBuilder, and Python is employed to run this model with different configurations in batches for generating hourly simulation data. Hourly weather data for Eindhoven in 2019 are collected from the Dutch meteorological institute for use in the simulations.

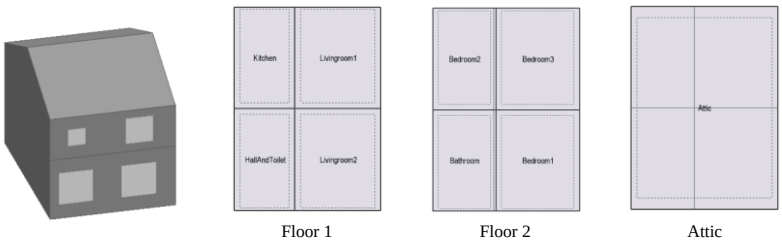

Figure 2. Geometry and zoning of the terraced house used for performance verification.

The configurations are sampled from the sample space listed in Tables 1-4. The sample space encompasses four types of variables affecting the renovation performance: building geometry (orientation and boundary condition), occupant behavior (occupancy schedule, indoor air heating setpoints, ventilation rate, and solar shading), space heating (hot water supply temperature and radiator renovation status), and building insulation (infiltration rate, Rc-values of floors/walls/roofs, and U-values of windows/doors). The rated heating capacity of each radiator in a zone is selected based on the renovation status and the rated heating capacities of radiators available in the Netherlands (https://radiatorendiscounter.nl/). The design heating load for the zone is calculated by EnergyPlus. If the radiator is not renovated, its rated heating capacity is determined by selecting the available rated heating capacity (at a 75 °C supply temperature) that is closest to the design heating load. If the radiator is renovated, its rated heating capacity is determined by selecting the available rated heating capacity (at the sampled supply temperature) that is closest to the design heating load. Two sampling approaches are compared: SRS and LHS. Each approach generates 1,000 variations of the building model for training the surrogate models. Additionally, 500 variations are randomly generated to verify the performance of trained surrogate model; note that these variations are different from the 2,000 variations in the training samples. Two commonly used accuracy metrics, i.e., R^2 and mean absolute error (*MAE*), are used for verification.

Table 1. Sample space related to the renovation of Dutch terraced houses.

No.	Variable	Unit	Space	Source
1	Orientation	-	North, south, east, west	-
2	Boundary condition	-	Between, corner	-
3	Occupancy schedule	-	Refer to Table 2	VLA, 2018
4	Indoor air heating setpoint	-	Refer to Table 3	BZK and CBS, 2019
5	Ventilation rate	-	Refer to Table 4	BZK and CBS, 2019
6	Solar shading	-	Refer to Table 4	BZK and CBS, 2019

7	Hot water supply temperature	ºC	45, 55, 75	Lund et al., 2018
8	Radiator renovation status	-	Renovated, not renovated	-
9	Rc-value of ground floors	$(m^2.K)/W$	0.15, 0.17, 0.52, 2.5, 3.5	RVO, 2023
10	Rc-value of walls	$(m^2.K)/W$	0.35, 0.43, 1.3, 1.7, 2.5, 4.5	RVO, 2023
11	Rc-value of roofs	$(m^2.K)/W$	0.35, 0.72, 0.86, 1.3, 2.5, 3.5, 6.0	RVO, 2023
12	U-value of windows	$W/(m^2.K)$	1.1, 2.8, 5.8	RVO, 2023
13	U-value of doors	$W/(m^2.K)$	1.4, 3.4	RVO, 2023
14	Infiltration rate	$dm^3/(s.m^2)$	[0.1, 3]	Bramiana et al., 2016

Table 2. Occupancy schedules for three typical Dutch families.

Family	Occupant	Occupancy schedule
Family 1	Adult (working)	**Workday: Bedroom:** 0:00-6:00, 23:00-0:00; **Living room:** 6:30-7:00, 18:00-18:45, 19:30-22:45; **Kitchen:** 6:15-6:30, 18:45-19:30; **Bathroom:** 6:00-6:15, 22:45-23:00 **Weekend: Bedroom:** 0:00-8:00, 23:00-0:00; **Living room:** 8:30-11:00, 14:00-18:45, 19:30-22:45; **Kitchen:** 8:15-8:30, 18:45-19:30; **Bathroom:** 8:00-8:15, 22:45-23:00
Family 2	Adult (staying at home)	**Bedroom:** 0:00-8:00, 23:00-0:00; **Living room:** 8:30-11:00, 14:00-18:45, 19:30-22:45; **Kitchen:** 8:15-8:30, 18:45-19:30; **Bathroom:** 8:00-8:15, 22:45-23:00
	Adult (staying at home)	**Bedroom:** 0:00-8:00, 23:00-0:00; **Living room:** 8:30-11:00, 14:00-22:45; **Kitchen:** 8:15-8:30; **Bathroom:** 8:00-8:15, 22:45-23:00
Family 3	Adult (working)	**Workday: Bedroom 1:** 0:00-6:00, 23:00-0:00; **Living room:** 6:30-7:00, 18:00-22:45; **Kitchen:** 6:15-6:30; **Bathroom:** 6:00-6:15, 22:45-23:00 **Weekend: Bedroom 1:** 0:00-8:00, 23:00-0:00; **Living room:** 8:30-11:00, 14:00-22:45; **Kitchen:** 8:15-8:30; **Bathroom:** 8:00-8:15, 22:45-23:00
	Adult (staying at home)	**Workday: Bedroom 1:** 0:00-6:00, 23:00-0:00; **Living room:** 7:00-11:00, 14:00-18:45, 19:30-22:45; **Kitchen:** 6:15-7:00, 18:45-19:30; **Bathroom:** 6:00-6:15, 22:45-23:00 **Weekend: Bedroom 1:** 0:00-8:00, 23:00-0:00; **Living room:** 8:30-11:00, 14:00-18:45, 19:30-22:45; **Kitchen:** 8:15-8:30, 18:45-19:30; **Bathroom:** 8:00-8:15, 22:45-23:00
	Three-year kid (staying at home)	**Workday: Bedroom 2:** 0:00-7:30, 19:15-0:00; **Living room:** 8:00-11:00, 14:00-19:00; **Kitchen:** 7:45-8:00; **Bathroom:** 7:30-7:45, 19:00-19:15 **Weekend: Bedroom 2:** 0:00-9:00, 20:15-0:00; **Living room:** 9:30-11:00, 14:00-20:00; **Kitchen:** 9:15-9:30; **Bathroom:** 9:00-9:15, 20:00-20:15
	Ten-year kid (going to school)	**Workday: Bedroom 3:** 0:00-7:15, 20:15-0:00; **Living room:** 7:45-8:00, 18:00-20:00; **Kitchen:** 7:30-7:45; **Bathroom:** 7:15-7:30, 20:00-20:15 **Weekend: Bedroom 3:** 0:00-9:00, 21:15-0:00; **Living room:** 9:30-11:00, 14:00-21:00; **Kitchen:** 9:15-9:30; **Bathroom:** 9:00-9:15, 21:00-21:15

Table 3. Typical indoor air heating setpoint schedules (ºC) for Dutch buildings.

Schedule No.	0:00-6:00	7:00-9:00	10:00-12:00	13:00-15:00	16:00-18:00	19:00-23:00
1	17.5	19	19	19	19.5	20
2	20.5	20.5	20.5	20.5	20.5	21
3	15	15.5	19.5	19.5	20	20
4	15	19.5	19.5	19.5	19.5	20
5	17	20.5	21	21.5	21.5	21.5
6	15.5	17.5	16.5	16.5	17.5	19.5

Table 4. Typical ventilation and solar shading control strategies for Dutch buildings.

Control type	No.	Strategy description
Ventilation	1	The ventilation rate is maintained at a low level of 0.75 $m^3/(h.m^2)$.
	2	The ventilation rate is maintained at a mid level of 1.50 $m^3/(h.m^2)$.
	3	The ventilation rate is maintained at a low level of 0.75 $m^3/(h{\cdot}m^2)$ when the house is unoccupied. When the house is occupied, the ventilation rate increases to a moderate level of 1.50 $m^3/(h{\cdot}m^2)$.
Shading control	1	No solar shading.
	2	External shading is used when the indoor air temperature exceeds 22 ºC, and the solar irradiance on windows surpasses 200 W/m^2. Otherwise, it remains inactive.
	3	External shading is used when the house is occupied, the indoor air temperature exceeds 24 ºC, and the solar irradiance on windows surpasses 300 W/m^2. Otherwise, it remains inactive.
	4	External shading is used from May to September, and not used in other months.

Three data-driven models are investigated in this case study (MLR, XGBoost, and ANN). The outputs are the hourly average indoor air temperatures on the 1st and 2nd floors, and the hourly building thermal load. The inputs for these outputs are listed in Table 5. The hyperparameter optimization space for XGBoost and ANN is shown in Table 6. For hyperparameter optimization, 75% of the training data are utilized to train the surrogate models, and the rest of the data are applied to evaluate hyperparameter combinations.

Table 5. Inputs of the surrogate models for hourly indoor air temperature and hourly thermal load simulation.

Input	Output		
	Hourly indoor air temperature on the 1st floor	Hourly indoor air temperature on the 2nd floor	Hourly thermal load
Orientation	Yes	Yes	Yes
Boundary condition	Yes	Yes	Yes
Indoor air heating setpoint	Yes	Yes	Yes
Hot water supply temperature	Yes	Yes	Yes
Radiator renovation status	Yes	Yes	-
Rc-value of ground floors	Yes	Yes	Yes
Rc-value of walls	Yes	Yes	Yes
Rc-value of roofs	Yes	Yes	Yes
U-value of windows	Yes	Yes	Yes
U-value of doors	Yes	Yes	Yes
Infiltration rate on the 1st floor	Yes	-	-
Infiltration rate on the 2nd floor	-	Yes	-
Infiltration rate of the house	-	-	Yes
Ventilation rate on the 1st floor	Yes	-	-
Ventilation rate on the 2nd floor	-	Yes	-
Ventilation rate of the house	-	-	Yes
Outdoor air temperature	Yes	Yes	Yes
Solar radiation	Yes	Yes	Yes
Solar shading status	Yes	Yes	Yes

Table 6. Search range for hyperparameter optimization.

Model	Hyperparameter	Search range
XGBoost	Number of trees	20, 40, 60, 80, 100, 120, 140, 160, 180, 200
	Learning rate	1, 0.5, 0.1, 0.05, 0.01
ANN	Number of hidden layers	1, 2, 3, 4, 5
	Activation function	ReLU, sigmoid, tanh
	Number of nodes in hidden layers	15, 20, 25, 30

3.2 Simulation accuracy of surrogate models

Figure 3 illustrates the accuracy of MLR, XGBoost, and ANN in simulating hourly indoor air temperatures and hourly thermal loads with different training sample sizes generated using LHS and SRS. According to the results, the three models trained using the samples generated by LHS exhibit similar accuracy to those trained using the samples generated by SRS. The main reason might be that most inputs are independent of each other. Additionally, the accuracy of the three models improves when increasing the sample size, however the accuracy no longer improves significantly when the training sample size reaches 400. This indicates that limited simulation data are sufficient to develop an accurate surrogate model. ANN demonstrates the highest accuracy among the three models. With a sample size of 400, it shows a R^2 of 0.99 for the indoor air temperature and a R^2 of 0.95 for thermal load. Moreover, it shows a *MAE* of 0.12 ºC for the indoor air temperature and a *MAE* of 700 W for the thermal load.

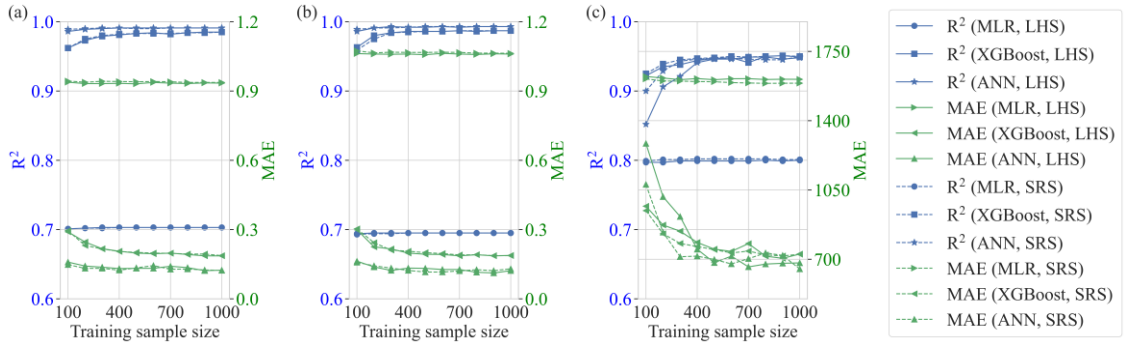

Figure 3. Accuracy of MLR, XGBoost, and ANN with different training sample sizes for the (a) hourly indoor air temperature on the 1st floor, (b) hourly indoor air temperature on the 2nd floor, and (c) hourly thermal load.

Figure 4 illustrates the ANN prediction results (400 LHS training samples) and EnergyPlus simulation results in six building variations with different occupant behavior. These variations are derived from the same base variation, with only one behavior modified in each variation. As shown, ANN results closely match those of EnergyPlus. Figures 4 (a) and (d) show the results on Feb. 1st for two variations with high and low heating setpoints (schedules 5 and 6 in Table 3), respectively. An increase in the setpoint significantly increases the heating load in winter. Figures 4 (b) and (e) illustrate the results on Aug. 1st for two variations with low and high ventilation rates (No. 1 and 2 strategies in Table 4), respectively. Increasing the ventilation rate slightly lowers the indoor air temperatures and cooling load in summer. Figures 4 (c) and (f) present the results on Jul. 22nd for two variations without and with solar shading (No. 1 and 2 strategies in Table 4), respectively. Solar shading significantly reduces the indoor air temperatures and cooling load in summer. Given the high accuracy of the ANN model, its prediction results are reliable for calculating specific KPIs such as thermal comfort hours, overheating hours, underheating hours, and peak thermal loads.

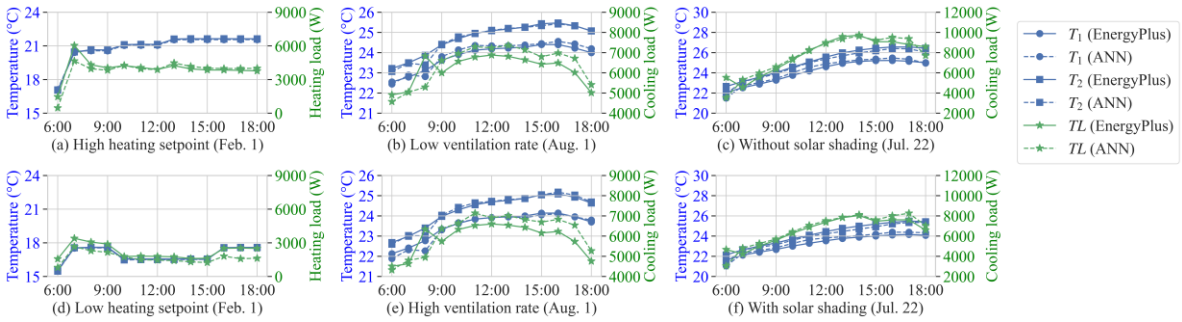

Figure 4. ANN results vs. EnergyPlus results for the hourly indoor air temperatures on the 1st floor (T_1) and 2nd floor (T_2), and the hourly thermal load (TL) in six building variations.

3.2 Simulation time of surrogate models

A laptop with a 2.3 GHz Intel Core i7-11800H processor is selected as the computational tool in this case study. The training time for the ANN surrogate model with a sample size of 400 is 25.9 min, while the simulation time is 0.01 s per simulation. As for EnergyPlus, its simulation time is 30.4 s per simulation. This implies that using surrogate models can reduce the simulation time by 99.97% when evaluating building renovation strategies in this case study.

4. CONCLUSIONS

This paper proposes a fast BPS method that can be used to evaluate large numbers of renovation strategies for terraced houses in a neighborhood. The basic idea is to train surrogate models using a limited dataset of EnergyPlus hourly simulation results for each relevant house. The simulation performance of surrogate models is verified and demonstrated for one terraced house in this study. In future research, the surrogate models will be applied to optimize renovation strategies for a variety of terraced houses in a neighborhood.

The results show that the surrogate models trained with simulation samples generated using Latin hypercube sampling demonstrate similar accuracy to those trained with samples produced by simple random sampling. Additionally, it is found that limited simulation data (sample size of 400) are sufficient for training an accurate surrogate model. Among three widely used data-driven models, artificial neural networks exhibit the highest accuracy in simulating indoor air temperatures (R^2 = 0.99 and MAE = 0.12 ºC) and building thermal loads (R^2 = 0.95 and MAE = 700 W). Regarding the computational time, it is shown that using surrogate models can reduce the simulation time by 99.97% compared to using EnergyPlus.

SUMMARY

In built environments, typical flow features such as wall-bounded flow and flow over flat surfaces can be well simulated with a hexahedral grid. In addition, under the same grid size, the use of hexahedral mesh better controls the overall number of grid cells. However, in the generation of a hexahedral mesh, connectivity modifications propagate through the mesh, resulting in a complex spatial partition of blocks. To address this complexity, the tool can automatically generate blocks for uniform grids by inputting characteristic coordinates and global grid size. It also supports the input of the first layer grid size, growth rate, and maximum grid size to automatically generate sub-blocks further for non-uniform grids. The definition of a boundary only requires inputting the diagonal coordinates of the surface. Additionally, the tool can automatically check the correctness of the definition of boundary parts. The tool will be open source on GitHub.

Keywords: indoor airflow, outdoor airflow, OpenFOAM, Structured mesh

1. INTRODUCTION

The mesh in a computational fluid dynamics (CFD) analysis is used to discretize a computational domain into numbers of control volumes, on which the conservation of mass, momentum, and energy is applied. Mesh generation can take up to about 40%-60% of the total time spent on a CFD mission (Liu et al., 2022). This is because a mesh should first be able to accurately describe the geometry of a computational domain. Besides, the mesh should be fine enough to capture the flow features or minimize the truncation error, and should not be too fine since beyond a certain level of refinement, the accuracy of the results does not improve significantly. Further, a smooth transition from small-scale grid to large-scale grid is needed as the discretized governing equations are solved dependently.

When generating a mesh, the choice of grid type is critical for optimizing computational accuracy, speed, and memory usage. The orthogonal hexahedral grid is widely favored for its high computational accuracy (Sarrate Ramos et al., 2014; Wang et al., 2021), excellent convergence properties (Baker et al., 2020; Liu et al., 2022), and efficient space-filling capabilities (Katz and Sankaran,

2011). It is commonly used in both indoor airflow simulations (Sheng et al., 2023; Yuan, Xu, et al., 2020) and outdoor wind field studies (S. Chen et al., 2024; Lin et al., 2024). For instance, Wang et al. (Wang et al., 2021) demonstrated that the hexahedral orthogonal mesh outperforms other grid types in terms of accuracy in outdoor wind field simulations. Similarly, Li et al. (Li and Okaze, 2024) found that hexahedral meshes provided better accuracy than polyhedral meshes when simulating flow over building arrays in various boundary layers. Duan et al. (Duan et al., 2015) also concluded that hexahedral grids were the most accurate for CFD simulations of air distribution in aircraft cabins, offering better control over grid size and simplifying grid independence analysis.

Several tools can generate hexahedral grids, such as ANSYS Meshing, ANSYS Fluent Meshing, ICEM CFD (Fluent, ANSYS, 2020), GAMBIT (ANSYS, Inc., 2009), StarCCM+ (CD-adapco, 2016), `blockMesh`, and `snappyHexMesh` (Jasak et al., 2007). While these tools can generate tetrahedral meshes for complex geometries, the quality of hexahedral grids varies. Tools like ANSYS Meshing, Fluent Meshing, ICEM CFD, and `snappyHexMesh` use octree algorithms to refine the grid progressively, generating hexahedral-dominant grids. However, this method struggles with complex geometries and may not generate sufficiently fine grids near boundaries. Some tools, such as ICEM CFD and GAMBIT, can create fully hexahedral grids, but these require manual geometry partitioning, making the process time-consuming. `blockMesh` in OpenFOAM can generate fully hexahedral grids for simple geometries but requires manual input, making it impractical for more complex shapes. In general, generating fully hexahedral grids involves complex spatial partitioning and manual geometry handling, which can be challenging for intricate structures.

Based on the challenges mentioned above, this study developed a scripting tool based on `blockMesh` that can automatically output the point, block, and boundary required by `blockMeshDict` through inputting typical geometric data and meshing parameters.

2. METHOD

The process starts with deriving characteristic points from the digital model as shown in Fig. 1, then the global block partitioning is automatically generated. Subsequently, the framework is able to generate either uniform or non-uniform grid per user's specification. For a uniform grid, a global grid size is needed. For an non-uniform grid, user needs to specify the corresponding mesh parameters. At last, boundary parts are defined, and the tool uses a staggered addition method to automatically check whether the boundary parts are correctly defined.

2.1. Geometry to Blocks

A geometric model consisting solely of orthogonal bodies can always be described as cubic volume $\mathbf{V}$ with cubic volumes $\mathbf{V}_i$ subtracted from it and rectangular surfaces $\mathbf{S}_i$ carved on volumes. Then the corresponding computation domain could be reproduced by characteristic points including two diagonal points of $\mathbf{V}$, two diagonal points of each $\mathbf{V}_i$, and two diagonal points of each $\mathbf{S}_i$.

Based on these characteristic points, sort the coordinate values in each direction to obtain n_x, n_y, and n_z different coordinates in x, y, and z directions, respectively. Using these coordinates, the volume $\mathbf{V}$ is partitioned into a total of $(n_x-1)\times(n_y-1)\times(n_z-1)$ blocks. Then, based on the characteristic points of $\mathbf{V}_i$, blocks inside $\mathbf{V}_i$ are deleted. The remaining blocks represent the computation domain.

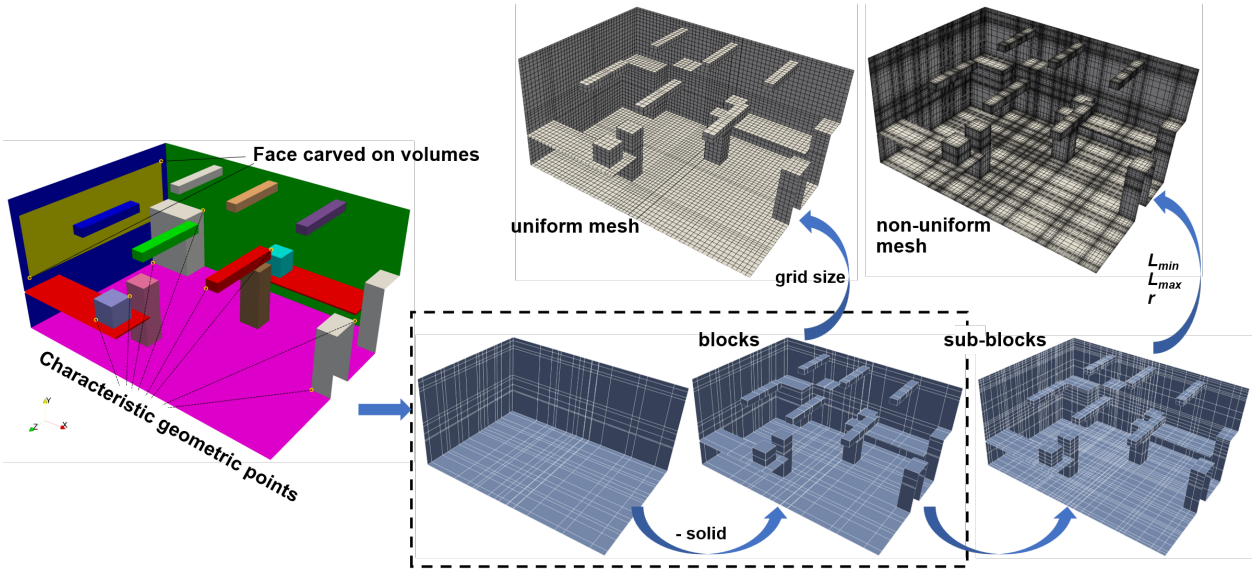

Figure 1. From geometry to block and mesh

2.2. Grid

For a uniform grid, the above block partition does not need to change. With a user specified global grid size, the number of grid cells is calculated based on the size of each block, which serves as the parameter for simpleGrading with a mesh growth rate of 1 in `blockMeshDict`.

In most scenarios, a non-uniform grid is needed. For built environments, fine grid is applied in the near-wall region where the gradient of air velocity and temperature could be large and coarse grid in those regions away from walls. Then a user needs to specify the minimum grid size $L_{\min}$, grid growth rate $r \in (1,2)$, and maximum grid size $L_{\max}$. To create such a grid, each of the aforementioned blocks may need to be further partitioned into sub-blocks. This is because the simpleGrading in `blockMesh` only allows grid size growth in one direction. Referring to Table 1, in either x, y, or z dimension, if the block length L_B is within the range $(0, 4 \times L_{min}]$, further partition is not needed and $N_u = [\frac{L_B}{L_{min}}]$ uniform grids are applied in this dimension. If $L_B > 4 \times L_{min}$, the grid size starts with L_{min} at the two ends and grows with rate r to the middle. If the maximum grid size L_{max} cannot be or is just reached, the block is divided into two sub-blocks in this dimension, with the mesh size growing from both ends towards the middle. The criterion for the division is that $L_B \leq 2D$, where the length D is determined by Eq. (1). The growth from L_{min} to L_{max} with rate r needs N_n grid cells determined by Eq. (2). If $L_B > 2D$, the block in this dimension is divided into three sub-blocks, with the two side sub-blocks having length D, and the middle sub-block using uniform grids with size L_{max}. Please note that sub-blocks generated in this section are temporary and will not affect the subsequent *Boundary parts* and *Boundary check*.

$$D = \frac{L_{max} - L_{min}}{r - 1} \tag{1}$$

$$N_n = [\log_r \frac{L_{max}}{L_{min}}] \tag{2}$$

Table 1. Number of sub-blocks for different block lengths.

Range of block length L_B	Number of sub-blocks
$(0, 4 \times L_{min}]$	1
$(4 \times L_{min}, 2 \times D]$	2
$(2 \times D, \infty)$	3

2.3. Boundary Parts

Using n_x, n_y, n_z different coordinates in x, y and z directions, there are a total of $n_x \times (n_y - 1) \times (n_z - 1)$, $(n_x - 1) \times n_y \times (n_z - 1)$ and $(n_x - 1) \times (n_y - 1) \times n_z$ faces perpendicular to the x, y, and z axes, respectively. Among these faces, those adjacent to only one block are boundary faces to be partitioned, while the remaining faces are internal faces of either fluid or solid regions and do not require boundary partitioning.

Each boundary to be defined can always be represented as a rectangle $\mathbf{R}$ with several rectangles $\mathbf{R}_j$ subtracted from it. Using the two diagonal points of $\mathbf{R}$ and $\mathbf{R}_j$, all faces within $\mathbf{R}$ can be defined, while faces within $\mathbf{R}_j$ will be skipped. Please note that $\mathbf{R}_j$ is an optional parameter. For a complete rectangular boundary part, $\mathbf{R}_j$ is not needed. Additionally, $\mathbf{R}_j$ does not need to be entirely within $\mathbf{R}$ because only the overlapped surfaces of $\mathbf{R}$ and $\mathbf{R}_j$ are skipped when defining a boundary part.

2.4. Boundary Check

To succinctly introduce the boundary check process, Fig. 2 presents a schematic diagram for a two-dimensional geometry. After partitioning the computational domain, a second rank tensor $\mathbf{B}$ of dimensions $\langle (n_x - 1), (n_y - 1) \rangle$ composed of 0 and 1 is defined. This tensor corresponds to the blocks, indicating that 1 represents a fluid domain where there is a block, and 0 represents a solid domain where there is no block. For checking cell faces perpendicular to the x axis, a column of zeros is added to the left side and right side of $\mathbf{B}$ that generates two new tensors $\mathbf{B}_{x-}$ and $\mathbf{B}_{x+}$, respectively. The dimension of $\mathbf{B}_{x-}$ and $\mathbf{B}_{x+}$ is $\langle n_x, (n_y - 1) \rangle$. The addition of $\mathbf{B}_{x-}$ and $\mathbf{B}_{x+}$ creates a new tensor $\mathbf{F}_x^*$. The same approach generates a new tensor $\mathbf{F}_y^*$ for cell faces perpendicular to the y axis. By mapping $\mathbf{F}_x^*$ and $\mathbf{F}_y^*$ to the cell faces, each cell face is assigned a value that can be either 0, 1 or 2. For a three-dimensional geometry, $\mathbf{B}$ will be a third rank tensor, and it will yield tensors $\mathbf{F}_x^*$, $\mathbf{F}_y^*$ and $\mathbf{F}_z^*$ for cell faces perpendicular to the x, y, and z axes, respectively. This process can be described by Eqs. (3, 4, and 5).

$$\mathbf{F}_x^* = \mathbf{B}_{x-} + \mathbf{B}_{x+} = \left[\ 0 \ \middle|\ \mathbf{B}\ \right] + \left[\ \mathbf{B} \ \middle|\ 0\ \right] \in \mathbb{R}^{n_x \times (n_y - 1) \times (n_z - 1)} \tag{3}$$

$$\mathbf{F}_y^* = \mathbf{B}_{y-} + \mathbf{B}_{y+} = \left[\ 0 \ \middle|\ \mathbf{B}^T\ \right]^T + \left[\ \mathbf{B}^T \ \middle|\ 0\ \right]^T \in \mathbb{R}^{(n_x - 1) \times n_y \times (n_z - 1)} \tag{4}$$

$$\mathbf{F}_z^* = \mathbf{B}_{z-} + \mathbf{B}_{z+} = \left[\ 0 \ \middle|\ \mathbf{B}^{\{T,\cdot\}}\ \right]^{\{T,\cdot\}} + \left[\ \mathbf{B}^{\{T,\cdot\}} \ \middle|\ 0\ \right]^{\{T,\cdot\}} \in \mathbb{R}^{(n_x - 1) \times (n_y - 1) \times n_z} \tag{5}$$

For each element within the tensor $\mathbf{F}_x^*$, $\mathbf{F}_y^*$ and $\mathbf{F}_z^*$, if it is 0, it indicates that the face is not adjacent to any blocks and does not belong to a boundary part. If the element is 1, it indicates that the face

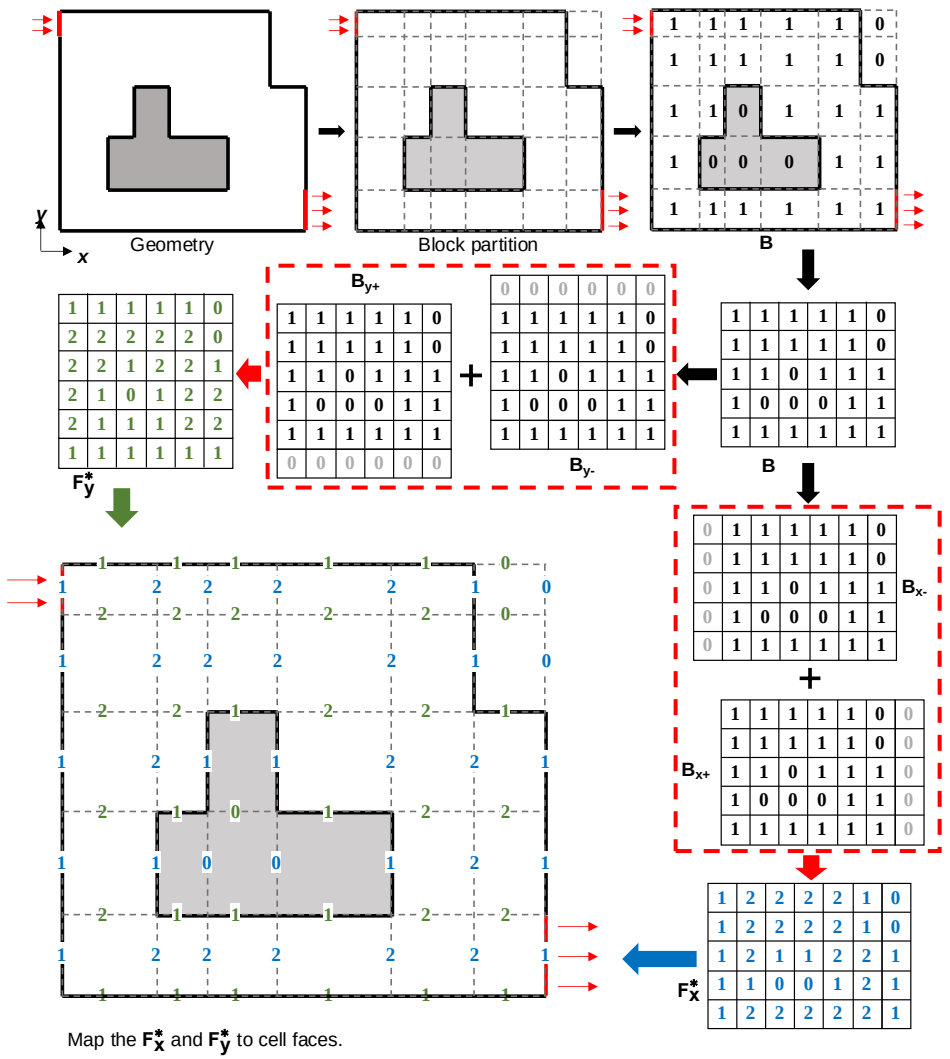

Figure 2. Boundary check: step 1

is adjacent to only one block and requires the definition of boundary parts. If the element is 2, it indicates that the face is adjacent to two blocks and is an internal face within the fluid domain.

Based on the diagonal points in section *Boundary parts*, the tool will generate three tensors $\mathbf{F}_x^{**}$, $\mathbf{F}_y^{**}$, and $\mathbf{F}_z^{**}$ of the same size as $\mathbf{F}_x^{*}$, $\mathbf{F}_y^{*}$, and $\mathbf{F}_z^{*}$, each composed of 0 and 1. In $\mathbf{F}_x^{**}$, a value of 1 indicates that the face belongs to the boundary, while a value of 0 indicates that the face does not belong to the boundary. Then the addition of $\mathbf{F}_x^{**}$ and $\mathbf{F}_x^{*}$ leads to $\mathbf{F}_x$. For this process, Fig. 3 provides a schematic diagram for a two-dimensional geometry. Similar operations are performed for $\mathbf{F}_y^{*}$ and $\mathbf{F}_z^{*}$. This process can be represented by the Eqs. (6, 7, and 8).

$$\mathbf{F}_x = \mathbf{F}_x^{*} + \mathbf{F}_x^{**} \tag{6}$$

$$\mathbf{F}_y = \mathbf{F}_y^{*} + \mathbf{F}_y^{**} \tag{7}$$

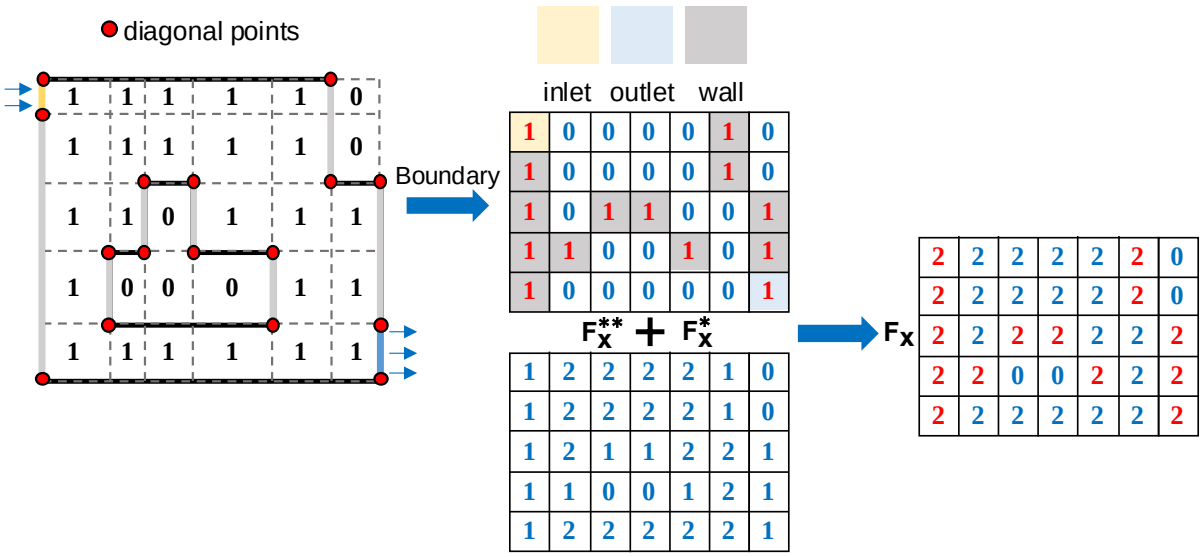

Figure 3. Boundary check: step 2

$$\mathbf{F}_z = \mathbf{F}_z^* + \mathbf{F}_z^{**} \tag{8}$$

If the elements that were 0 or 2 in the tensors $\mathbf{F}_x^*$, $\mathbf{F}_y^*$ and $\mathbf{F}_z^*$ remain unchanged in $\mathbf{F}_x$, $\mathbf{F}_y$ and $\mathbf{F}_z$, and the original 1 become 2, the boundary parts are correctly defined. Otherwise, there is an error and the reason and position for the error will be given. Table 2 gives the reasons for error in defining boundary parts.

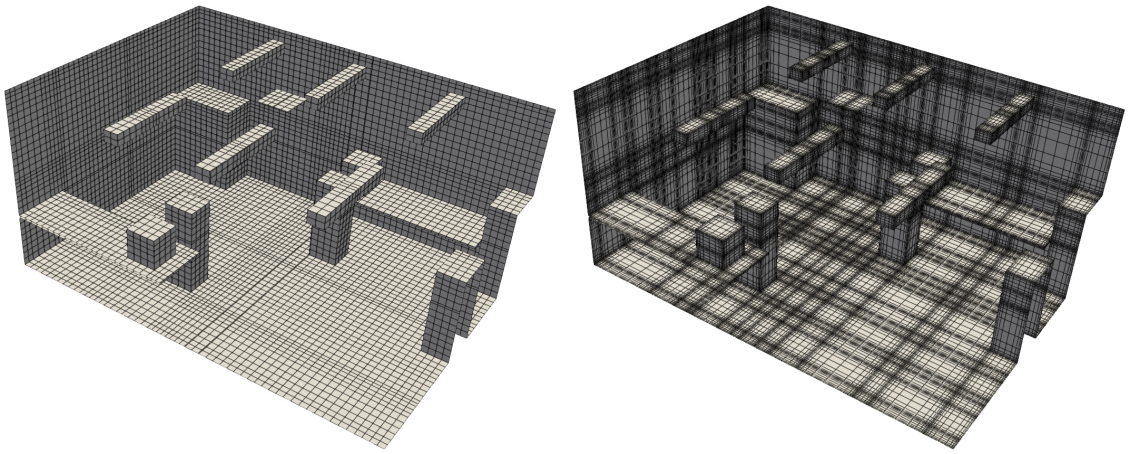
Table 2. Reasons for error in defining boundary parts

Element in $\mathbf{F}_x^*$, $\mathbf{F}_y^*$ and $\mathbf{F}_z^*$	Element in $\mathbf{F}_x$, $\mathbf{F}_y$ and $\mathbf{F}_z$	Reasons for error
$=0$	>0	This face is an internal face of a solid domain and cannot be defined.
$=1$	$=1$	This face has not been assigned to any boundary parts.
$=1$	>2	This face is defined in multiple boundary parts.
$=2$	>2	This face is an internal face of the fluid domain and cannot be defined.

3. RESULTS

This study firstly tests the mesh tool using an office model (5.16 m $\times$ 3.65 m $\times$ 2.43 m) (Yuan, Q. Chen, et al., 1999). The fluid domain is formed by subtracting furniture, including two people, two computers, two tables, six lamps, and one diffuser. The room is meshed into a uniform grid and a non-uniform grid. For the uniform grid, with a grid size of 0.1m (Fig. 4a), the grid number is $59 \times 30 \times 44$. For the non-uniform grid, with $L_{min} = 0.01$ m, $L_{max} = 0.2$ m, and $r = 2$, the grid number is $131 \times 70 \times 132$, with finer grids near the walls (Fig. 4b).

The second case is a high-rise slab building with a height of 27 m, which has 9 floors with a floor height of 3 m, and the total construction area is 10,459 m². Fig. 5 shows the floor plan of the building, with four suites on each floor.



(a) Uniform mesh (grid size 0.1 m)

(b) Non-uniform grid ($L_{min} = 0.01$ m, $L_{max} = 0.2$ m, and $r = 2$)

Figure 4. Block partition and grid generation for an office with displacement ventilation.

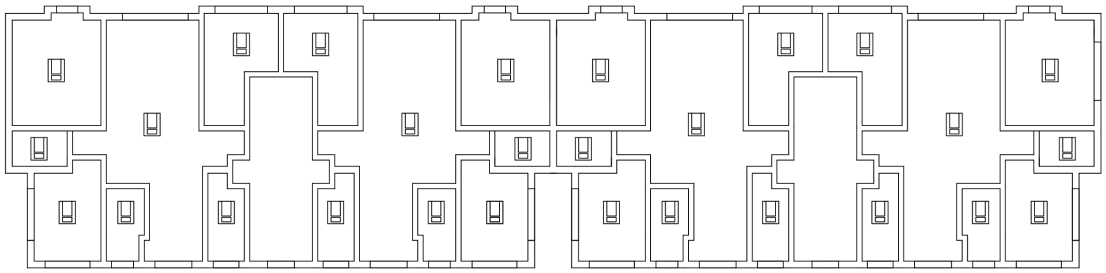


Figure 5. Floor plan of the building

Based on the building plan, in the mesh tool, walls and windows are treated as rectangular obstacles for input. Windows can be optionally included to simulate their opening or closing states. The characteristic points only require the diagonal coordinates of the computational domain and obstacles. Fig. 6a and 6b give the isometric and front view of the grid on the external surface of the building.

(b) Front view

Figure 6. Grid of the nine-story high-rise slab building with $L_{min} = 0.3$ m, $L_{max} = 3$ m, and $r = 2$ m.

4. CONCLUSION

This study developed a mesh tool based on the `blockMesh` utility from the open source CFD program OpenFOAM. The tool is able to generate fully hexahedral grid with either uniform or non-uniform grid. Users only need to input the information of geometry, boundary parts, and global grid size. For the geometry, two diagonal points of all orthogonal bodies are needed. For the grid size, uniform grid needs a global size and non-uniform grid needs a minimum grid size, maximum grid size, and growth rate. The mesh tool conducts boundary check to ensure the correct definition of boundary parts. Case 1 is a typical office with displacement ventilation and case 2 is an outdoor case with detailed building internal configurations. The mesh tool and the two cases will be made open source on GitHub.

SUMMARY
Energy poverty is a critical issue impacting numerous households globally, where rising energy costs and inefficient buildings exacerbate the problem. Existing studies often overlook the broader impact of energy efficiency interventions, such as how many individuals can be lifted out of energy poverty. This study investigates the impact of building envelope improvements and lighting control systems on reducing energy poverty risks at a national scale. By considering the socio-economic context, including household income, and applying an energy poverty indicator based on the 10% threshold, the research explores how specific energy efficiency measures, such as insulation upgrades and daylight-responsive lighting, can alleviate the financial burden of high energy costs. A case study of the archetype demonstrates how these interventions reduce the proportion of energy-poor households. The results indicate that, with the proposed enhancements, fewer households fall below the 10% energy expenditure threshold, offering promising solutions to combat energy poverty. These findings underscore the importance of targeted building interventions and the role of socio-economic factors in shaping energy poverty outcomes.

Keywords: Energy efficiency, Building Envelope, Energy poverty, Lighting control, Energy retrofit.

1. INTRODUCTION

Energy poverty appears in various forms and can be evaluated through several commonly used methods. These include subjective indicators, which focus on household perceptions of comfort and affordability; expenditure-based approaches, which evaluate energy costs relative to income; and multi-dimensional indicators, which integrate multiple factors to capture the multidimensional nature of energy poverty (Siksnelyte-Butkiene et al., 2021). One of the earliest and most widely used measures is the 10% indicator, which defines a household as energy-poor if its energy expenses exceed 10% of total income. While simple and widely adopted, this approach has been criticized for not accounting for variations in income levels and energy needs (Al Kez et al., 2024).

Energy poverty significantly affects daily life, limiting access to basic needs such as warmth and electricity, which are essential for improving living standards, health, education, and productivity (Halkos and Gkampoura, 2021). This issue is a significant societal issue impacting millions of households across Europe and globally. Europe faces harsh winters and rising energy costs, posing significant challenges for its population. In 2021, 7% of Europeans struggled to keep their homes warm, a figure that increased to 9.3% in 2022 and 10.6% in 2023 (Teixeira et al., 2024, Filippidou et al., 2024). Moreover, recent findings from the U.S. Energy Information Administration indicate that approximately one-third of households in the United States face energy poverty (Batlle et al., 2024). A 2022 report by Ireland's ESRI revealed that 29% of households (approximately 415,000 homes) were affected, with vulnerable groups disproportionately impacted. If energy prices rise further, up to 43% of households could face energy poverty, highlighting the need to identify those most at risk (Barrett et al., 2022). Addressing energy poverty requires a multi-faceted approach, including energy efficiency improvements, behavioural interventions, financial support, renewable energy integration, and policy reforms. Initiatives like the US Weatherization Assistance Program (WAP), the Energy Poverty Observatory (EPOV), and Ireland's Warmer Homes Scheme provide funding for energy-efficient upgrades, reducing energy costs for low-income households (Heller et al., 2024). Integrating climate-focused policies with energy poverty objectives ensures comprehensive and equitable outcomes, as evidenced by cross-country analyses (Belaid et al., 2023). Studies have demonstrated that behavioural interventions can lead to reductions in household energy consumption (Dietz et al., 2009, Composto and Weber, 2022). Enhancing energy efficiency in affordable housing can significantly reduce energy costs for low-income households, thereby alleviating energy poverty (Shwashreh et al., 2024). Despite growing research on energy poverty, less than 10% of studies address poor building conditions—a key contributor to high energy costs (Fabbri, 2024). Poorly constructed buildings with inadequate insulation and inefficient systems exacerbate energy poverty for low-income families (Fabbri, 2024). Retrofitting measures, such as insulation, airtightness, Passivhaus windows, solar PV, and mechanical ventilation with heat recovery (MVHR) systems, can significantly mitigate these issues. For instance, a case study housing retrofit in England reduced energy costs by 89%, fuel consumption decreased from 1,581 kWh to 550 kWh, representing 65% reduction, and improved indoor temperatures from 6 °C to 19.27 °C in winter (Shwashreh et al., 2024). Building envelope insulation, particularly using cost-efficient prefabricated panels, has been identified as a long-term solution to energy poverty in Italian social housing, offering significant heating cost reductions. Structural upgrades, such as facade insulation, could cut energy poverty by 30%, outperforming temporary subsidies (Fabbri et al., 2023). The effectiveness of these measures varies with energy prices, income, and rent levels (Fabbri et al., 2023). Such interventions highlight the economic and indoor environmental benefits of addressing poor building conditions alongside energy poverty alleviation strategies. However, despite these recent interesting findings, some limitations in these studies remain. The research by Shwashreh, Taki, and Kagioglou (2024) is constrained by its focus on a single case study, limiting the generalizability of findings to other regions or building archetypes. Similarly, Fabbri et al. (2023) primarily explore insulation strategies without integrating complementary measures, such as advanced artificial lighting performance. These gaps highlight the need for more comprehensive frameworks that address household's energy poverty, integrate advanced modelling techniques, and control devices for artificial lighting. Moreover, the

studies mentioned do not account for the number of individuals who would benefit from reducing energy poverty, which is a crucial aspect when assessing the broader impact of such interventions. By addressing some of these gaps, this paper aims to provide a robust approach to mitigating energy poverty through integrated strategies that align structural improvements with socioeconomic realities.

2. METHODOLOGY

This study aims to develop a comprehensive framework for evaluating and potentially mitigating energy poverty through integrated household energy enhancements and interventions at a national scale. The effectiveness of interventions is evaluated by analyzing their potential for energy savings, which in turn determines their impact on reducing energy poverty. The methodology involves three core phases as detailed below, which are also shown in Fig. 1:

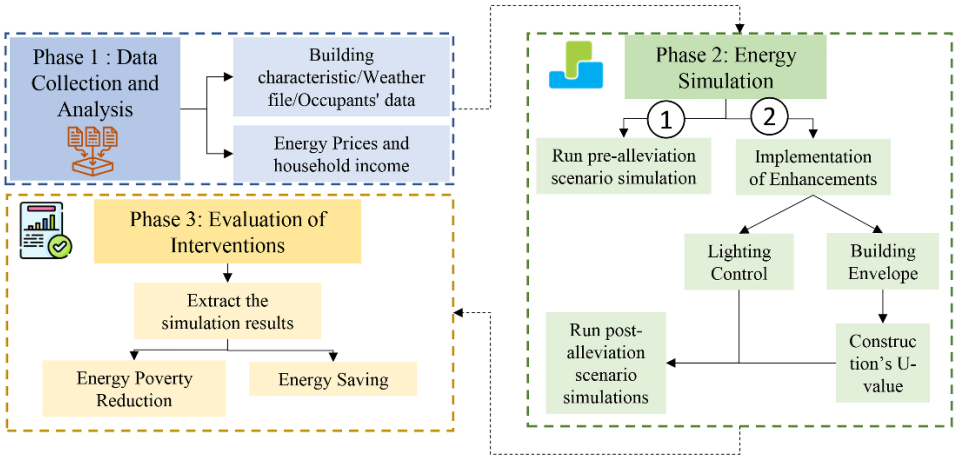

Figure 1. Comprehensive Methodology for Energy Savings and Addressing Energy Poverty

2.1. Phase 1: Data Collection and Analysis

Data collection focused on capturing quantitative variables influencing household energy consumption and expenditure. The key components include:

- Household characteristics: information related to a two-story, 4-bedroom, detached house in Ireland was extracted from a previous study (Egan et al., 2018);
- A relevant, updated weather file was added to the pre-retrofit archetype, and the building envelope for this archetype was assessed in terms of thermal performance and compliance with Irish standards.
- Energy Pricing and Socioeconomic Data: household income data from 2022, obtained from the Central Statistics Office (CSO), and 2024 energy pricing data from the Sustainable Energy Authority of Ireland (SEAI) were utilized in the analyses.

Detailed explanations for both components are provided in Section 3.

2.2. Phase 2: Energy Simulation

This section focuses on simulating the pre-retrofit and post-retrofit scenarios for the archetype to

evaluate building energy consumption. Simulation modelling was conducted using the DesignBuilder software tool. The process included creating a virtual representation of the case study, incorporating relevant parameters and constraints. The energy intervention includes envelope enhancements and daylight-responsive lighting control systems. Envelope enhancements focused on improved insulation and energy-efficient windows. Building regulations specify maximum allowable U-values for renovated or repurposed dwellings: 0.16 W/m²·K for pitched roofs with ceiling insulation and for ceilings, 0.35 W/m²·K for external walls, and 1.6 W/m²·K for external windows and doors (Building Regulation, 2022). Daylight-responsive lighting control systems, as encouraged by the Technical Guidance Document L 2022, optimize energy efficiency in Irish buildings by dynamically adjusting artificial lighting based on natural daylight availability (Building Regulation, 2022, SEAI, 2017). These systems dim or switch off lights when natural light is sufficient, ensuring functionality at a consistent workplace height of 0.8 meters. As a result, the building's energy efficiency strategies were implemented, with each step conducted independently rather than incrementally. The retrofit process started with insulating the external wall using sprayed polyurethane foam in the air gap layer (U-value: 0.338 W/m²·K). Next, the semi-exposed ceiling and pitched roof were insulated with 12 cm and 8 cm layers of polyurethane foam, reaching U-values of 0.165 W/m²·K and 0.150 W/m²·K, respectively. Triple-clear glazing with argon-filled gaps (U-value: 1.620 W/m²·K) was used to upgrade the windows, and the external door was also insulated with foam (U-value: 0.800 W/m²·K). Daylight-responsive lighting systems automatically adjust artificial lighting based on the amount of natural light available. Finally, all of these measures were integrated into a holistic approach to enhance the building's energy performance.

Table 1. Energy Poverty Actions in each step

	Construction	Intervention	Thermal Conductivity	U value (W/m2-k)
Step 1	External Wall	Sprayed Polyurethane Foam in the Air Gap	0.022	0.338
Step 2	Semi-Exposed Ceiling	Apply a 12 cm layer of Polyurethane Foam on the outer face	0.022	0.165
	Pitched Roof (Unoccupied)	Apply an 8 cm layer of Polyurethane Foam on the inner face	0.022	0.150
Step 3	External Window	Triple-clear glazing with a 3 mm pane thickness and a 13 mm argon-filled gap	-	1.620
	External Door	Sprayed Polyurethane Foam in the Air Gap	0.03	0.800
Step 4	Lighting Control			
Step 5	Combination of Steps 1 to 4			

2.3. Phase 3: Evaluation of Interventions

The effectiveness of energy renovation interventions was assessed using a comprehensive analysis of two key aspects of energy performance: energy savings and energy poverty mitigation. Simulated reductions in electricity and gas consumption were calculated to determine the overall energy savings achieved. Additionally, using the 10% indicator, the study assessed how many individuals fell below the energy poverty threshold and examined the reduction in the number of people affected by energy poverty relative to the pre-retrofit archetype.

3. CASE STUDY

A two-story detached, four-bedroom dwelling in Dublin's climate was selected as a case study in this research. According to Ireland's Census of Population 2016, there were 715,133 occupied detached houses, representing approximately 42% of all occupied dwellings at that time. Additionally, around 25% of occupied dwellings in Ireland had four bedrooms (CSO, 2017). Fig. 2 illustrates the layout of spaces in the detached house under study, with the relevant area given for each space.

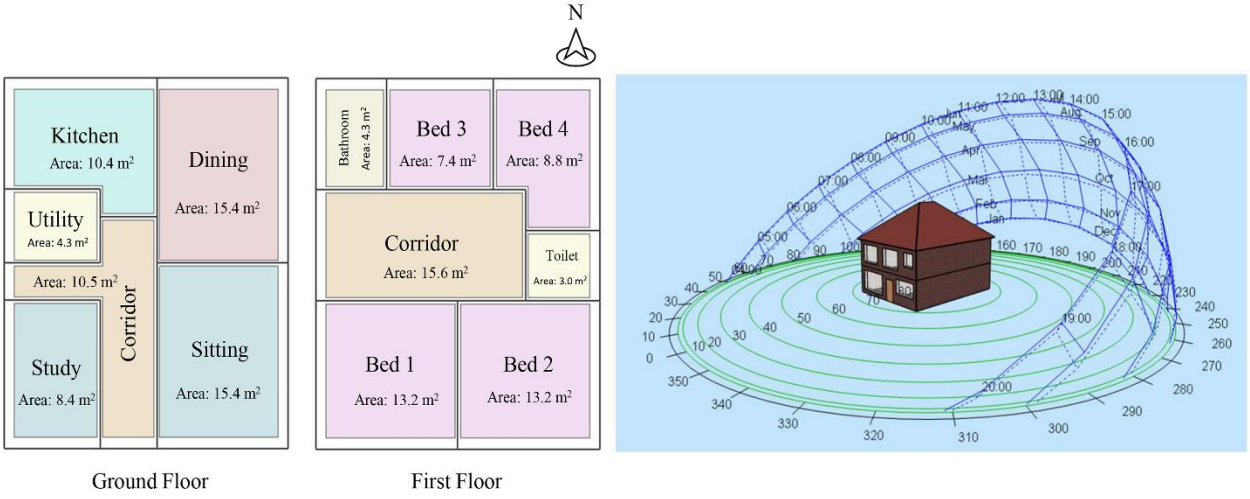

Figure 2. Detached building's space layout

As discussed in Section 2, energy pricing and household income levels were incorporated to assess the economic implications of the proposed interventions. As of the first half of 2024, the average electricity price for households in Ireland, including VAT, was approximately €0.354 per kilowatt-hour (kWh); for natural gas, the average price, including VAT, was €0.128 per kilowatt-hour (kWh), according to the Sustainable Energy Authority of Ireland (SEAI, 2024). According to the CSO, the median annual disposable household income in 2022 was €41,823, with significant variation across economic sectors and regions (CSO, 2022). The year 2022 was specifically chosen for this analysis due to the availability of highly detailed income data, allowing for an in-depth examination of income distribution and its relationship to energy poverty. Comparable datasets for 2023 and 2024 are either not yet available or lack the same level of granularity, making 2022 the most suitable reference point for this study. The granular analysis is crucial for evaluating energy poverty in this research because it is essential to recognize people who are living in 4-bedroom houses.

4. RESULTS

4.1. Archetype Simulation: Energy Consumption, Bills, and Poverty Assessment

The results of the simulations are shown in Table 2. The pre-retrofit archetype consumes 3,030.20

kWh/year for electricity and 24,097.91 kWh/year for gas. Based on calculations using the building's energy consumption and current energy prices (€0.354 per kWh for electricity and €0.128 per kWh for gas, including VAT), the annual energy cost amounts to €4,157.23. When assessed using the 10% energy poverty indicator, this represents approximately 10% of the average annual disposable income of an Irish citizen, which is €41,823 (CSO, 2022). According to the Individualised Gross Income Distribution report, 2,646,440 individuals out of a total population of 3,859,076 earn less than €40,000 annually (Revenue Commissioners, 2022). However, given that the selected building was designed for larger families (currently or previously), the analysis specifically focuses on individuals responsible for household expenses. These include married couples (both earning or one earning), widows, and widowers. The same report indicates that 1,099,382 individuals out of 1,832,859 people in these categories earn below €40,000 annually, accounting for 59.98% of this group (Revenue Commissioners, 2022). These findings underscore the critical need for targeted energy efficiency measures to reduce energy poverty, especially for vulnerable households in Ireland.

4.2. Effectiveness of Energy Efficiency Interventions

According to Table 2, the energy consumption analysis clearly illustrates the impact of each intervention on energy consumption. Initially, Step 1 (External Wall Enhancement) reduced gas consumption by 1,245.46 kWh/year, with electricity consumption remaining unaffected. Step 2 (Roof Insulation) reduced gas consumption by 2,783.59 kWh/year, maintaining the same level of electricity consumption. Following this, Step 3 (Window and Door Improvements) achieved the most significant gas reduction of 6,056.94 kWh/year, again without impacting electricity. In contrast, Step 4 (Lighting Control) led to a reduction of electricity consumption by 385.681 kWh/year, though it slightly increased gas consumption by 291.6 kWh/year. Ultimately, Step 5, which integrates all the previous interventions, delivered the most substantial reduction in both electricity and gas consumption, lowering electricity to 2,644.52 kWh/year and gas to 13,680.76 kWh/year, thereby showcasing the greatest overall energy savings. This combined approach clearly shows how integrating multiple energy-saving measures leads to better outcome.

4.3. Energy Poverty Reduction

Table 2 provides a comprehensive overview of energy consumption and cost reductions achieved through each intervention step, highlighting their impact on reducing energy poverty. Step 1, focused on External Wall Enhancement, achieved a modest 3.83% reduction, bringing the bill to €3,997.81/year. Building on this, Step 2, which addressed Semi-Exposed Ceiling and Pitched Roof Insulation, delivered a more notable reduction of 8.57%, lowering the bill further to €3,800.93/year. Step 3, targeting External Window and External Door Improvements, marked a significant turning point with an 18.65% decrease, reducing the bill to €3,381.94/year. Additionally, Step 4, which introduced Lighting Control, resulted in a smaller reduction of 2.39%, causing a slight decrease in the bill to €4,058.02/year. Finally, Step 5, combining all interventions, achieved the most substantial impact with a 35.36% reduction, lowering the energy bill to €2,687.30/year. Collectively, assuming that people can get free grants, these interventions played a critical role in addressing energy poverty by making energy bills more affordable and reducing the minimum income required to cover them. While Steps 1, 2, and 4 successfully eased the

financial burden on households, the income range classifications defined by the Revenue Commissioners limit the ability to precisely quantify the number of individuals lifted out of energy poverty by these measures. Nonetheless, their positive impact on vulnerable households remains clear. Step 3 emerged as particularly impactful, reducing the number of individuals affected by energy poverty by 131,141. The cumulative benefits of all interventions became most evident in Step 5, where the number of individuals affected by energy poverty decreased by 363,381 people. This underscores the effectiveness of integrated strategies in enhancing energy affordability and alleviating financial strain, providing a robust framework for future policymaking.

Table 2. Comparison of each step in reducing the energy bill

Intervention	Energy Consumption (kWh/year)		Energy bill (€/year)	Energy bill Reduction (%)
	Electricity	Gas		
Pre-retrofit Archetype	3,030.20	24,097.91	4,157.23	-
Step 1: External Wall	3,030.20	22,852.45	3,997.81	3.83
Step 2: Semi-Exposed Ceiling and Pitched Roof	3,030.20	21,314.32	3,800.93	8.57
Step 3: External Window and External Door	3,030.20	18,040.97	3,381.94	18.65
Step 4: Lighting Control	2,644.52	24,389.51	4,058.02	2.39
Step 5: Combination of Steps 1 to 4	2,644.52	13,680.76	2,687.30	35.36

These results are particularly relevant when considered alongside national funding schemes such as SEAI's grant programmes, which can cover up to 80% of retrofit costs for eligible homes (SEAI, 2025). For example, the Individual Energy Upgrade Grants offer up to €3,200 for retrofitting works, such as insulating cavity walls and ceilings (SEAI, 2025), making the interventions more financially accessible. With reduced utility bills, the payback period for households becomes significantly shorter, further strengthening the case for large-scale policy support.

5. DISCUSSION AND CONCLUSION

This study helps to fill an important gap in the literature, as previous studies did not quantify how many individuals directly benefit from such building interventions. For instance, Shwashreh et al. (2024) and Fabbri et al. (2023) provide valuable insights into retrofit impacts in the UK and Italian social housing contexts, respectively. However, their analyses are either limited to single-case studies or lack integration of complementary measures and socio-economic scaling. In contrast, the present study not only combines building envelope and lighting-control interventions but also uniquely quantifies the number of individuals lifted out of energy poverty at a national scale, an aspect that has not been addressed in previous literature. This is specifically discussed in Section 4.3 and detailed in Table 2, where we demonstrate that integrated interventions can reduce the number of energy-poor individuals by over 360,000.

This study shows that upgrading the building envelope and adding daylight-based lighting controls can significantly reduce household energy use and lower the share of homes falling below the 10% energy poverty threshold across Ireland. Specifically, the analysis shows that this approach reduced the number of income-earning individuals responsible for household expenses experiencing energy poverty by 33.05%, from 1,099,382 to 736,001. Additionally, the stepwise comparison of interventions supports scalable analysis of individual and combined retrofit

packages. These findings underscore the value of national retrofit grant schemes (e.g., SEAI) in improving affordability and uptake, while also providing actionable insights for policymakers seeking to advance both energy efficiency and social equity. Future work should explore the scalability of these interventions across various housing types and assess the potential for integrating more interventions, such as renewable energy sources and heating systems, to further enhance energy resilience.

Performance improvement of airflow distribution and contamination control for a biotech cleanroom

Rahmadi Aulia Pramudantoro[1], Chu-Cheng Wei[1], Bowo Yuli Prasetyo[2], Parisya Premiera Rosulindo[2], Fu-Jen Wang[1]

[1] *Department of Refrigeration, Air Conditioning and Energy Engineering, National Chin-Yi University of Technology, Taichung, Taiwan, fjwang@ncut.edu.tw*
[2]*Department of Refrigeration and Air Conditioning Engineering, Politeknik Negeri Bandung, Bandung, Indonesia*

SUMMARY
Cleanrooms are widely used in many industries such as semiconductor, bio-tech, microelectronics, pharmaceuticals, and nanotechnology. However, pharmaceutical industries (such as vaccine production) need a critical clean environment and contamination control is always a vital concern for the manufacturing process. This study investigates a bio-tech cleanroom through a comprehensive field measurement and numerical analysis. Computational fluid dynamics (CFD) simulation was also conducted to validate the numerical results and to identify strategies for performance improvement of a bio-tech cleanroom. The results reveal that based on cleanroom standard of ISO and PIC/S, the field test results conform to the design specification satisfactorily after the necessary adjusting. Higher air change rate per hour (ACH) results in a higher cleanness level. Room pressurization conforms to the design specification and all HEPA filters have been tested extensively. Performance improvement through CFD can be obtained through the layout arrangement for supply and return air grille. Airflow patterns improve contamination control through optimizing the ACH and supply air face velocity of HEPA filters extensively.

Keywords: biotechnology, cleanroom, field measurement, numerical simulation, contamination

1. INTRODUCTION

With the development of technology industries nowadays, the need for a better cleanrooms design has been increase especially in bio-tech industries. This increasing demand that could be related with a larger number of semiconductor industry, research laboratory, bio-tech, microelectronics, pharmaceutical, and nanotechnology. Cleanroom are classified according to the number and size of particle permitted per volume of air within a specific amount of time. There are three levels of condition (occupancy states) for testing and characterizing the performance of cleanrooms: as-built; at-rest; and operational. Standards such as ISO (2015, 2019) and GMP (2007) pertain to the cleanroom and associated environments. Industries require specific environment to prevent contamination because the manufacturing process or products are sensitive to indoor environmental parameters such as temperature, relative humidity, airborne particles, room pressurization, and illumination (Yang, 2007). To achieve these requirements, cleanrooms are designed and built to control these environmental parameters.

Field measurement tests are essential to assure the cleanroom performs satisfactorily and achieves the contamination standards (Yang, 2021). Additionally, it has been reported that contamination cannot be completely eliminated, thus targeted monitoring should involve reviewing data for trends (Sandle, 2015). Testing results form the basis for validating cleanroom performance.

Furthermore, Computational fluid dynamics (CFD) represent an important tool to do simulation especially in the HVAC field like predicting of airflow pattern in a cleanroom and its ability to remove airborne particles (Tung, 2009). Otherwise to full scale ventilation performance test, the CFD methods is cheaper and less interfering than the traditional experimental test and it allows to investigate different case and solution without intrusive the original case (Sun, 2010). Some CFD studies of indoor ventilation systems have been already carried out, Memarzadeh et. al. (2002) have used CFD to represent that unidirectional flow conditions are the best option for an operating room through of controlling the risk of contamination. Srebric et al. (2008) have demonstrated the accuracy of CFD simulation is depend on the considered obstacles in the room, e.g., occupants, equipment, the appropriate settings of boundary condition and numerical simulation parameters like heat flux and contaminant source.

This study investigates the indoor environment parameter for a bio-tech clean-room through comprehensive field measurement test to verify the effectiveness of the cleanroom system. The experimental data were analysed and validated with the numerical simulation in order to find the improvement strategy for a better approach design.

2. METHODOLOGIES

2.1. System Description

The layout of the investigated bio-tech cleanroom is displayed in Figure 1. The HVAC system for this cleanroom uses central air conditioning. Supply air was distributed from air handling unit (AHU) through ducts and high efficiency particulate air (HEPA) filters above the cleanroom. A regulating damper is installed in each room to adjust airflow rate. The field measurement test was conducted for all of main room process. The dimensions of the cleanroom are 15.4 m (length), 16.35 m (width), and 2.8 m (height), with a total volume of 524.2 m^3. Based on ISO 14644, this clean-room has a cleanliness level of 10,000 and 100,000 (Grade C and D). Total of the grade C cleanroom is equipped with 10 pieces of small HEPA filters (0.6 m × 0.6 m) and 10 pieces of large HEPA filters (1.2 m × 0.6 m) at the filtration efficiency over 99.97% (above 0.5 μm). The grade C room is used for a main manufacturing process such as weighing room, material storage, mixing raw material and take a material sample from bio-safety cabinet and fume hood. The grade D clean room is equipped with 2 pieces of small HEPA filters. The Grade D room is used for garbing and hand washing. The last room is a changing room for personnel and this room is equipped with 3 pieces of small HEPA filters.

2.2. Field Measurement Test

This study examined the indoor environmental parameters of the investigated bio-tech cleanroom during an unoccupied (at-rest) period. After inspection, the next step was validating the data using numerical simulation. All of the experiments were done during a construction of this factory. The tests for field measurement are as follows:

1. Airflow Rate

A contamination control is the primary purpose of the cleanroom. A way of contamination control by a controlled the air supply system. A TSI model 8380 was employed to monitor the velocity of each HEPA. To get the air flow rate, measure a HEPA dimension. After that, measure the air supply velocity with an apparatus and cover the hood to HEPA.

2. HEPA Leak Test

To qualify as HEPA the air filter must remove at least 99.97% of all airborne particles greater than

0.5µm in diameter from the air that passes through it. Poly Alpha Olefin (PAO) testing is a very quick process that tests the integrity of the High Efficiency Particulate Air (HEPA) filter using PAO solutions in their operational conditions. These tests generate a gas type smoke and then generate gas particles that will be greater than 0.5 micrometres. The test will certify the HEPA filter is fully functioning and there is no leakage or damage. PAO tests were conducted as well with an ATI TDA-2H photometers. The schematic of HEPA leak test is shown in Figure 2.

3. Particle Counts

The most important test used to ensure a cleanroom is working correctly is the measurement of the airborne particle concentration. A particle counter is used to count particles in the air of a cleanroom. A measurement of particle counts was performed with Beckman Counter model 3413 particle counter, sensitive to particles larger than 0.5 µm. The sampling flow rate for particle counter operated at 28.3 l/min (1 ft3/min) with sampling period 1 minute.

4. Room Pressurization

A cleanroom must have sufficient clean air supplied to dilute and remove the air-borne contamination generated within the room. A pressure is critical to the proper functioning of the clean room, the pressure test should be established in order to determine that the clean room can set-up a stable pressure difference between the environment to avoid a cross-contamination. A TSI model 9555-P digital manometer was be used to monitor the pressure difference of the bio-tech cleanroom. There are 10 measurement point and 3 times of measuring at each measurement point.

5. Temperature and Relative Humidity

Temperatures is required for comfort, precision measuring equipment, the handling of sensitive products, and compounds or ingredients. Humidity control is the most complex parameters because this parameter can make a big impact for personal comfort and a product. Too high humidity can encourage the growth of bacteria and microbes and corroding sensitive metals whether in products or equipment. There are 25 measurement point and 3 times of measuring at each measurement point. The variation of temperature and humidity were recorded by TSI model 9555-P.

Figure 1. Layout of the investigated bio-tech cleanroom; (a) HEPA location; (b) particle counts measurement point.

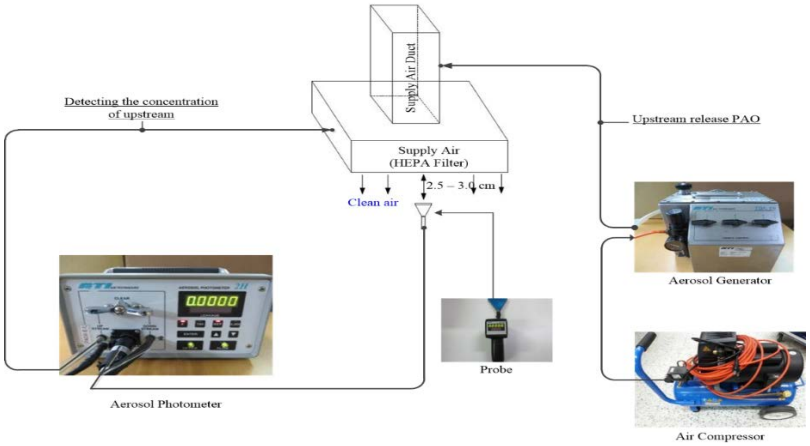

Figure 2. Schematic diagram of HEPA leak test apparatus.

Table 1. Typical input parameters of building for building simulation.

Apparatus Model	Operative range	Accuracy
TSI-8380	0.125 - 12.5 (m/s)	3%
ATI TDA-2H	0.0001%-100ug/L	1%
Beckman Counter 3413	0.3, 0.5, 1, 3, 5, 10 µm	5%
	-3735 ~ +3735 Pa	1 Pa
TSI-9555-P	-10 ~ 60 (℃),	0.3℃
	0 - 100 (%RH)	3%RH

2.3. Numerical Simulation

The 3D model of the investigated bio-tech cleanroom is shown in Figure 3. Some manufacturing machines were sketched in the layout as well. The main process clean-room of Grade C is chosen to be the research object. The geometry of the research object according on the actual size. The dimension of the investigated cleanroom is at length of 11.0 m, width of 8.25 m, height of 2.8 m, and total area of this cleanroom 90.75 m3. Total of the investigated bio-tech cleanroom is equipped with nine pieces of HEPA filters and two return air grilles. The dimension of HEPA is at length of 1.2 m and width of 0.6 m then the dimension of the return air grille is at length of 0.6 m and width of 0.3 m. This investigated bio-tech cleanroom is used for main manufacturing process such as weighing room, material storage, mixing a raw material, and take a material sample from bio-safety cabinet.

The computational fluid dynamics (CFD) simulation has been proven to be powerful tool and efficient in airflow distribution and concentration profile case. In this study, steady state numerical simulation has been carried out using Ansys Fluent Workbench version 2020 R2. The solution of simulation analysis is divided into two categories, the steady-state and unsteady state (transient) solution. This research will be carried out in two phases stage of the simulation. The first stage is for airflow distribution simulation analysis, it has been simulated with steady-state solution. The coupling iterative calculation for this stage is solved by SIMPLE (Semi-Implicit Method for Pressure Linked Equations) method. The second stage is the exclusion of the contamination airborne analysis with unsteady solution (transient) to simulate. The simulation time is 450 second with time step size is 0.25 second. The numerical method is used to establish the difference equation for the finite-volume method. The coupling iterative calculation is solved by PISO (Pressure Implicit with Splitting of Operator) method. The residual value is set to 10-6. The contamination airborne is set at the species model used species transport with carbon-monoxide as

a mixture material. The CO2 concentration in the outdoor atmosphere is about 400 ppm, which will be used as the concentration value for supply air from HEPA. The initial contaminant concentration in the bio-tech cleanroom is set to 3,000 ppm.

The performance improvement strategy was proposed and analysed by numerical simulation. The temperature and velocity of the HEPA filters have been measured through field measurement test to provide reliable measurement data as the boundary condition of CFD simulation. Furthermore, all of the boundary conditions for solution domain were clearly defined according to the actual field measurement tests data to carry out the accurate solutions. The heat flux from machine is based on the machine specification. The boundary condition for numerical simulation is displayed in Table 2. Numerical simulation of different approaches to improve performance of the bio-tech cleanroom was conducted and assessed comprehensively.

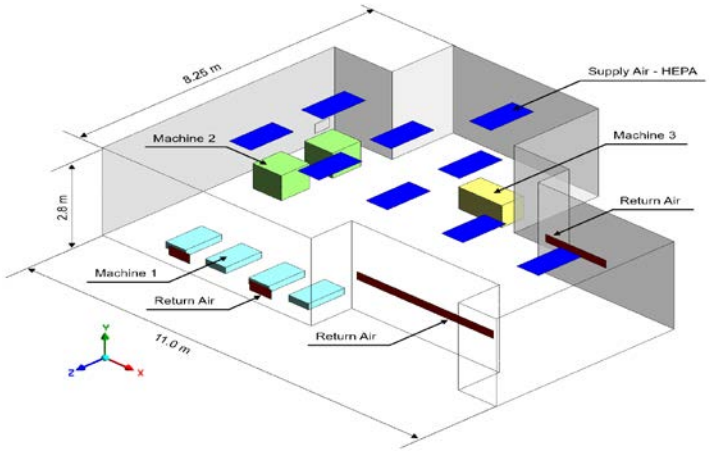

Figure 3. Computational model of the investigated bio-tech cleanroom

Table 2. Boundary condition for numerical simulation.

Parameters	Type	Value
Supply Air	Velocity Inlet	Velocity: 0.205 m/s Temperature: 19.2°C
Return Air	Pressure Outlet	Pressure: -8.2 Pa Temperature: 24°C
Machine 1	Wall	Heat Flux: 20 W/m^2
Machine 2	Wall	Heat Flux: 30 W/m^2
Machine 3	Wall	Heat Flux: 35 W/m^2

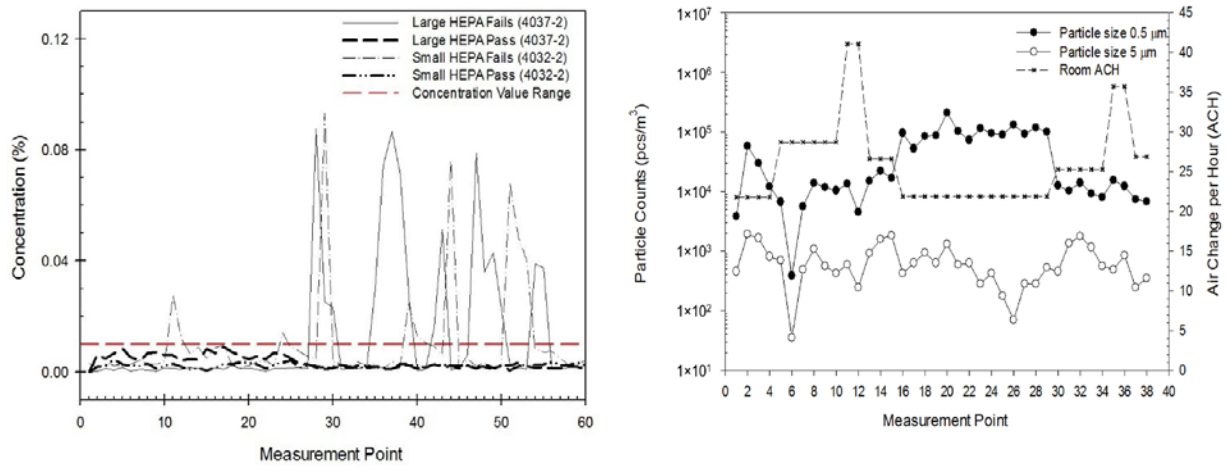
3. RESULTS AND DISCUSSION

3.1. Experimental Results

The experiments on the bio-tech cleanroom were conducted under at-rest occupancy conditions. Field measurement were carried out for all room. In this study will focus only on Ether Treatment room for numerical simulation. HEPA leakage testing is necessary to ensure the HVAC system in a good condition. Figure 4 (a) represent the field measurement data of a HEPA leak test. HEPA filter must remove at least 99.97% of all airborne particles greater than 0.5 micrometres. The leak test was performed twice and the maximum permissible leak-age should be 0.01%.

The indoor environmental condition design including temperature are maintained at 20±5°C,

relative humidity at 40-60%, and pressure at -5 Pa. The experimental data shows a good in the range of acceptance with temperature between 20.5°C - 21.6°C, relative humidity 54.2% - 55.4%, and pressure at -8.2 Pa. The bio-tech cleanroom is classified into Grade C which the particle size at 0.5µm should be less than 325,000 pcs/m3 and 5µm less than 2,900 pcs/m3 in at-rest occupancy state condition. The airflow rate for Grade C should be greater than 20 ACH and for Grade D should be greater than 10 ACH. As shown in Figure 4 (b), the results are appropriate with the standard. A higher particle counts occurs in the main process room because of production machines but still less than the standard. A higher airflow rate also is about 41 ACH occurs in the Grade C rooms. The increasing of ACH may increase the cleanliness level in a room.



(a) (b)

Figure 4. Field measurement test; (a) particle counts and ACH; (b) HEPA leak test

3.2. Validation

During the simulation process, the parameters could change the level of accuracy. As the number of elements in the mesh will increase the accuracy of the simulation results. However, this requires a long time and sufficient resources. In this research, there are four sets of grids number are selected to verify accuracy of simulation, 280,064 grids, 310,013 grids, 530,127 grids, and 630,75 grids. Moreover, increasing the number of grids makes the simulation results more precise and effectively reduce required time to simulate. In this research, the grid number of 530,127 is chosen as a follow-up numerical simulation of the grid number. The numerical simulation has been conducted to validate the field measurement result. As a main production room is used for a numerical simulation in this case. The error rate result of the temperature between numerical simulation and field test are less from 8% and for error rate of the velocity is less than 9%.

3.3. Numerical Simulation Results

In order to increase the performance improvement and contamination control, a higher velocity or ventilation rate is increased to 0.25 m/s and 0.3 m/s respectively and analysed numerically. Temperature will be reached quickly with higher ventilation rate. Not only the temperature desire level, but also a higher cleanliness level will increase. Figure5 shows the results of velocity, temperature, and concentration distribution in each case. Increasing face velocity improved airflow distribution, reaching the corners of the cleanroom.

The temperature data collected were conducted at the height of 1.4 m above the floor for both field measurement test and numerical simulation. The total of 7-point measurement were recorded and

analysed. The effect of increasing face velocity result in a distributed temperature. The point 1 in the case 1 has a higher temperature around 24°C, it is located upper the position of machine 2. While in the point 6 and point 7 have a lower temperature around 20°C. In that area have no heat flux from machine, so the temperature could result in a lower than others point. By increasing the face velocity, the temperature could result in more distributed and lower, especially in the point 2 near the heat flux generated area.

Contamination control is one of way for improving and maintaining the cleanliness level in the bio-tech cleanroom. The contaminant concentration in bio-tech clean-room is displayed in three-dimensional plane at the height of 1.4 m above the floor in the time condition at 450 seconds. The high contaminant concentration in case 1 is happened around the monitoring point 1, point 3, and point 5. It was showed that the contaminant concentration is around 700 ppm in the monitoring point 3. In addition, it also shows the accumulation of contamination at the corner of bio-tech cleanroom, the reason of the air distribution is not evenly distributed to cleanroom especially to the corner. Face velocity of the HEPA or supply air grille did not distribute to the outer part or corner and may cause the contamination residue due to the return air pattern between the return air is open. In the area that more airflow was distributed evenly such as monitoring point 6 and point 7 has better performance of contamination removal.

Another assessment, ventilation efficiency is the ratio between contaminant concentration in the occupied spaces and the concentration in the exhaust air. It is a measure of how effectively the air present in a space is replaced by fresh air from the ventilation system. Table 3 depicts the results of the ventilation efficiency in different case study. The lower concentration in the cleanroom result in a higher ventilation efficiency. Case 3 has the highest ventilation efficiency with 96.55% efficiency. While, case 1 and case 2 result in 85.47% and 90.42% of efficiency.

Table 3. Ventilation efficiency results

Case Study	Concentration Average (ppm)	Concentration at Supply Air (ppm)	Concentration at Outlet Air (ppm)	Ventilation Efficiency (%)
Case 1	579	400	553	85.47
Case 2	494	400	485	90.42
Case 3	458	400	456	96.55

4. CONCLUSIONS

The following conclusions may be drawn:

- All indoor environmental conditions met the design specifications in the experiments. However, some location result in a higher concentration generated.
- The numerical simulation was conducted in different face velocity which to analysed a better concentration distribution. Case 3 with a higher ventilation rate result in a lower concentration.
- Increasing face velocity resulted in lower pressurization in each case, but still within the acceptable range.
- The lower concentration in the cleanroom result in a higher ventilation efficiency. Case 3 has the highest ventilation efficiency with 96.55% efficiency. While, case 1 and case 2 have efficiency of 85.47% and 90.42% respectively.

SUMMARY
This study introduces innovative passive cooling technology for latent thermal energy storage systems (TES) using Phase Change Materials (PCMs), aimed at improving the operational performance of BiPV façade systems under dynamic conditions. The focus was to investigate and compare different passive BiPV cooling principles at the back of the PV module. Specifically, the present concept employs two innovative high-content PCM incorporated systems. First by integrating a honeycomb structure with microencapsulated PCM (mPCM) and second using a PCM composite panel. The operational performance of the proposed systems has been evaluated to assess the efficiency of these two innovative PCM configurations. A comparative investigation was conducted using numerical computational methods. Multidimensional, non-stationary heat transfer was solved using the control volume method, while the thermal effect of the phase change was modelled using the effective thermal capacity method. Accordingly, the heat conduction effect for sufficient thermal stratification inside the PCM was investigated.

Keywords: Building integrated Photovoltaic, Phase change material, numerical simulation, operational performance.

1. INTRODUCTION

According to projections by the Energy Information Administration (EIA, 2023), global energy demand is expected to increase by 50% by 2050. Buildings currently account for approximately one-third of global energy consumption and greenhouse gas (GHG) emissions, a share that is anticipated to grow as the International Energy Agency predicts building energy consumption will double by 2050, exacerbating environmental challenges. Increasing energy efficiency and the use of renewable solar energy could be one way to reduce greenhouse gas emissions. Recently, a wide range of novel façade solutions directly utilizing the potential of solar energy gains has been described. Photovoltaic (PV) systems for building integration (BiPV) have a relevant contribution to the field of solar energy exploitation in building energy performance. However, novel building materials and components need to possess the ability to dynamically adjust their physical properties and energy performance in response to environmental stimuli.

BiPV integrated into the building envelope, represents an established solution to address current

challenges (Singh et al., 2021). Meanwhile, integrating phase change materials (PCM) within building components still emerges as a promising and innovative approach (Cunha et al., 2016). In BiPV systems, a portion of the solar radiation is converted into electricity, while part of it is absorbed by the system leading to an increase in operating temperature and a consequent decrease in both efficiency and lifespan (Sohani et al., 2022). To address this, different cooling strategies have been implemented and investigated by the scientific community, with the integration of passive cooling using PCM standing out as particularly effective. Indeed, coupling BiPVs with PCM not only reduce overheating of BiPVs, but also improves the generation of renewable energy, bridge the gap between demand and supply, reduce peak consumption and enhances indoor thermal comfort (Chinnaiyan et al., 2022). Different BiPV-PCM solutions have been investigated to reduce the operating temperature and store excess thermal energy by integrating a PCM layer on the back side of the BiPV module. These include PCM plastic bags (Fayaz et al., 2019), biochar derived from water hyacinth impregnated with PCM (Das et al., 2021), and PCM matrix with expanded graphite (Karthikeyan et al., 2020), demonstrating how the integration of a BiPV system with an appropriate PCM module has high potential and is extremely valuable.

This work investigates and compares the performance of a passive cooling system with two different PCM modules on the back of the PV. The first involves a previously studied technology (Lai & Hokoi, 2014; Wang et al., 2018) based on a honeycomb structure incorporating mPCM. The second introduces an innovative technology that utilises a novel PCM-impregnated panel (Cottone et al., 2025). In particular, the operational performance of both design proposals was evaluated and compared using numerical calculation methods of a validated simulation model. This comparative analysis aims to evaluate their effectiveness in reducing operating temperatures, storing excess thermal energy, and enhancing the overall performance of BiPV systems.

1.1 Problem statement and research relevance

The application of a honeycomb structure has been shown to have a direct impact on the improvement of PV cooling and solar energy absorption efficiency of the PCM. However, this method is associated with a significant leakage problem of PCM (solid/liquid transition). Therefore, in this study, two configurations of PCM systems were utilised, a micro-capsulated PCM (mPCM) used for numerical validation using experimental campaign (Čurpek et al., 2025) and novel composite system (Cottone et al., 2025) to compare both technologies. Honeycomb has been demonstrated to facilitate effective heat conduction enhancement, thereby preventing thermal stratification within the PCM. Furthermore, the PCM ensures that the BiPV module operates at a reduced temperature and that the time lag of the peak load is increased. This study also provides insights into performance prediction using numerical simulations to identify thermo-responsive reactions for novel BiPV PCM facades (Čurpek et al., 2023). Numerical complexity of thermo-responsive mechanisms in both modelling and simulation is of a relevant significance to reliable predicting the operational performance of BiPV coupled with PCMs (Čurpek & Čekon, 2022). The development of numerical simulation models may allow comprehensive analyses, as well as optimization of the novel TES system for real applications (Čorić et al., 2025).

2. METHODOLOGY

First, the validation of a model is demonstrated for the purpose of modelling and simulating a BiPV/PCM experimental prototype. Second, the capability of real and modelled performance is

analysed to theoretically describe the thermal performance of the BiPV/PCM façade model. Finally, the material parameters of the new composite PCM system are used for the simulation of the thermal performance of the new BiPV/PCM façade model.

2.1. Materials and methods

An experimental investigation was carried out in summer using an outdoor test cell for two scenarios (case A and case B in Figure 1), and the measurement results were used to validate numerical calculation models. An integrated model was developed to simulate the thermal performance of the BiPV façade systems within which summer boundary conditions were implemented. The performance of three unventilated façade configurations was compared. Specifically, case A was an experimental honeycomb-based without PCM, case B experimental honeycomb-based filled with mPCM, and case C simulated new composite PCM system. This approach enabled the thermal characterisation of BiPV/PCM systems to be reliably obtained from the simulation to identify the theoretical performance for novel BiPV/PCM façade configurations.

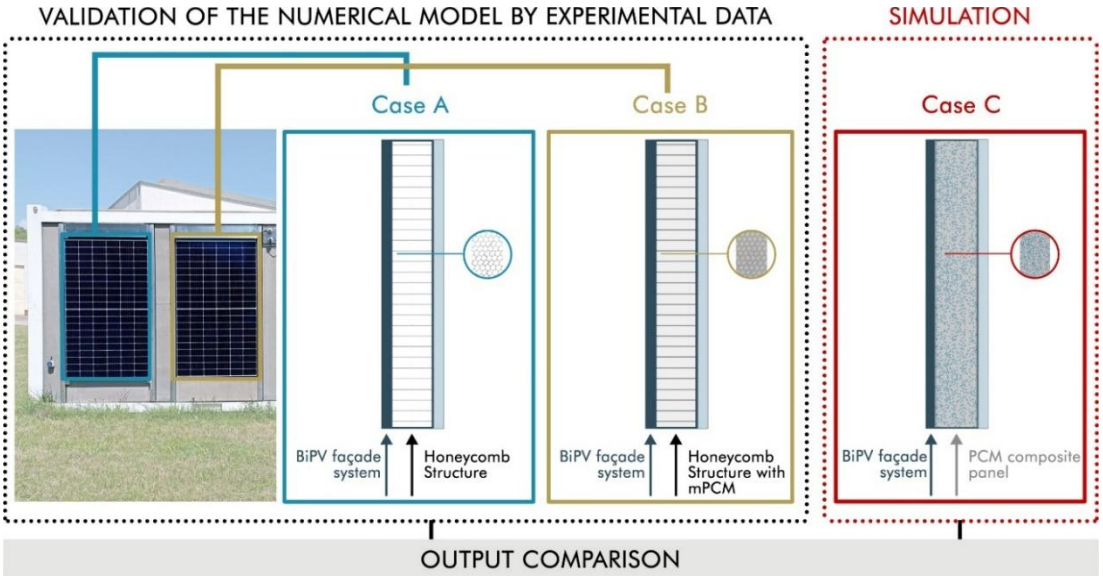

Figure 1. Test cell and design strategies of two BiPV/PCM concepts, experimental (A and B) and numerical (C)

2.1.1. Experimental study

The experimental campaign focused on the assessment of the operational performance of the reference BiPV (case A) and the proposed BIPV/T-mPCM façade (case B) under real-world conditions. For the façade application, the honeycomb is sandwiched between two layers of the rear of the BiPV panel and cement-bonded particleboard, as shown in Figure 1. The honeycomb structure consists of an aluminium with a hexagonal cell size of 9 mm and a thickness of 30 mm. The cavities for test case B were filled with mPCM (type MPCM 37D), a melting point of 37 °C and a heat of fusion of 190 J/g. The specific heat capacity (Figure 2) required for numerical calculations for two PCMs integrated in BiPV facades (experimental mPCM37 and simulated R35HC+CS) was measured using differential scanning calorimetry.

The day used in this study is characterised by incident solar radiation of a 600 W/m^2 with outdoor air temperatures of up to 23 °C and 12 °C minimum. Climate response of typical BiPV facades

can reach PV operating temperature up to 52 °C. According to experimental results, the cooling effect of the PCM in the honeycomb structure behind the BiPV can provide a reduction of 10 K in the afternoon peaks compared to a honeycomb PV façade without PCM.

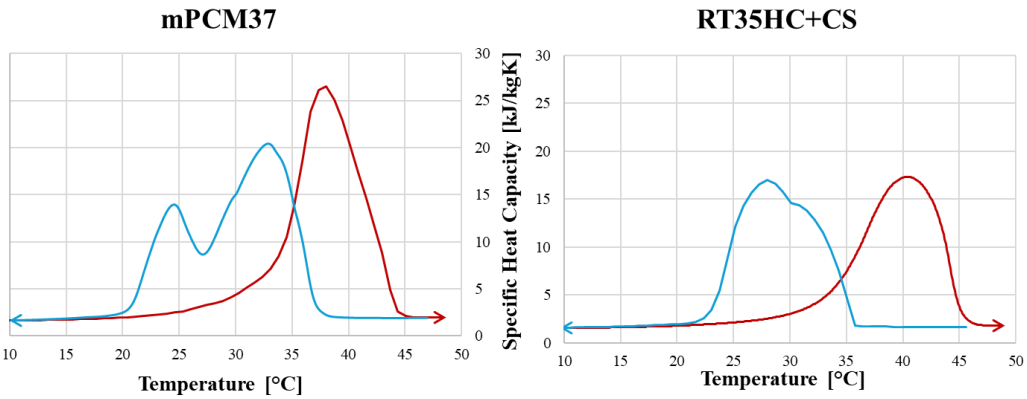

Figure 2. Specific heat capacity of two PCMs used, microencapsulated mPCM37 and RT35HC composite system

2.1.2. Numerical validation and optimization

The numerical modelling and simulation are based on the following assumptions: the influence of natural convection of the liquid phase of the PCM on heat transfer is neglected and only non-stationary heat conduction is considered in a 2D rotationally symmetric computational domain with Dirichlet, Robin + Neumann and adiabatic boundary conditions (Figure 3). The numerical model is based on an implicit solution by the finite volume method implemented on a structured computational grid in CalA 4.0 software (Sikula & Plasek, 2015). The Gauss-Seidel iterative method with convergence criterion 1E-5 is used to solve the model. Detailed materials parameters used in numerical simulations are presented in Table 1.

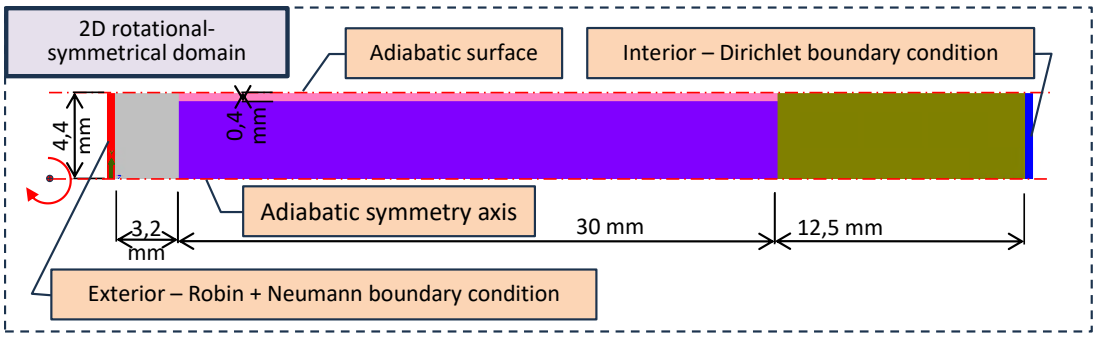

Figure 3. Numerical simulation model and basic assumptions used

Table 1. Materials parameters used in calculations.

Materials	Thickness mm	Density kg/m^3	Specific Heat J/(kg.K)	Therm. conductivity W/(m.K)
Photovoltaic panel	3.2	2330	677	11 (effective)
Aluminum	0.05 (0.8)	900	56	200 (12.5 effective)
Air cavity in honeycomb	30	1.15	1010	0.0624 (effective)
mPCM microencapsulated	30	485	$c_{eff} = f(T)$ Fig. 2	0.2
PCM panel composite system	30	830	$c_{eff} = f(T)$ Fig. 2	0.2
Cement-bonded particleboard	12.5	1200	1580	0.35

In the model, the measured net heat flux, including the both short- and long-wave radiation from the surroundings of the tested façade, is applied to the external boundary condition, and the measured surface temperature is applied to the interior boundary condition. The model validation was performed on both cases A and B. Based on the results, a new case C with a composite panel was then calculated to evaluate the suitability of this new component solution for PV cooling.

3. RESULTS AND DISCUSSION

The results presented in Figure 4 show all measured, validated and optimized data. In general, good agreement in the results was obtained for both the case without PCM (case A) and the model with mPCM (case B). The strong correlation between the experimental measurements and the simulation predictions underscores the reliability of the modelling approach and validates the efficacy of integrating PCM into photovoltaic façade systems.

According to results (see Figure 4, left), the data illustrates a notable reduction in peak temperatures by approximately 8 K when mPCM is utilized, in contrast to the system without PCM. This decrease in peak temperature is indicative of the PCM's effectiveness in absorbing excess thermal energy during periods of high solar irradiance. By transitioning from a solid to a liquid state, the mPCM absorbs heat, thereby mitigating the temperature spikes that typically occur during peak sun hours. This thermal buffering effect is essential for maintaining a stable indoor environment and reducing the thermal load on building HVAC systems. Additionally, the analysis reveals a delay of approximately 1.5 hours in the occurrence of peak temperatures when mPCM is employed. This delay is crucial for optimizing energy management strategies, as it allows for a more gradual release of stored thermal energy during the evening hours. Consequently, the building component can maintain a more consistent temperature profile, reducing the need for mechanical cooling during peak demand times. This delay not only enhances occupant comfort but also contributes to energy savings by shifting the load away from peak energy pricing periods, further underscoring the economic advantages of incorporating PCM into building design.

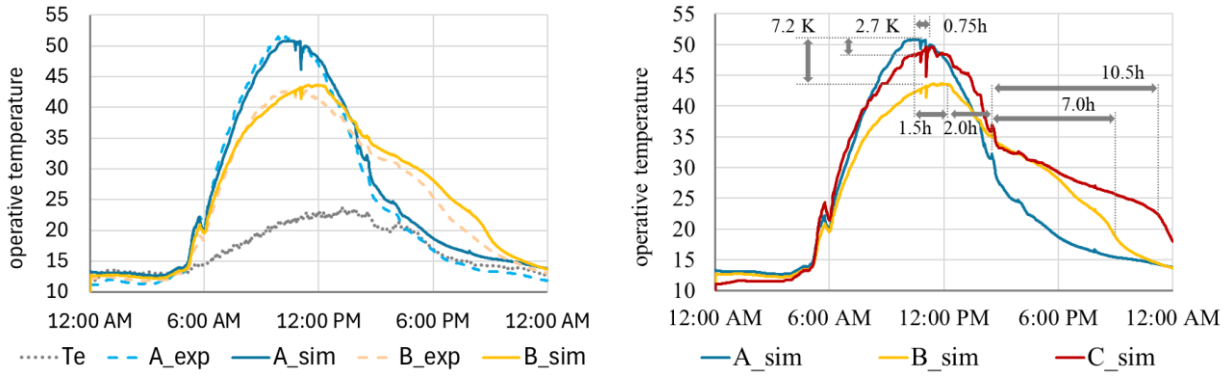

Figure 4. Numerically validated results for case A and B on the left side, comparison between all simulated cases including the new composite system with integrated PCM

The experimental and numerical results (case A and B) validate the premise that PCM can effectively manage thermal energy within building envelopes, thereby optimizing the operational efficiency of BiPV systems. The observed improvements obtained numerically in thermal performance (operative temperature difference around 7 K) can be attributed to the inherent

properties of PCM, particularly its high latent heat capacity and the ability to absorb and release heat during phase transitions. On the contrary, the results presented for optimisation purposes (case C) using the newly developed RT35HC composite system (Fig. 4, right) show that its efficiency decreases significantly and that a reduction in peak temperatures by a maximum of 3 K is theoretically achieved. In addition, the time lag between two modelled PCM systems is more than 3 hours during the night. This indicates that increasing the thermal conductivity of the PCM system is very important to ensure a proper efficiency, and the suitability of new composite system application needs to be further investigated to improve its overall performance.

4. CONCLUSION

In this study, numerical calculations were conducted to identify the thermal performance of a photovoltaic façade system enhanced with Phase Change Material (PCM) of two different configurations. This innovative approach aims to enhance the energy efficiency and thermal comfort of building-integrated photovoltaic (BiPV) systems. The primary focus of this research was first to validate simulation models that predict the latent thermal energy storage capabilities of PCM. To achieve this, experimental data obtained from real-world tests were utilized, which served as a benchmark for assessing the accuracy of our theoretical models. The results of this study indicate a strong correlation between the measured data and the predictions made by used simulation models for both experimental configurations used. This alignment underscores the reliability of used modeling approach and its applicability in real-world scenarios.

However, the theoretical results from the optimization tests with the new composite system reveal some limitations, as the system exhibited a smaller reduction in peak temperature and a longer time lag compared to the mPCM system. This suggests that while the new composite system shows potential, improvements in thermal conductivity are necessary to enhance its overall efficiency. Therefore, further research and development are essential to explore and optimize the performance of composite PCM systems, ensuring they can effectively compete with existing mPCM solutions in building design applications. Overall, these findings underscore the importance of PCM in enhancing the operational efficiency of building-integrated photovoltaic systems and contribute to the ongoing pursuit of sustainable and energy-efficient architectural solutions. Future studies may explore further configurations and material compositions to optimize the performance of PCM in diverse climatic conditions, paving the way for broader adoption of this technology in the building.

ACKNOWLEDGEMENTS

This research was supported by Scientific Grant Agency of the Ministry of Education, Science, Research and Sport of the Slovak Republic, project VEGA 2/0145/24, and from the European Union's Horizon Europe research & innovation programme under the HORIZON-MSCA-2021-DN-01 grant agreement No. 101072598 – "ActaReBuild". The authors would like to thank M. Žemlička and J. Čurpek for their technical assistance during the construction of the experiment at the Institute of Construction and Architecture of the Slovak Academy of Sciences.

Characterization of the flow around a model low-rise house in the presence of a deciduous tree

Ryan Aziz [1], Kamran Siddiqui [2]

[1]*Western University, London, Canada, jaziz22@uwo.ca*
[2]*Western University, London, Canada, ksiddiq@uwo.ca*

SUMMARY
Buildings are often surrounded by trees that influence the airflow patterns around the building and hence, the external energy exchange. The present study reports the airflow behaviour around a model house in the presence of a model deciduous tree using particle image velocimetry (PIV). The investigation aims to characterize the flow behaviour at different tree positioning with respect to a house under foliated and defoliated conditions. The results show that the location of the tree impacts airflow patterns. The presence and absence of foliage also has recognizable influence on the airflow behaviour. Generally, when the distance of the tree from the house increases, the turbulence in the separated shear layer from the leading edge of the house slightly increases. In general, the tree without foliage induced slightly more turbulence along the house. These changes in airflow around the house indicate an alteration in the external energy exchange of the house.

INTRODUCTION

Trees are a common feature in the surroundings of buildings. However, the effect of trees on the airflow around buildings is not well understood. A deeper insight into the flow alteration due to trees is vital for understanding the impact that trees have on the external energy exchange of buildings. A noteworthy aspect of deciduous trees is that they do not have foliage in winter in many regions and hence, the impact of such a tree on the airflow around a building has seasonal variation. Such behavior has not been extensively investigated. A better understanding of how trees affect airflow around a building can lead to improved understanding of building energy use and improved building energy modelling.

Limited research work has been reported on the impact of trees on the airflow around buildings. A numerical study investigated how coniferous trees in a shelterbelt alter the convective effect of wind, and the effect that the shelterbelt has on shading. The study observed a reduction in the heating requirements of a low-rise office building in Scotland when a tree shelterbelt was present (Liu & Harris, 2008). These shelterbelts are not typical of many houses where trees are typically placed without wind breaking in mind. A recent study by Li et al. (2024) has numerically investigated the impact that tree morphology and leaf area density have on the air blockage. The effect of trees on wind-comfort levels in high rise building environments was simulated. It was concluded that in such an environment, building arrangement is the main contributor to comfort level. It was also shown that trees can reduce wind speeds, but when near a building corner, trees had limited impact because of flow acceleration past corners (Kubilay et al., 2024). Manickathan et al. (2018) investigated various scale model trees in a low turbulence wind tunnel including trees lacking foliage, and natural trees. Particle image velocimetry (PIV) was used to measure the velocity field and loads cells were used to determine tree drag coefficients. These models featured

reconfiguration. The study found that the defoliated trees have lower drag coefficients than those with foliage. PIV and drag coefficient data revealed that the defoliated trees investigated had minimally influenced the flow when compared to trees with foliage. It was also found from PIV that some model trees exhibited very similar wake structure to natural trees. Another study conducted wind tunnel experiments to analyze how trees at differing growth stages in street canyons affect outdoor pedestrian level temperature. A model street canyon was heated, and temperatures at the pedestrian level were found to be cooler with the presence of trees for moderate heat conditions, but not extreme heat. Generally, trees were found to increase street canyon temperature. In this study, however, heat reduction from shading was not considered, which is significant (Zhao et al., 2023).

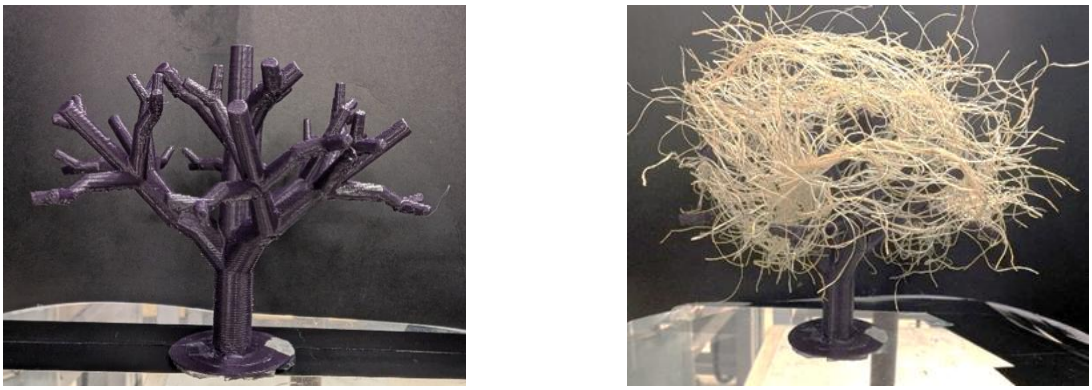
Limited knowledge on how the presence of trees alters airflow around a building is known. The present paper is focused on a detailed characterization of airflow around a model-scale two-story house in the presence of a tree to investigate how the presence of a tree alters the flow behaviour around the house. A specific focus is on the impact of a deciduous tree with and without foliage on the airflow around the house. It also in investigates the effect of the distance and position of a tree relative to a house has on the airflow behaviour around the house. Aziz & Siddiqui (2024) previously reported the mean and turbulent flow behaviour around a house in the presence of a tree, but only with foliage present, and without altering the distance from the house.

METHODOLOGY

All experiments were conducted using a closed loop wind tunnel with low turbulence at Western University. The test section is composed of transparent acrylic walls. The test section is 122cm long, with a square cross section perpendicular to the airflow of 46cm × 46cm. The test section features removable testing plates and removable side panels. All experiments were run with a freestream velocity of 10.0m/s.

A model house with a scale of 1:65 was constructed to represent an idealized two-story house with a height of 10cm, length of 19.5cm, and width of 13cm. The slope of the roof is 6:12 (26.6 degrees). The house was manufactured using an FDM 3D printer using a dark filament to reduce reflections. The model house was fastened from the inside to a testing plate. The testing plate was covered in black foil and black tape to reduce reflections from the bottom of test section.

A deciduous style tree was manufactured using an FDM 3D printer. The tree was designed using a 3D L-system (Lindenmayer system) approach. L-system can be used to represent organic growth patterns (Chan et al., 2020; Prusinkiewicz, 1990). The model tree has a height of 7cm, and the crown has a diameter of 9cm, located 2cm from bottom of a cylindrical trunk. Tree foliage consisted of sisal fiber, however a correlation to leaf area index has not been determined (Gromke & Ruck, 2008). A packing density of sisal fiber similar to that of Gromke & Ruck (2008) was used. Fig. 1 shows the model tree with and without foliage. The foliage makes up the crown with a volume of approximately 180cm^3. The foliage had a mass of 1.3g, resulting in a packing density of around 7g/dm^3. All experiments were conducted with and without tree foliage.



Defoliated tree | Tree with sisal fiber foliage

Figure 1. Model tree configurations

The house was positioned so the long side (L) was perpendicular to the wind direction. Three positions of the tree in relation to the house were considered. The tree was positioned L/4 distance from the side (W) of the house and three distances upstream from the house. All layouts are shown in Fig. 2.

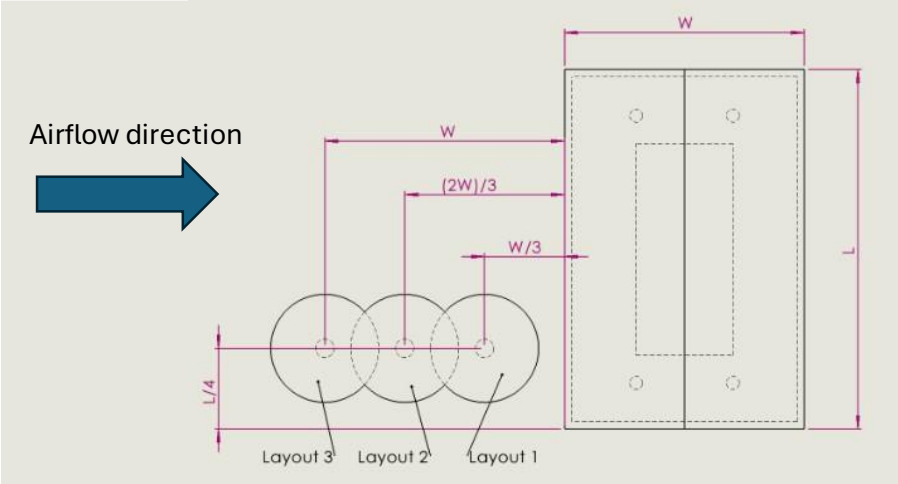


Figure 2. Tree and house layouts

Particle image velocimetry (PIV) was used to measure the velocity of the airflow around the model tree and the model house. A schematic of the PIV setup can be seen in Fig. 3. The PIV system included a dual-cavity 120 mJ Nd:YAG laser illuminating at 15Hz per cavity. The laser emitted through a cylindrical lens creating a flat sheet parallel to the ground and 5cm above the bottom of the test section. Two 12-Megapixel (4096x3072 pixel) CMOS sensor cameras (Flare, IO Industries) were used overhead to allow for a wider field of view and to capture enough seeding detail. Both cameras used lenses with 60mm focal length (60mm f/2.8 Micro-NIKKOR AF-D, Nikon) set to f/8 with an APS-C size sensor.

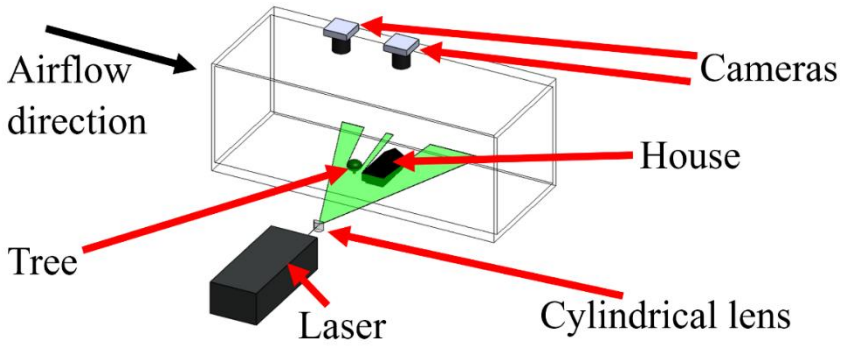

Figure 3. PIV Setup

The cameras were synchronized, and images were recorded at 30 frames per second (image pairs at 15 frames per second) using CoreView software. A digital pulse generator was used to synchronize laser pulses with camera frames. The first frame in the image pair used 200μs shutter speed, and the second used automatic exposure to determine shutter speed. The camera sensor planes were parallel to ground and 68cm above the laser sheet. The position of the camera was moved to capture different areas of interest. Images were taken over one-minute periods, that is, 1800 images were taken for each one-minute run resulting in 900 image pairs. The time delay between the laser pulses in each image pair was 60μs.

The instantaneous velocity fields were computed by cross correlating image pairs using an in-house algorithm running in the MATLAB environment. For cross correlation, the size of the interrogation window was set to 32 pixels, and the size of the search window was set to 64 pixels. The velocity vectors were interpolated onto a regular grid with 32 pixels spacing using AGW interpolation scheme. As the laser sheet was illuminated from one side, it created shadows of the tree and the house (see Fig. 3), creating erroneous vectors in the dark regions. Therefore, masking was implemented for each layout to eliminate any data in the dark regions or from the regions where the exposure was too high or too low. A local medial filter was used to detect and correct spurious vectors (which were typically very few). The uncertainty in the PIV velocity vectors was estimated using the methodology presented in (Cowen & Monismith, 1997; Prasad et al., 1992). The maximum uncertainty in the velocity for all experiments was estimated to be ±0.13m/s or 1.3% of the free stream velocity. The mean velocities were computed by time-averaging instantaneous velocity data over the one-minute duration. Turbulent velocity fields were obtained by subtracting the mean velocity field from each instantaneous velocity field. The turbulent kinetic energy (TKE) was computed from the two-dimensional turbulent velocity fields.

RESULTS

The effect of the tree on the airflow around the house was characterized through mean velocity and turbulent kinetic energy (TKE), for all layouts.

For layout 1, where the tree was positioned upstream and closest to the house (W/3 distance from the front of the house as seen Fig. 2), the colormaps of the mean velocity field are illustrated in

Fig. 4 for both foliated and defoliated cases. The plots show that the presence of the tree caused the flow acceleration on the side, which is expected due to the mass conservation. The flow acceleration is found to be relatively stronger in the foliated case, which is likely due to the higher flow resistance caused by the foliage. The results also show that in the absence of the foliage, the flow separation region on the side of the house was suppressed. Downstream from the house, the characteristic wake region is visible. The comparison between the foliage and no foliage cases shows that the mean flow behaviour in this wake region has negligible difference. The results also reveal the flow separation occurring at the leading edge of the house on the upstream side. The TKE plots in Fig. 5 show that the turbulent flow structure is relatively similar for both cases, however, the turbulence along the side of the house and in the wake region is relatively stronger in the absence of the foliage. This indicates that the convective heat transfer on the exterior side of the building is impacted by the absence of the foliage.

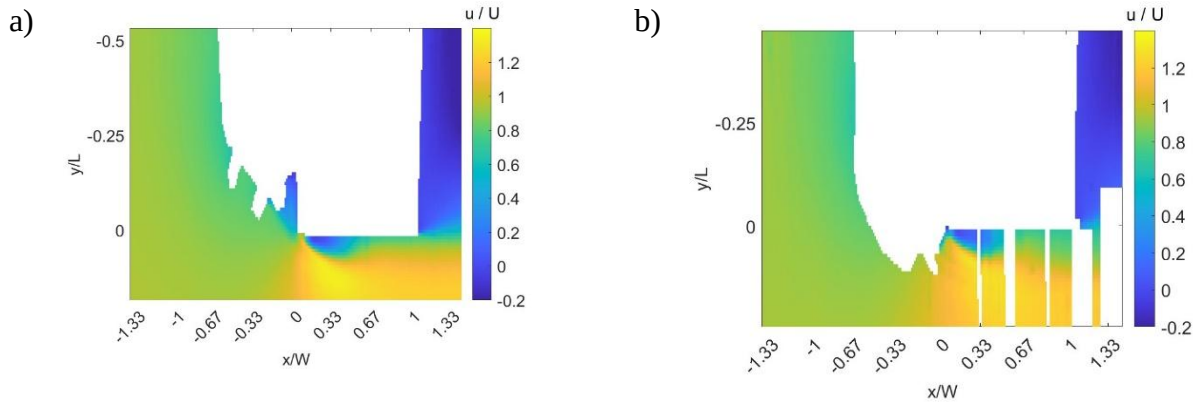

Figure 4. Contours of normalized average streamwise velocity for layout 1. For the coordinate system, the origin is located at the left upstream corner of house. a) defoliated tree b) foliated tree

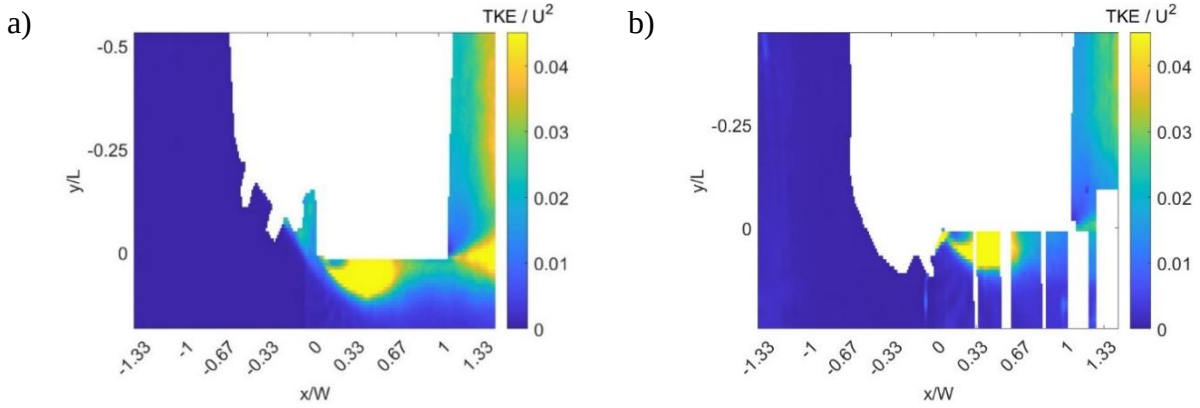

Figure 5. Contours of normalized average TKE for layout 1. For the coordinate system, the origin is located at the left upstream corner of house. a) defoliated tree b) foliated tree

Fig. 6 shows the mean velocity field as the tree was positioned further upstream of the house at a distance of 2W/3. The results show the presence of a wake behind the tree (defoliated case), as expected, covering the entire region between the tree and the house. Such measurements were not

possible for the foliage case due to the extent of the foliage, covering that region. The comparison between the two cases shows that similar to the Layout 1, the flow separation on the side of the house was suppressed in the absence of the foliage. The results also show that the wake region downstream from the house Fig. 6 is not altered significantly by the presence of foliage in the tree compared with the case without foliage. The TKE plots in Fig. 7 show a relatively similar structure of the turbulent flow along the side and in the downstream wake region, with a slightly higher turbulence in the absence of the foliage. Strong turbulence in the wake of the tree is also visible, as expected.

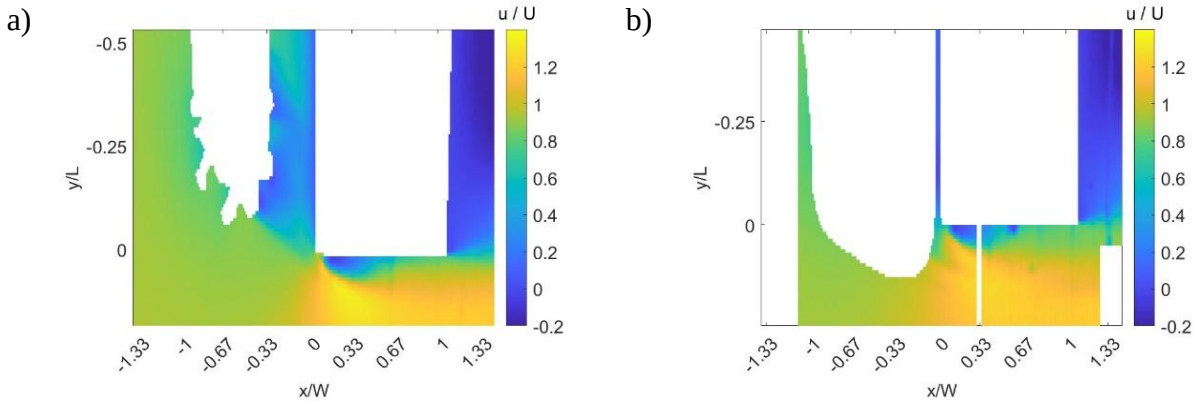

Figure 6. Contours of normalized average streamwise velocity for layout 2. For the coordinate system, the origin is located at the left upstream corner of house. a) defoliated tree b) foliated tree

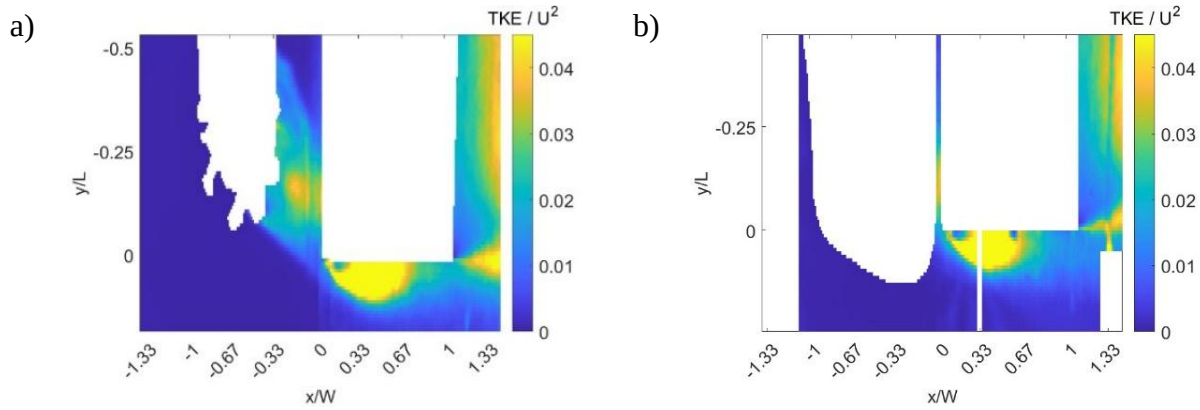

Figure 7. Contours of normalized average TKE for layout 2. For the coordinate system, the origin is located at the left upstream corner of house. a) defoliated tree b) foliated tree

For layout 3, when the tree is farthest from the house at the distance of W, differences in the flow behaviour in the wake of the tree are observed in the presence and absence of the foliage. The mean velocity fields in Fig. 8 show localized wake regions immediately downstream from the tree in the defoliated case, which are expected to be induced by the defoliated branches of the tree. However, in the foliated case, a uniform wake is observed behind the tree. Similar to the other cases, in the absence of the foliage, the flow separation on the side of the house was suppressed. The TKE plots in Fig. 9 show stronger turbulence behind the tree in the defoliated case, which was

extended over a relatively wider region. The results also show that the turbulence magnitudes on the side and behind the house are relatively higher in the absence of the foliage and extended over a wider region.

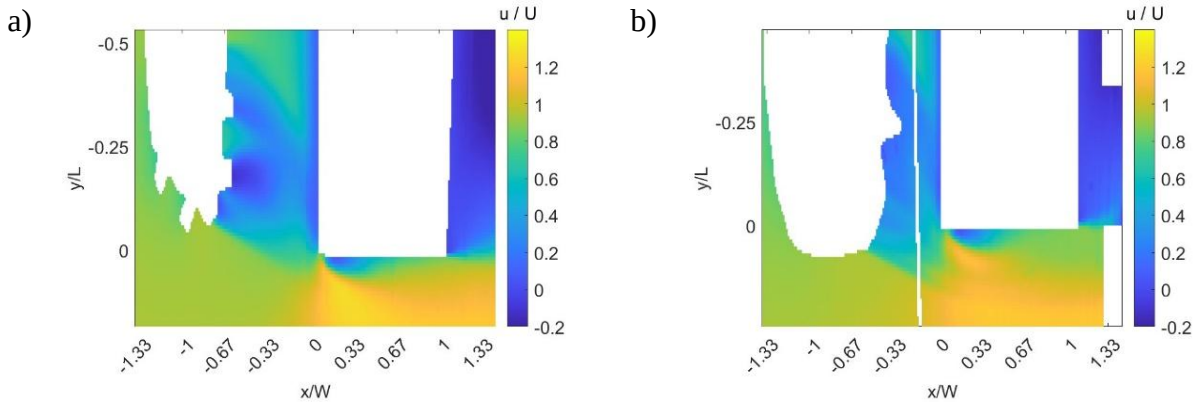

Figure 8. Contours of normalized average streamwise velocity for layout 3. For the coordinate system, the origin is located at the left upstream corner of house. a) defoliated tree b) foliated tree

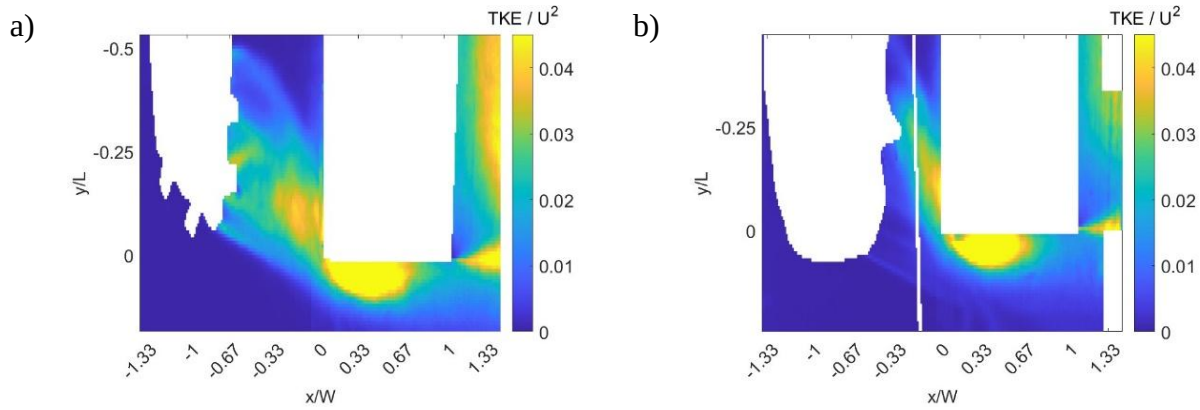

Figure 9. Contours of normalized average TKE velocity for layout 3. For the coordinate system, the origin is located at the left upstream corner of house. a) defoliated tree b) foliated tree

Comparing the characteristics of the airflow between layouts, it is observed that as the tree moves farther away from the house in the upstream direction, a non-uniform wake region is established between the tree and the house, when the tree is defoliated. The presence of the tree upstream of the house also causes the flow acceleration on the side of the house, which is relatively stronger in the absence of the foliage. The TKE plots show that the turbulence behind the tree becomes relatively stronger as the location of the tree is moved further upstream of the house. In the absence of the foliage, the turbulence becomes relatively stronger on the side of the house and in the wake of the house.

CONCLUSIONS

The present study investigated the influence of tree foliage on the flow around a house for different tree locations. Particle image velocimetry was used to characterize the two-dimensional mean and

turbulent airflow fields. The results show that when a tree is located upstream of a building, the flow accelerates on the side. Where the flow reattaches to the wall downstream, the flow is more turbulent is this region in the presence of the defoliated tree. The air was found to be more turbulent in the wake of the defoliated tree that in the wake of the tree with foliage. When comparing the distance of the tree from the upstream side of the house, the separated shear layer size and turbulence increases slightly as the distance of the tree from the house increases. The results from this study show that as a tree defoliates in the colder season, it alters the airflow behaviour around the house and hence alters the external building energy exchange.

SUMMARY
Computational fluid dynamics is used to simulate urban wind conditions and wildfire smoke dispersion in the city of Montréal. A case study for the day of July 17, 2023, in Montréal is used, which was characterized by moderate southwest winds and significant amounts of wildfire smoke. Steady-state RANS simulations testing the standard k-ε and Shear Stress Transport (SST) k-ω model as well as different values of turbulent Schmidt number are validated against lidar, anemometer, and air quality monitoring station measurements. Both models predict the urban boundary layer winds, although the SST k-ω model fails to capture some complex urban dynamics. The wind flow is analyzed to address issues of wind comfort. Wildfire smoke dispersion dynamics are also investigated, and an optimum value of 0.6 for the turbulent Schmidt number is found. The resulting smoke distributions throughout the city reveal areas prone to worse air quality.

Keywords: computational fluid dynamics, urban wind conditions, pollutant dispersion, wildfire smoke.

1. INTRODUCTION

The wind conditions found in cities significantly affect the daily lives and comfort of urban residents. Strongly connected with this are issues of air quality and pollution. With over half of the world's population living in cities (Ritchie et al., 2024), it is vitally important to study how atmospheric flow affects urban air quality. Smoke from wildfires is increasingly becoming a concern as it is often transported by the wind into cities. Exposure to wildfire smoke can be very harmful, causing eye and respiratory irritation, the exacerbation of preexisting lung diseases, and even death (Liu et al., 2015). As climate change begins to increase the frequency of wildfires, their detrimental effects on urban air quality will only amplify (Abatzoglou & Williams, 2016).

Micro-scale urban wind and dispersion dynamics can be investigated using multiple approaches, such as field measurements and wind tunnel experiments. Recently, the approach of using computational fluid dynamics (CFD) has shown to provide many benefits over previous methods. CFD, which works by numerically solving simplified versions of the Navier-Stokes equations, provides predictions of the wind field and pollutant concentrations at every location within the domain, whereas in-situ and wind tunnel measurements are limited to discrete locations. CFD simulations also give control over meteorological conditions, useful in predicting and modelling events that have not yet occurred. Instead, field measurements and wind tunnel tests often serve as the necessary initial and boundary conditions for running CFD models.

CFD models use one of two main approaches, either large eddy simulation (LES) or Reynolds-averaged Navier-Stokes (RANS) simulations. While LES provides time-dependent simulated fields and resolves large-scale turbulence, RANS models parameterize all scales of turbulence and provide only the time-averaged, mean flow. The potential increased accuracy of LES is offset by significantly higher computational expense and complexity, resulting in the frequent use of RANS in industry and research (Blocken 2018). The technique of RANS is also supported by more robust best practice guidelines, preventing incorrect model initializations common with the higher complexity of LES. However, RANS simulations do require the selection of turbulence model, which can have a large effect on the accuracy of the simulations. No one turbulence model is appropriate for all scenarios, and as such, multiple must be tested (Franke et al. 2007). Among the most frequently used are the standard k-ε and the Shear Stress Transport (SST) k-ω models, both of which have been shown provide accurate simulations of pollutant dispersion in various circumstances (Gousseau et al. 2010; Tominaga & Stathopoulos 2007; Wang & McNamara 2006). In particular, the standard k-ε model is known to overestimate turbulent kinetic energy (TKE) at a building's windward edge (Tominaga & Stathopoulos 2007), for which the SST k-ω was introduced to correct, but this model is known to poorly predict flow in the wake regions of buildings (Wang & McNamara 2006). This research aims to test the accuracy of these two turbulence models in predicting wind flow and wildfire smoke dispersion in downtown Montréal. An additional RANS model parameter that is tested is the turbulent Schmidt number, Sc_t, which further affects the model's prediction of pollutant concentration. This parameter can vary between 0.2 and 1.3, with the optimum value dependent on the characteristic flow structures (Tominaga & Stathopoulos 2007). This study's goal is to validate a RANS based numerical model testing multiple turbulence models and turbulent Schmidt numbers for urban wind flow and wildfire smoke dispersion in downtown Montréal. The model's predictions are compared against anemometer, lidar, and air quality monitoring station measurements in the city center. The wind field and smoke distribution are analyzed to investigate urban wind comfort and air quality issues.

2. METHODOLOGY

This study simulates the conditions of July 17, 2023, for downtown Montréal, which experiences moderate southwest flow transporting significant amounts of wildfire smoke into the city. Canada's wildfire season was its worst on record in 2023 (Copernicus 2024), and Montréal saw many similar days of decreased air quality due to wildfire smoke. Here, $PM_{2.5}$ (particulate matter with a diameter of less than 2.5 μm) is used as a proxy for wildfire smoke concentration as it constitutes over 90% of the mass within the smoke (Vicente et al. 2013) and is more chemically stable than other components of wildfire smoke (Atkinson 2000). Weather and air quality monitoring stations at the Montréal-Pierre Elliott Trudeau International Airport (45.4678°N, 73.7417°W) were for the boundary conditions of wind speed and direction and $PM_{2.5}$ concentration. Eight hours (15:00–22:00 UTC) were simulated, representing the time period during which the wildfire smoke peaked inside the domain and began to dissipate.

Validation of the model is done using an anemometer at the McTavish Reservoir (45.5047°N, 73.5792°W) and a lidar on the roof of McGill University's Burnside Hall (45.5047°N, 73.5751°W) for predictions of wind speed and direction, and an air quality monitoring station downtown (45.5122°N, 73.5667°W) for predictions of $PM_{2.5}$ concentrations. Lidar, standing for light detection and ranging, can serve as a more complete validation tool for CFD models than

the more common anemometers, as lidars are able to measure wind velocities across many different heights. This provides much more detail as to the vertical structure of urban wind flow. While lidars have been frequently deployed in investigations of the urban boundary layer (Drew et al. 2013), their use in validating CFD models is still limited.

The numerical model is run using the open-source CFD software OpenFOAM. The mesh was created using OpenFOAM's SnappyHexMesh and includes explicitly modeled buildings and topography. Designed following best practice guidelines (Frank et al. 2007), the domain measures 10 × 8 × 1.7 km and was mesh using three different grid resolutions to ensure grid independence. The medium resolution mesh, consisting of 80 million cells, was used in all simulations for its accuracy and reduced computational expense. Details of the computational domain are shown in Fig. 1. Inlet wind profiles are assigned with the approach of Richards and Hoxey (1993), with the wind speed given by:

$$U_h = \frac{u_*}{\kappa} \ln\left(\frac{z+z_0}{z_0}\right), \quad (1)$$

where u_* is the friction velocity found with the 10 m height airport reference velocities, κ is the von Kármán constant of 0.41, and z_0 is the roughness length estimated from the Wieringa updated Davenport classification system (1992). TKE is assumed to be constant with height according to:

$$k = \frac{u_*^2}{\sqrt{C_\mu}}, \quad (2)$$

where C_μ is a model constant equal to 0.09. Finally, for the standard *k*-*ε* model the profile of TKE dissipation rate is given as:

$$\varepsilon = \frac{u_*^3}{\kappa(z+z_0)}, \quad (3)$$

while in the case of the SST *k*-*ω* model the profile of specific turbulent dissipation rate is given by (Wilcox 2006):

$$\omega = \frac{\varepsilon}{C_\mu k}. \quad (4)$$

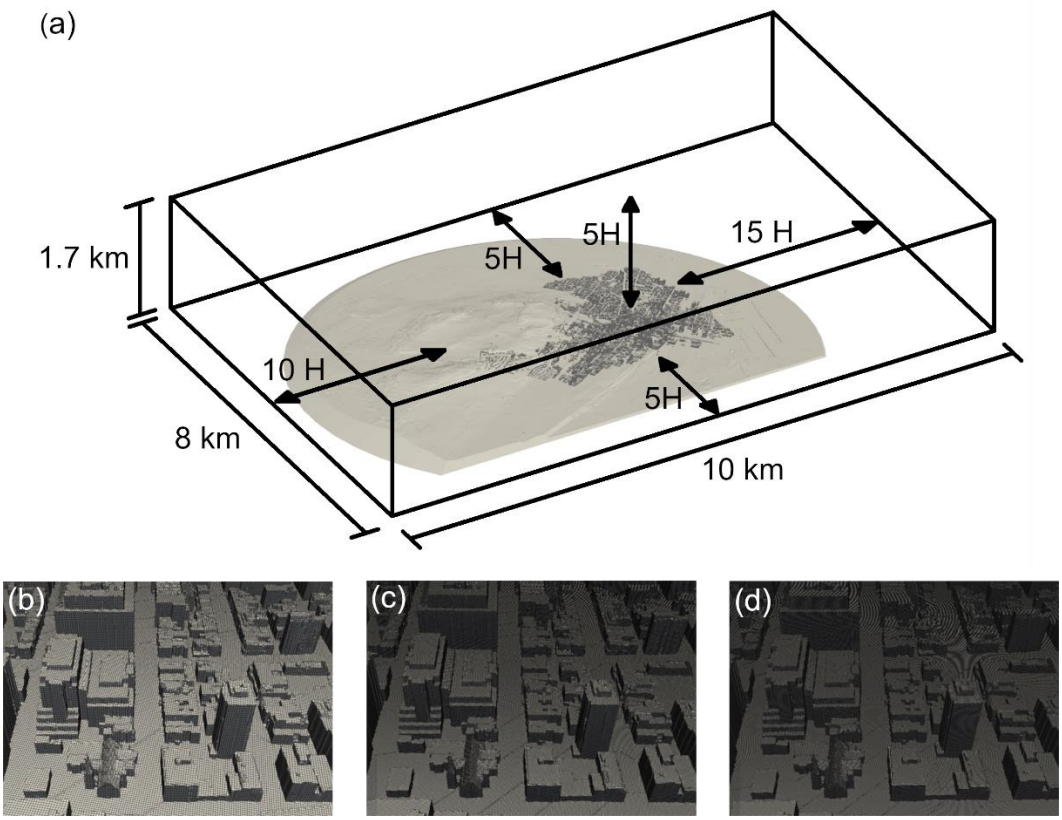

Figure 1. (a) Computational domain dimensions. (b) Coarse grid resolution. (c) Medium grid resolution. (d) Fine grid resolution.

The solver simpleFoam was used, which assumes incompressible flow, first finding the converged wind field, and then a modified version including turbulent diffusion and scalar transport was used to simulate the wildfire smoke dispersion. During these simulations, the value of Sc_t was varied between 0.4 and 1 to investigate its effects on the wildfire smoke dispersion.

3. RESULTS

The predicted wind speeds by the two turbulence models are first compared to the 20-minute averaged lidar wind speeds (Fig. 2). This comparison shows good agreement by the models across many of the hours, with the *k*-ε and SST *k*-ω models performing similarly. The characteristic logarithmic profile of ABL flow is well captured at the lower altitudes for which this profile is the proper representation of the boundary layer. Later in the day (Fig. 2e-h), with the development of the mixing and residual layer responsible for more complex dynamics, the models provide less accurate predictions of wind speed. The models' predictions of wind speed and direction at the McTavish weather station are shown in Fig. 3, from which can be seen that at this location the SST *k*-ω model significantly underpredicts the wind speed while the *k*-ε model shows much better agreement with an average error of only 13.2%. This is found to be the result of the SST *k*-ω model's difficulty in simulating wake reattachment length.

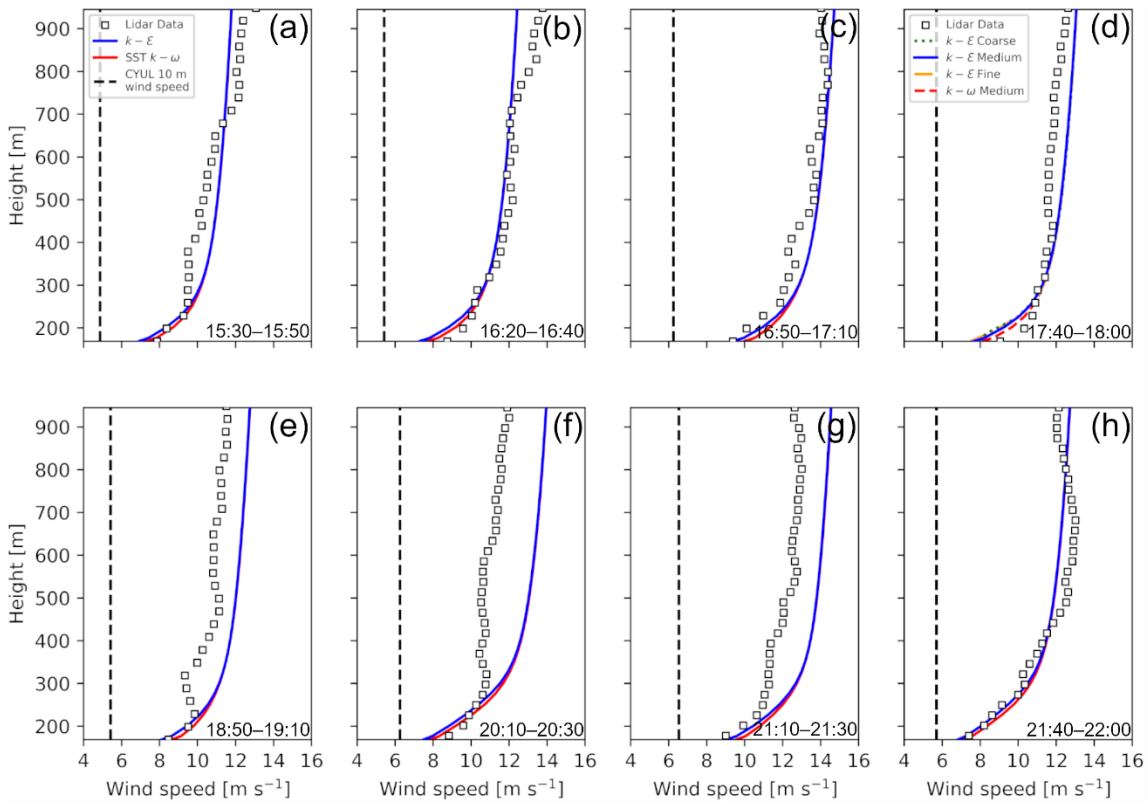

Figure 2. Modeled and lidar measured wind speeds for the averaging periods indicated in the bottom right of each subplot.

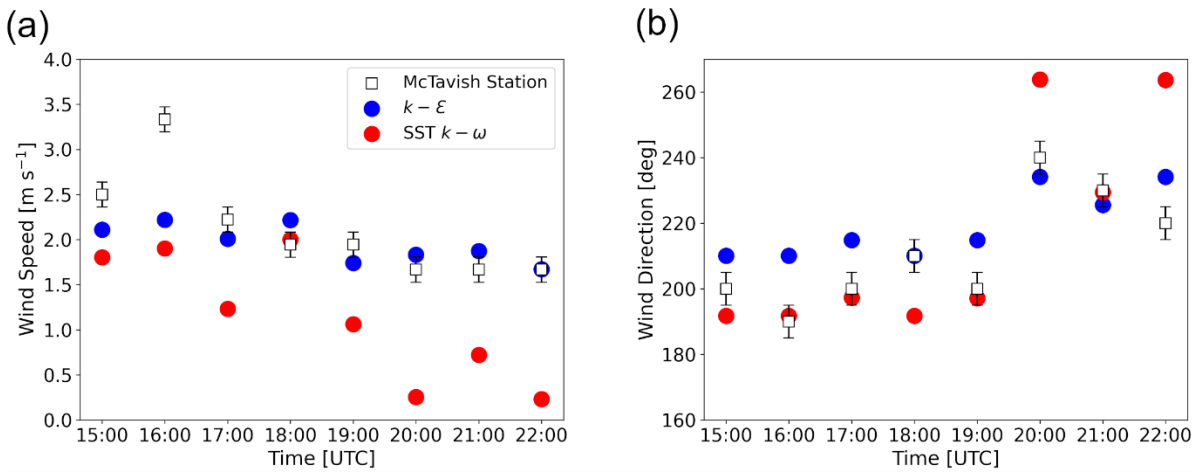

Figure 3. Modeled and anemometer measured (a) wind speed and (b) wind direction.

The validated numerical model is able to investigate features of the urban wind flow such as wind comfort and implications for air quality. Figure 4 show the wind speeds 1.75 m above ground level predicted by the standard *k-ε* model for 18:00 UTC. Most of the city experiences low wind speeds, partly due to the mountain of Mount Royal blocking higher wind speeds. Two

areas in the city are found to be susceptible to higher wind speeds, potentially causing uncomfortable pedestrian level wind conditions. The first is found in the south of the domain where the city's tallest buildings are located. Across many of the hours simulated, wind speeds here approach and exceed 5 m s^{-1}, the threshold beyond which winds pose a danger to those with reduced mobility and the elderly (Blocken & Carmeliet 2004). Another location in the eastern part of the city, near both a metro station (Sherbrooke) and retirement home, also experience high pedestrian level wind speeds, affecting both commuters and those susceptible to being injured by strong wind. Both locations are in regions where tall buildings force the strong winds aloft down to the ground, emphasizing the importance of this consideration when designing new high-rises to decrease uncomfortable and dangerous wind conditions.

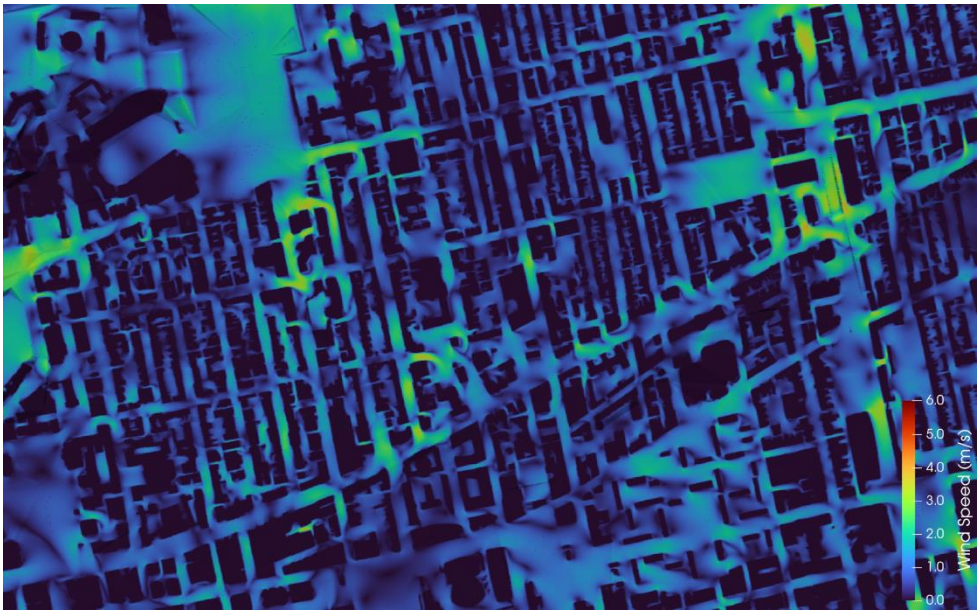

Figure 4. Standard *k-ε* model predicted wind speeds 1.75 m above ground level at 18:00 UTC

After the converged wind fields are found, wildfire smoke is introduced into the domain, which then dispersed throughout the city. Figure 6. shows the predicted concentration of $PM_{2.5}$ with different values of Sc_t. The best agreement with the air quality monitoring station is achieved with Sc_t = 0.6, which is on the higher end of previously derived values (Gousseau et al. 2010) but aligns well with a study by Toja-Silva et al. (2017) investigating urban dispersion characteristics. This value of Sc_t = 0.6 was then also test using the SST *k-ω* model, and a similar level of accuracy to the standard *k-ε* model was found. The characteristics of the smoke dispersion is also investigated by analyzing the smoke's spatial distribution throughout the city. Figure 5 shows the concentration of $PM_{2.5}$ for two separate hours at the heights of 1.75 and 30 m above ground level. Heightened concentrations of smoke are found near the base of the mountain where wind speeds are lower and decreased natural ventilation. Conversely, a region of lower elevation and sparser urban density exhibits lower concentrations due to the higher wind speeds. These local differences in smoke concentrations point to the complex dispersion dynamics of urban regions. They also suggest particular areas of cities may be more or less susceptible to decreased air quality, which could affect the long-term health of city residents.

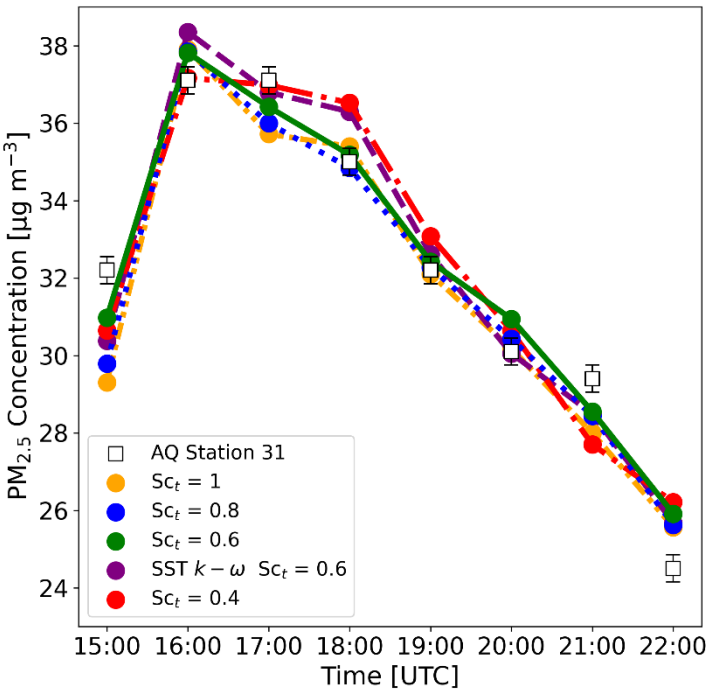

Figure 5. Model predictions of $PM_{2.5}$ using different values of Sc_t compared with air quality monitoring station measurements.

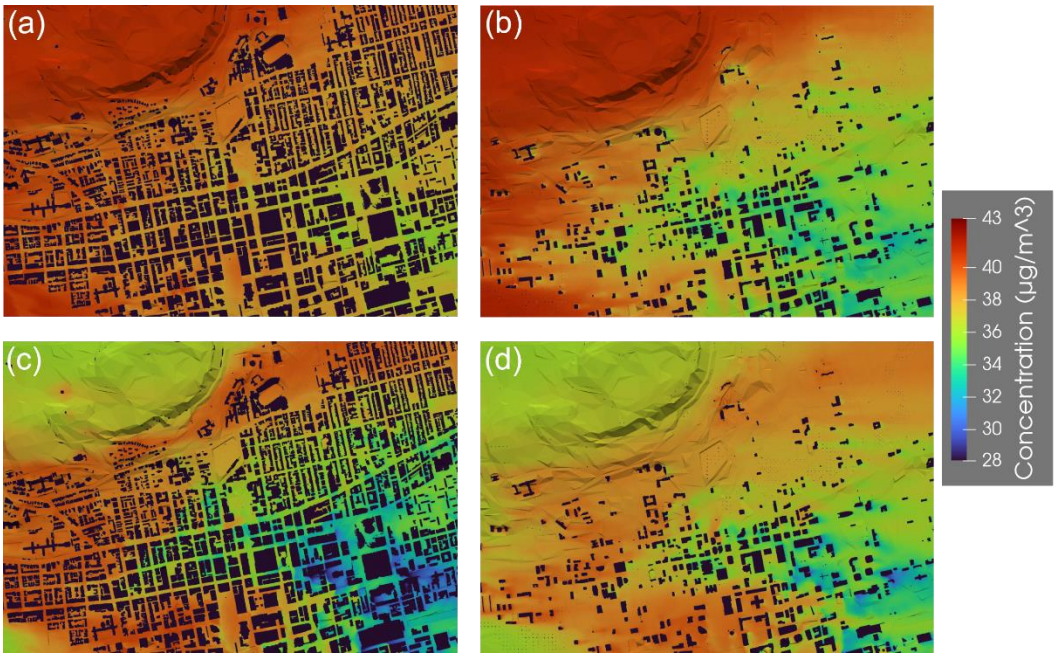

Figure 6. Predicted $PM_{2.5}$ concentrations for 16:00 UTC (a) 1.75 m above ground level and (b) 30 m above ground level and for 18:00 UTC (c) 1.75 m above ground level and (d) 30 m above ground level.

4. CONCLUSIONS

Urban wind flow and dispersion characteristics in the downtown region of Montréal on the day of July 17, 2023, were simulated, validating two turbulence models and choice of turbulent Schmidt number. Lidar measurements are shown to provide valuable validation data for urban CFD models. The standard k-ε model with Sc_t = 0.6 was found to be highly accurate in simulating both the wind field and smoke concentrations. The validated model was then used to analyze issues related to wind comfort and air quality.

SUMMARY
Large Eddy Simulation (LES) has been widely used to investigate urban airflow and heat removal processes. Due to the high computational costs associated with implicit filtering in LES, wall-modelled (WM) LES is often preferred over wall-resolved (WR) LES. However, the effectiveness of LES-WM for canyon flow under surface heating has not been thoroughly explored. This study assesses the performance of both WMLES and WRLES for reproducing the flow and temperature fields in a street canyon model with surface heating in a wind tunnel. Three computational grids with different resolutions, i.e., n/δ = 40, 10, and 2.5, are generated. WRLES is conducted with the grid with n/δ=40, and WRLES is conducted for all three grids. WRLES and WMLES with n/δ = 40 and n/δ = 10 demonstrate relative good agreement with the experiment, in terms of velocity, turbulent kinetic energy, and air temperature. In contrast, the WMLES simulation at n/δ = 2.5, significantly underpredicts the turbulent kinetic energy and overpredicts the air temperature near the heated wall.

Keywords: Best practice recommendations, Large-eddy simulation; Buoyancy flow; Surface heating

1. INTRODUCTION

Understanding the airflow patterns and dissipation of heat from building surfaces is critical for addressing urban heat islands, which exacerbate energy consumption, public health risks, and thermal comfort issues in cities. Large Eddy Simulation (LES) is commonly used to examine the aerodynamics and heat removal from the building surfaces. Due to the high computational costs associated with implicit filtering in LES for flows at relatively high Reynolds numbers, (WM) LES is often preferred over wall-resolved (WR) LES (Chew et al. 2018, Iousef et al. 2023). However, the effectiveness of WMLES for such applications has not been thoroughly explored. Therefore, this study assesses the performance of both WMLES and WRLES for reproducing the flow and temperature fields within a street canyon model with surface heating in a wind tunnel.

2. METHODOLOGY

2.1. Description of the wind tunnel experiment

The wind tunnel experiment conducted at the University of Surrey examined the effects of local heating on flow dynamics in a street canyon (Marucci and Carpentieri 2019). Each of the building models that form the street canyon measures 0.166 m in height (H), 0.166 m in width, and 2.490 m in length. Electric heating mats were utilized to achieve local heating to the windward and leeward walls. Velocity measurements were performed using a two-component laser-Doppler

anemometer. Air temperatures were measured using a calibrated fast-response cold-wire probe. The reference wind speed (U_{ref} = 0.65 m/s) was recorded upstream of the canyon model. In the experiment, different heating conditions were examined. The present validation study takes the condition of windward wall heating under a neutral boundary layer.

2.2. COMPUTATIONAL SETTING AND PARAMETERS

The LES simulations are performed with OpenFOAM-v2012. The computational domain and boundary conditions follow the setups in the wind tunnel. Synthetic turbulence at the inlet is generated using the digital filter method (Xie and Castro 2008), which modifies the inlet velocity profiles by incorporating the Reynolds stress tensor, length scale, and white noise. As shown in Fig 1., three computational grids with different resolutions are generated, i.e., n/δ = 40, 10, and 2.5. Note that n represents the number of cells used to discretize the turbulence boundary layer thickness $\delta = H/2$ (Mukha et al. 2019). Only the grid n/δ = 40 is used for the WRLES. WMLES is conducted using the three computational grids. All WMLES simulations employ Spalding's law (Spalding and others 1961), which is valid for the wall region of $0 \leq y^+ \leq 350$:

$$y^+ = u^+ + e^{-\kappa B}\left[e^{-\kappa u^+} - 1 - \kappa u^+ - \frac{1}{2}(\kappa u^+)^2 - \frac{1}{6}(\kappa u^+)^3\right]$$

After the simulation reaches statistical steadiness, the sampling is taken from 81 seconds following (Qin et al. 2024).

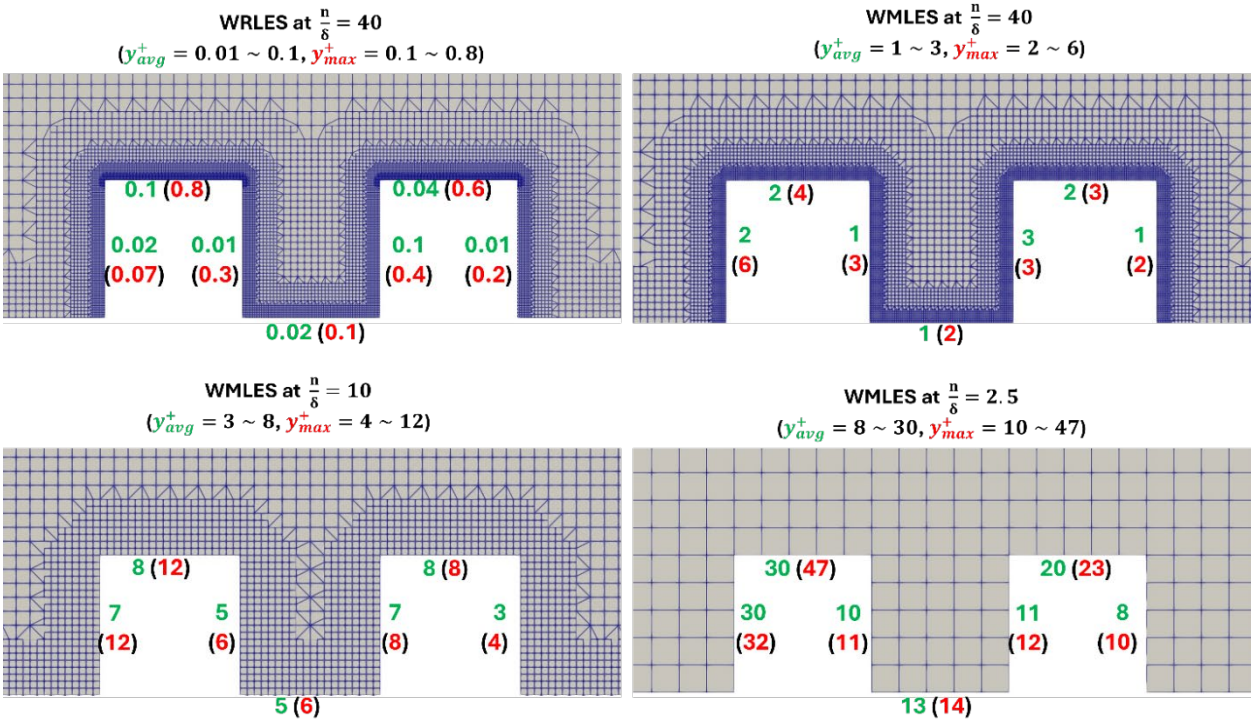

Figure 1. Area-averaged y⁺ values (y^+_{avg}, numbers in **green** color), area-maximum y⁺ values (y^+_{max}, numbers in **red** color), and the grid configurations of WRLES simulation at n/δ=40 and WMLES simulations at n/δ=40, 10, and 2.5 for the street canyon with the heated windward wall.

3. RESULTS

3.1. Wind flow and pollutant field

At a grid resolution of $n/\delta = 40$, WRLES simulation shows a y^+_{avg} ranging from 0.01-0.1, and y^+_{max} ranging from 0.1 to 0.8. These y^+ values indicate an adequate resolution of the boundary layer. All three WMLES simulations demonstrate y^+ values ranging from 0 to 350, indicating that the grid resolution is suitable for modeling turbulence in the boundary layer. It should be noted that WRLES simulation at $n/\delta = 40$ and WMLES simulation at $n/\delta = 40$ yield different y^+ values, probably due to different predictions for the velocity close to the wall.

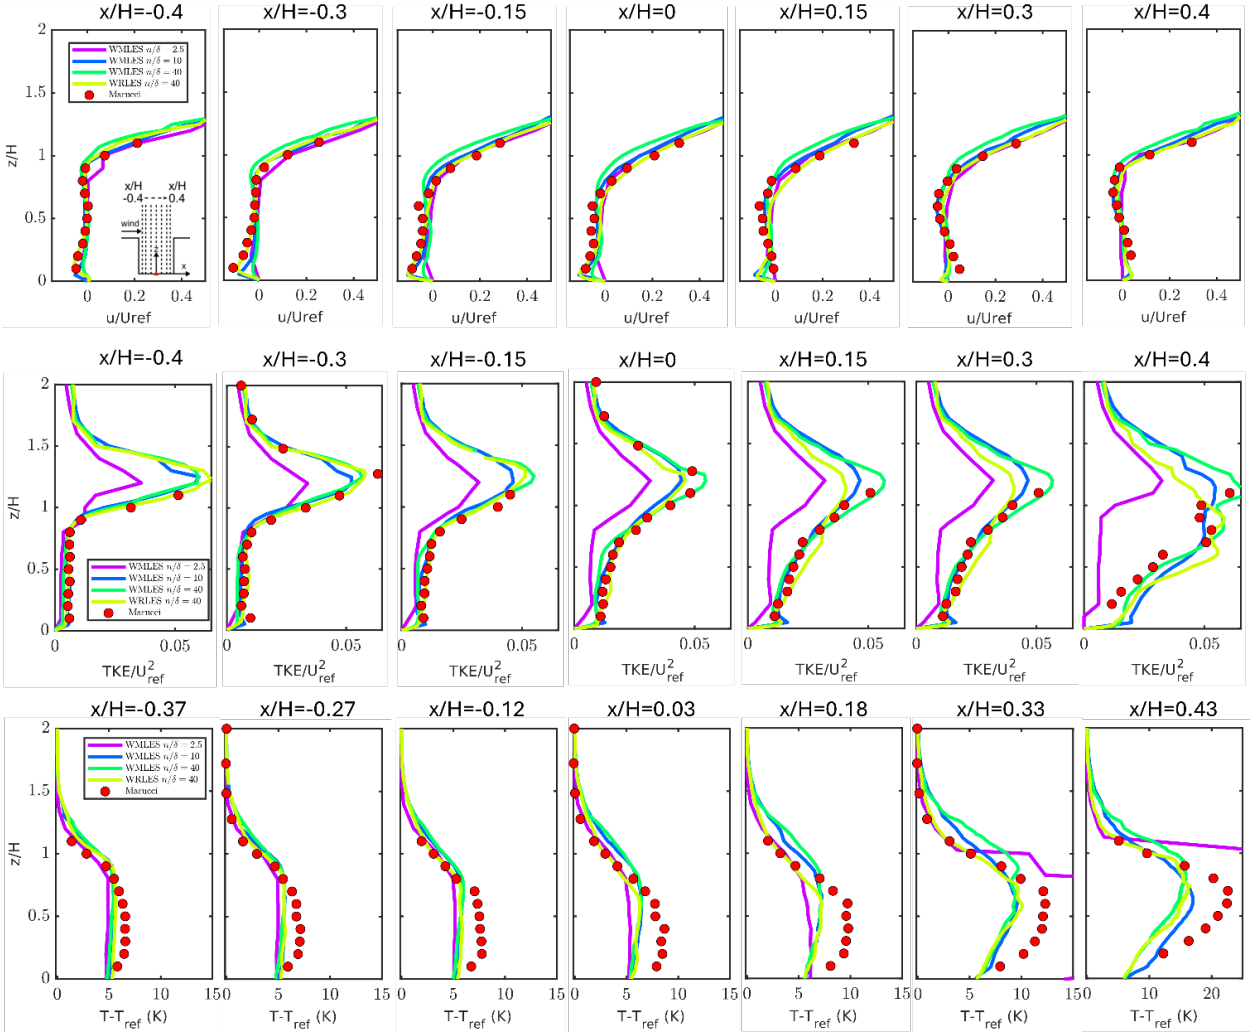

Figure 2. Comparison of the vertical profiles of (top) normalized streamwise velocity, (mid) normalized turbulence kinetic energy, and (bottom) relative temperature (T-T_{ref}) at different x values in the center section (y=0) between the wind tunnel experiment, WRLES simulation with n/δ =40 and WMLES simulations with n/δ =40, 10 and 2.5 replicating this experiment for a street canyon with heated windward wall

For the vertical profiles of the normalized streamwise velocity (see the top row in Fig. 2), WRLES simulation with n/δ = 40 and WMLES simulation with n/δ = 40 and n/δ = 10 demonstrate good agreement with the experiment. In contrast, the WMLES simulation at n/δ = 2.5 does not capture the flow in the anti-stream direction at ground level (0 < z/H < 0.2) at some locations, e.g., x/H = -0.15 or x/H = 0. For the vertical profiles of the normalized turbulence kinetic energy (see the middle row in Fig. 2), WRLES with n/δ = 40 and WMLES with n/δ = 40 and n/δ = 10 maintain consistency with the experiment by accurately capturing the TKE in the shear layer above the canyon within the range 1 < z/H < 1.5. In contrast, WMLES simulation with n/δ = 2.5 underpredicts the TKE in this region. For the

vertical profiles of the relative temperature, the WRLES simulation with n/δ = 40 and the WMLES simulations with n/δ = 40 and n/δ = 10 captures the shape of the profile, with an underprediction of less than 3K within the height range of 0.3<z/H<0.6. However, WMLES with n/δ = 2.5 significantly overpredicts air temperature near the heated wall, given that the big cell occupies the near wall region.

The results of the intermediate and full-scale simulations will be presented at the conference.

SUMMARY
Optimizing the built environment is essential for mitigating the adverse effects of extreme heat events; however, comprehensive studies on the impact of 2D and 3D built environment morphology on local thermal comfort remain scarce. This study focuses on Xi'an, China, and aims to assess the influence of morphology indicators by: 1) quantifying urban thermal comfort using the modified temperature-humidity index (MTHI), and 2) applying boosted regression trees (BRT). The results indicate that: (1) 71.27% of blocks in the study area experience uncomfortable thermal conditions, (2) the normalized difference vegetation index (NDVI) is the primary factor influencing MTHI, and (3) the 2D built environment is most strongly associated with the thermal environment during hot summer. These findings provide a quantitative foundation for enhancing urban thermal comfort and promoting sustainable development through modifications to the built environment.

Keywords: thermal comfort, multi-dimensional urban factors, boosted regression tree (BRT).

1. INTRODUCTION

Urban heat island (UHI) effect and rapid urbanization are increasing the frequency of extreme heat events worldwide, with the United Nations Environment Program (UNEP) projecting that by 2050, 1.6 billion urban dwellers will experience extreme heat. This escalating heat presents significant risks to infrastructure, public health, and mortality. The World Health Organization (WHO) estimates that, between 2030 and 2050, extreme heat will result in 250,000 deaths annually, primarily due to heat-related illnesses, heart failure, and respiratory complications, with the elderly being particularly vulnerable. Studies from Europe, the United States, China, and Japan have consistently shown that older populations bear the highest risk during extreme heat events (Ballester et al. 2023; Carr, Falchetta, and Sue Wing 2024; Chen et al. 2023; Zeng, Baptista, and Kakinuma 2024). Given this alarming trend, there is an urgent need for urban adaptation strategies to mitigate the impacts of climate change.

Research leveraging remote sensing and field measurements has demonstrated a clear connection between urban planning and thermal characteristics. Urban green infrastructure such as parks, have been shown to provide a cooling effect that helps reduce urban heat (Zhou et al. 2022). In contrast, high building and road densities are typically associated with elevated land surface temperatures (LST) (Xu et al. 2024). Furthermore, land use types, such as industrial areas, are often warmer due to the heat generated by infrastructure and activities (Su et al. 2021). With increasing urban verticalization, the impact of 3D urban structures on the thermal environment is gaining more

attention (Yuan et al. 2024). Research has indicated that building heights and street canyon configurations (e.g., openness and orientation) can influence temperature distribution at the street level (Han et al. 2023; Ali-Toudert and Mayer 2006). Additionally, compact urban spaces with higher floor area ratios tend to lower LST (Luo et al. 2023), while shadows from vertical structures (such as buildings and trees) can block solar radiation, improving thermal comfort (Park, Guldmann, and Liu 2021). These 3D characteristics, along with traditional 2D urban features, provide new insights into how the built environment affects urban heat dynamics.

Temperature is a key indicator of thermal exposure, and numerous studies have explored the impact of urban morphology on surface and air temperatures. However, thermal comfort is not only influenced by temperature but also by humidity, which plays a crucial role in how heat is perceived (Liu, Zhang, and Deng 2016). Indices that combine temperature and humidity, such as the discomfort index (DI), physiological equivalent temperature (PET), and the Universal Thermal Climate Index (UTCI), offer a more comprehensive and sensitive measure of thermal comfort, reflecting the combined effects of heat and moisture on the human body (Thom 1959; Bröde et al. 2012; Höppe 1999). These indices provide a more accurate assessment of urban microclimates, yet few studies have comprehensively examined the impact of 2D and 3D built environment variables on urban thermal comfort using temperature and humidity indices.

To address these research gaps, this study integrates thermal discomfort data and 2D and 3D built environment variables to analyze the spatial distribution of urban thermal comfort and the impact of urban built environment on it. The main objective is to identify how multidimensional built environment indicators can enhance thermal comfort, promote equitable heat mitigation, and inform climate adaptation urban planning policies.

2. MATERIALS AND METHODS

2.1. Study area

The study area (34°11′–34°22′ N, 108°47′–109°06′ E, Fig. 1a) is located in the central region of Xi'an, covering 45,734.37 ha and enclosed by the Xi’an Bypass Highway. As a pivotal city in Northwest China, Xi'an is characterized by rapid urbanization and a high population density and also faces considerable heat challenges, with the Xi'an Weather Station reporting an average of 43 days in 2023 when temperatures surpassed 35°C. Given these conditions, there is a pressing need for research on thermal comfort during extreme heat events in the region.

2.2. Datasets

The datasets used in this study include remote sensing images with a 30-meter spatial resolution from Landsat8 TIRS satellite, as well as data from the Shuttle Radar Topography Mission (SRTM), the Advanced Land Observing Satellite (ALOS), and building and road network data from AutoNavi Map and Baidu Map Street View images, both primarily captured in 2020. The study is carried out in two main stages.

First, urban thermal comfort is assessed at the block level using the modified temperature-humidity index (MTHI). MTHI values are derived from LST and normalized difference moisture index (NDMI), calculated using Landsat 8 imagery acquired on August 2, 2021 (https://glovis.usgs.gov/, path 127, row 36, cloud cover: 5.41%). On this observation day, typical summer conditions were

recorded, with a maximum temperature of 39°C, no precipitation, and light breezes classified as force 2 within the study area. Secondly, this study explores the relationship between three environmental indicators (MTHI, LST and NDMI) and environmental variables affecting urban thermal comfort. The 2D built environment indicators of cities, derived from city maps and remote sensing images, have long been important references for urban planning studies. However, digital elevation models (DEMs) and 360° street images captured through panoramic photographs now offer a more multidimensional perspective for urban studies. STRM (https://glovis.usgs.gov/) is a globally unique terrain dataset that provides uniform, consistent and high-resolution imagery (Yang, Meng, and Zhang 2011), while the ALOS (https://www.eorc.jaxa.jp/) offers the most accurate global-scale elevation data available (Nikolakopoulos 2020).

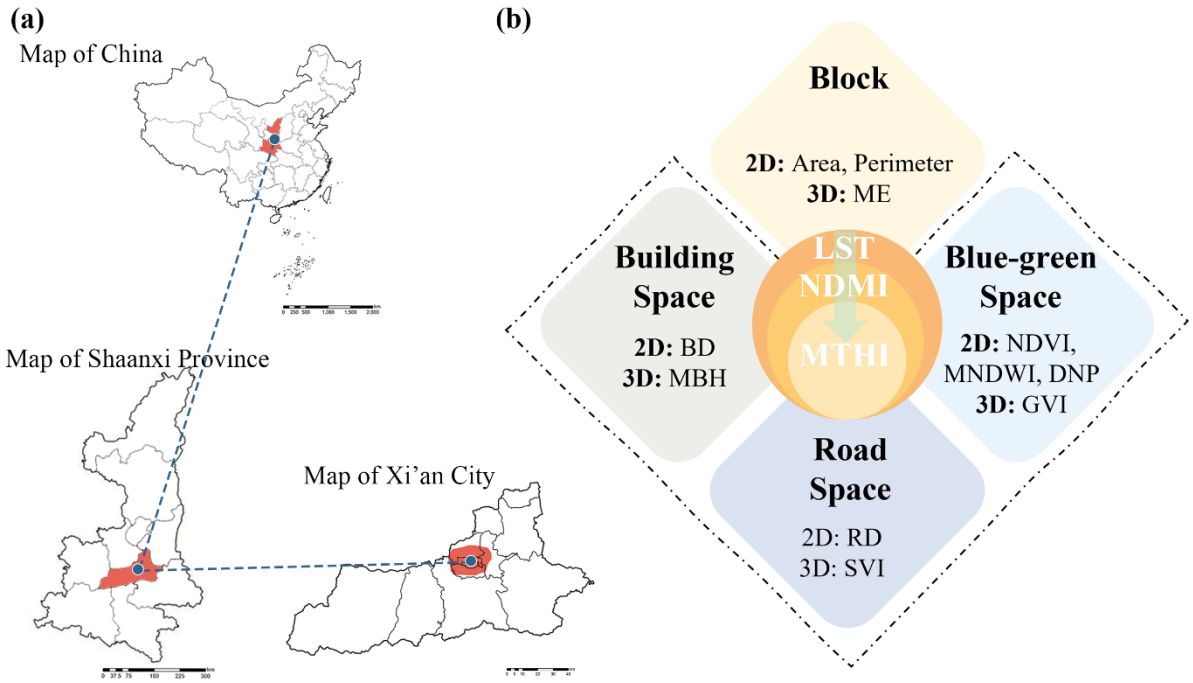

Figure 1. (a) The location of the study area and (b) indicators used in the study.

2.3. Quantification of urban thermal comfort

Quantifying urban thermal comfort and exposure requires consideration of both temperature and humidity, as the latter significantly influences human thermal comfort. The DI, based on dry-bulb (Td) and wet-bulb (Tw) temperatures, is a widely used thermal comfort metric (Thom 1959). This concept evolved into the temperature-humidity index (THI), which relies on air temperature (AT) and relative humidity (RH) (Nieuwolt 1977):

$$THI(℃) = 1.8 \times AT + 32 - 0.55 \times (1 - 0.01 \times RH) \times (1.8 \times AT - 26) \quad (1)$$

However, thermal comfort studies based on meteorological data are constrained in urban contexts due to sparse observation networks. For instance, Xi'an has only one state-run weather station (Jinghe Weather Station) near the central city. To address this limitation, a modified method using remote sensing data has been developed, substituting LST for AT and NDMI for RH. This approach, known as the MTHI, has proven reliable (Zeng et al. 2024; Feng et al. 2020):

$$MTHI(℃) = 1.8 \times LST + 32 - 0.55 \times (1 - NDMI) \times (1.8 \times LST - 26) \quad (2)$$

To validate the MTHI method for Xi'an, we compared three-day AT and RH data from Jinghe National Weather Station with LST and NDMI values derived from Landsat 8 imagery (July 28, August 13, and August 28, 2019). The computed THI and MTHI showed strong correlations (average $R^2 = 0.986$). Following THI's thermal comfort grading, MTHI values were normalized as:

$$TI = \frac{MTHI - MTHI_{mean}}{MTHI_{mean}} \quad (3)$$

where TI represents the normalized MTHI, and $MTHI_{mean}$ is the average MTHI value in the study area. Based on standard deviation, thermal comfort was classified into five levels, with lower TI values indicating higher summer comfort (Table 1) (Feng et al. 2020).

Table 1. Thermal comfort grading in summer.

Thermal comfort grading	Rang of TI value	Meaning (Relatively)
1	$TI \leq -1.5a$	More comfortable
2	$-1.5a < TI \leq -0.5a$	Comfortable
3	$-0.5a < TI \leq 0.5a$	Less comfortable
4	$0.5a < TI \leq 1.5a$	Uncomfortable
5	$1.5a < TI$	More uncomfortable

a is the standard deviation of TI.

2.4. Indictors of built environment

In this study, MTHI, LST and NDMI were used as the dependent variable, while 2D and 3D built environment indicators served as independent variables. This approach enabled a comprehensive analysis of the built environment's multifaceted impact on urban thermal comfort. The independent variables were extracted from four primary spatial dimensions: block morphology, architectural space, blue-green space, and road space (Fig. 1b).

For block morphology, key variables such as block area, perimeter, and mean elevation (ME)—accounting for buildings, greenery, and other structures—were considered. In the building space, building density (BD) and mean building height (MBH) were included as critical descriptors. For blue-green and street spaces, data from Baidu Maps Street View were incorporated. Using Python, we crawled 14,213 panoramic data points, each comprising four 90° segmented images (0°–90°, 90°–180°, 180°–270°, and 270°–360°). Semantic segmentation techniques, trained with the Cityscapes dataset (Cordts et al. 2016) , were applied to calculate the pixel occupancy for greenery and sky in these images. The Green View Index (GVI) and Sky View Index (SVI) were then derived as the average of the four images at each point. Additional blue-green space indicators included the normalized difference vegetation index (NDVI), the modified normalized difference water index (MNDWI), and the distance to the nearest park (DNP). For road space, road density (RD) was calculated. Table 2 summarizes the definitions and units of these built environment indicators.

Table 2. Built environment (2D/3D) indicators.

Type	Indicator	Definition / Equation	Unit
2D	Area	Total area of the block	ha
	Perimeter	Total perimeter of the block	km

	BD	$BD = \frac{S_{building}}{Area}$	
	NDVI	$NDVI = \frac{NIR - RED}{NIR + RED}$	
	MNDWI	$MNDWI = \frac{GREEN - SWIR}{GREEN + SWIR}$	
	DNP	Spatial distance from nearest park boundaries	m
	RD	$RD = \frac{L}{Area}$	
3D	ME	$ME = DSM - DEM$	m
	MBH	$MBH = \frac{V_{building}}{S_{building}}$	m
	GVI	$GVI = \frac{\sum_{i=1}^{4} Greenery\ Pixels}{\sum_{i=1}^{4} Total\ Pixels}$	
	SVI	$SVI = \frac{\sum_{i=1}^{4} Sky\ Pixels}{\sum_{i=1}^{4} Total\ Pixels}$	

Here, $S_{building}$ and $V_{building}$ represent the building footprint and volume, respectively; L is the total length of roads classified as level 3 or higher within the block. NIR, RED, GREEN and SWIR are near-infrared, red, green and short-wave infrared spectrum values of Landsat image. Elevation data, including DEM and digital surface model (DSM), were sourced from SRTM and ALOS, respectively.

2.5. Boosted regression trees

The boosted regression tree (BRT) method, a robust machine learning approach, is well-suited for analysing complex, multidimensional, non-linear data. It is particularly effective in addressing the intricate relationships between urban morphological features and thermal comfort (Elith, Leathwick, and Hastie 2008). In this study, the BRT model was implemented using the 'dismo' package and the 'gbm' function in R. The model examines the effects of multiple independent variables on the dependent variables—MTHI, LST, and NDMI—by iteratively constructing a series of decision trees. To interpret the results, partial dependence plots were generated to visualize the marginal effects of the five most influential variables, providing a quantitative means to understand the relationships between urban environmental characteristics and thermal comfort. The BRT model parameters were configured as follows: a learning rate of 0.01, a bag fraction of 0.5, a tree complexity of 5, and 10-fold cross-validation.

3. RESULTS AND DISSCUSION

3.1. Thermal comfort in Xi'an

The data of MTHI in the central area of Xi'an around 11:19 a.m. local time are shown in Fig. 2a and the average value (range) of MTHI is 35.89 °C (25.58 to 51.43 °C), respectively. The results show that lower MTHI is mainly concentrated in urban parks and large water bodies, etc., while higher MTHI is predominantly found in dense residential areas and industrial areas. This demonstrates that blue-green spaces effectively mitigate urban extreme heat events, while human activities and urban impermeable surfaces significantly degrade the urban thermal environment. Of the 1848 blocks, only 79 (4.27%) are more comfortable, 452 (24.46%) are comfortable, 744 (40.30%) are less comfortable, 435 (23.54%) as uncomfortable, and 138 (7.47%) as extremely uncomfortable. With over 70% of the city's blocks experiencing discomfort during extreme heat

events, addressing the thermal environment issue is crucial.

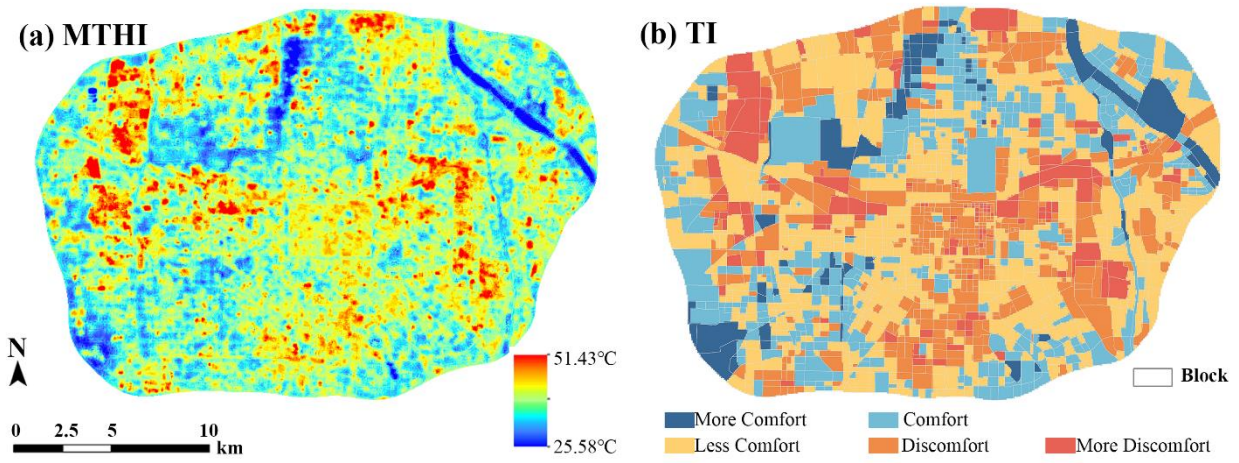

Figure 2. The spatial distribution of (a) MTHI and (b) TI.

3.2. Relative contributions of 2D/3D built environment

According to the fitted BRT model, the relative contributions of the indicators on LST, NDMI and MTHI are shown in Figure 3, with the sum of the contributions of all indicators equal to 100. Since the correlation between NDMI and NDVI exceeded 0.8, NDVI is excluded from the contribution of the indicators on NDMI. In LST, NDVI has the highest contribution of 48.54%, which is significantly higher than other indicators. In NDMI, MNDWI and BD held a contribution of 32.48% and 18.14% respectively, while the rest of the indicators had a relatively small effect on NDMI. Panel (c) shows the relative contributions to MTHI, where BD and NDVI are the highest contributors, each accounting for 21.17% and 20.42%. This underscores that both the built environment and vegetation have a major impact on modifying thermal conditions and heat perception. The results show that 2D indicators, such as BD, NDVI and MNDWI, contribute significantly to all three variables. This indicates that the influence of 2D indicators on thermal comfort is still greater than that of 3D indicators. Meanwhile, the relative contributions of building height (MBH) are 8.13%, 5.11%, and 10.04% for LST, NDMI, and MTHI, respectively, making it the next most significant factor following the previous 2D indicators. This suggests that the influence of 3D environmental indicators on thermal comfort should not be overlooked. It maintains a stable negative correlation with LST and MTHI, providing a cooling effect due to the shading caused by high buildings. Finally, the relative contributions of block morphological indicators, such as perimeter and area, are minimal and show similar trends across all three variables. In addition to considering 2D and 3D perspectives, the contribution of blue-green space indicators to all three variables is significantly greater, with all showing a negative correlation. This suggests that land cover significantly impacts thermal comfort, and that green spaces and water bodies should be effectively utilized in urban design to mitigate urban heat.

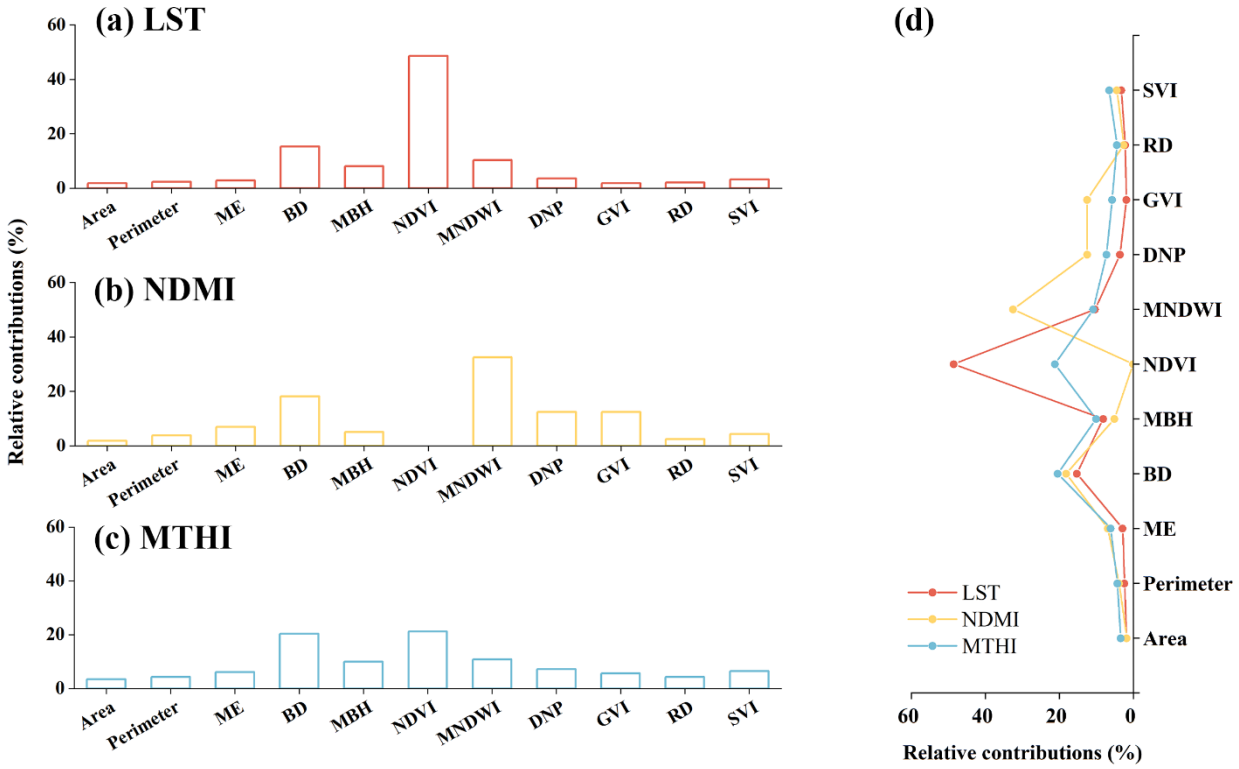

Figure 3. Relative contributions of the selected indicators on the (a) LST, (b) NDMI, (c) MTHI and with (d) comparisons.

4. CONCLUSION

This paper takes Xi'an as the study area, with blocks as the smallest study unit, based on data from Landsat 8, AMAP, etc. and BRT to explore the current thermal comfort conditions in the city and assess the impacts of 2D/3D urban morphology. The key findings are as follows: (1) Over 70% of blocks experience thermal discomfort, highlighting the urgent need for effective thermal mitigation measures. (2) Considering the average impact of 2D/3D indicators on LST, NDMI and MTHI, the three 2D indicators, NDVI, BD and MNDWI, are the most important indicators. In terms of their relative impact, the order of importance is as follows: blue-green space > building space > road space > block pattern. The findings of this study contribute to the understanding of the relationship between 2D and 3D urban morphology and thermal comfort, providing practical recommendations for mitigating UHI effect through rational urban planning.

ABSTRACT
The dispersion of dust during vehicle unloading in semi-open industrial buildings poses environmental and health risks. This study aims to evaluate the potential of air curtains as a solution for this issue. To validate the used turbulence model and numerical methods, comparisons are made with wind tunnel experimental results. Furthermore, a 1:30 scale model of a semi-open industrial building is subsequently established to assess the impact of air curtains at varying flow speed (6, 8, 10, 12, 14, 16 and 18 m/s) and flow angles (0°, 5°, 10° and 15°) on pollutant leakage. Results show that as the air curtain flow speed increases from 6 m/s to 14 m/s, the control efficiency rises from -41.12% to 98.10%. Meanwhile, further increases of flow speed show a slight decrease in efficiency, down to 97.18%. This study provides preliminary insights into the application of air curtains in semi-open industrial buildings.

Keywords: Semi-open industrial building, Air curtain, Pollutant control, CFD simulation.

1. INTRODUCTION

Dust pollution is a prevalent issue in both global industrial sectors and urban environments, with significant adverse impacts on ecological systems, human health, and economic development (Guo et al. 2022). With studies showing that inhalable particles such as PM_{10} and $PM_{2.5}$, which are highly mobile and persist in the air for extended periods, present a higher inhalation risk for workers near the building and residents in downwind areas (Li et al. 2024). The primary sources of these particles are industrial material handling processes, including loading, transportation and unloading. This is particularly concerning during unloading operations, where dust and particulate matter are stirred up and can be carried downstream by wind, posing a significant health risk to workers. Therefore, addressing dust pollution in such production scenarios is critical.

Controlling pollutants within enclosed spaces during production appears to be the simplest and most effective approach. However, semi-open industrial buildings are commonly used in these industries for material unloading operations (Liu et al. 2022; Chu et al. 2024). Unlike fully enclosed structures, these buildings typically lack walls on one side, allowing dust generated inside to be easily affected by external wind, resulting in the dispersion of pollutants into the surrounding environment. Previous studies have demonstrated that semi-open building designs can hinder air circulation, leading to the accumulation of pollutants. As a dust suppression technology, air curtains have been widely applied in mining faces (Zhang et al. 2022), tunnel construction, and other fields (Chen et al. 2021). Wang et al.(2021) proposed a local ventilation system that combines push-pull ventilation with an air curtain. The study showed that increasing the air curtain jet velocity effectively reduces pollutant leakage from aircraft painting factories. Additionally, there

remains a lack of in-depth investigation into the performance and optimization of air curtains in semi-open industrial buildings, which presents a unique challenge due to the unpredictable nature of wind and the dynamic characteristics of the unloading process. Furthermore, the effects of air curtain performance parameters (e.g., angle and velocity) on controlling pollutant dispersion during material unloading in semi-open industrial buildings have not been thoroughly studied.
This study aims to evaluate the performance of air curtains in controlling pollutant dispersion during vehicle unloading in semi-open industrial buildings. To analyze the effects of different parameters on the dust suppression performance of the air curtain under outdoor natural wind conditions, this study employs numerical simulation. The key parameters of air curtain in the model include the jet velocity (6 m/s, 8 m/s, 10 m/s, 12 m/s, 14 m/s, 16 m/s and 18 m/s), the jet angle (0°, 5°, 10° and 15°). This study provides preliminary insights into the application of air curtain in semi-open industrial buildings for improving air quality in the surroundings.

2.METHODOLOGY

2.1 Turbulence model

In this study, the RNG k-ε model was employed to simulate the characteristics of dust control by air curtains during unloading operations at a single semi-open industrial building. For an isothermal turbulent process, an additional term in the ε equation makes the model particularly suitable for strained and swirling flows, enabling effective performance prediction in low Reynolds number flows and near-wall regions. The governing equations are as follows:

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial \left(\rho \overline{u_i u_j}\right)}{\partial x_i} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right] + \frac{\partial}{\partial x_j}\left(-\rho \overline{u_i' u_j'}\right) \tag{2}$$

where the velocity components of x and y direction were u_i and u_j, respectively; the ρ, μ and $-\rho \overline{u_i' u_j'}$ were the air density, dynamic viscosity and Reynolds stress, respectively. The local mass fraction of each species Y_S, was predicted by solving a convection diffusion equation for the species in Eq. (3):

$$\frac{\partial}{\partial x_i}\left(\rho_m u_i Y_S\right) = \frac{\partial}{\partial x_j}\left[\left(\rho_m D + \frac{\mu}{s_c}\right)\frac{\partial Y_S}{\partial x_j}\right] \tag{3}$$

where ρ_m was the density of the mixture, D was the mass diffusion coefficient for the species in the mixture, and s_c was the turbulent Schmidt number (the default s_c was 0.7 for RNG k-ε model). The mass fraction Y_S could be converted to the volume concentration C by the Eq. (4):

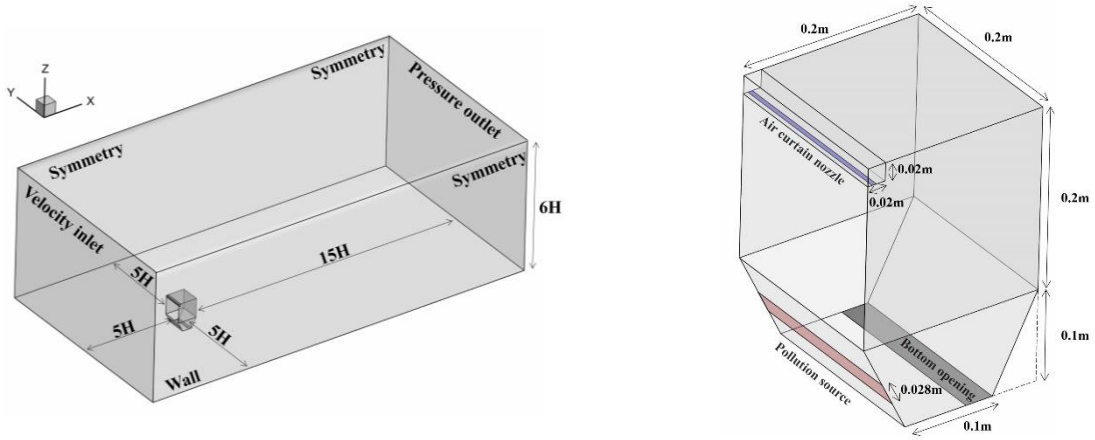
$$Y_S = \frac{C\rho_S}{C\rho_S + (1-C)\rho} \tag{4}$$

where ρ_S was the tracer gas density.

2.2 CASE DESCRIPTION

The building had a height (H) of 0.2 m and a 1:1:1 aspect ratio ($L \times W \times H$), with a scale factor of 1:30. The silo had a vertical depth of 0.1 m (0.5H) and a bottom width of 0.1 m. Part of the silo's bottom was left open to simulate a connection to the transportation chamber below, although the chamber itself was not modeled. The pollutant source, being generated by vehicle unloading, was simplified and located on a quarter of the silo's side wall. The air curtain's length matched the building's width, with an outlet width and height of 0.02 m × 0.02 m, and an air outlet width of

0.006 m. The models were placed in a computational domain with dimensions of 21H × 11H × 6H (length × width × height), where H denoted the height of the semi-open industrial building (Figure. 1(a)). The upstream and lateral boundaries of the computational domain were positioned 5H from the building, while the downstream boundary was set at 15H from the building's leeward wall. Three measurement lines (Lines A, B, and C) were set to capture pollutant concentration levels around the building, which is critical for assessing pollutant dispersion and evaluating the effectiveness of the air curtain in controlling pollutant spread (Figure. 1(b)).



(a) (b)

Figure 1. Detail model information of test cases: (a) computational domain and boundary conditions, (b) semi-open building model.

A total of 11scenarios were modelled, each incorporating different influencing parameters: air curtain jet velocity and air curtain jet angle. Detailed information on these scenarios is provided in Table 1.

Table 1 Detailed parameter setting information for 11 cases.

Case No.	Air curtain Jet velocity (m/s)	Air curtain Jet angle (°)	Change Parameters
1	\	\	Basic case
2	6	0	
3	8	0	
4	10	0	
5	12	0	Jet velocity
6	14	0	
7	16	0	
8	18	0	
9	12	5	
10	12	10	Jet angle
11	12	15	

2.3 BOUNDARY CONDITIONS

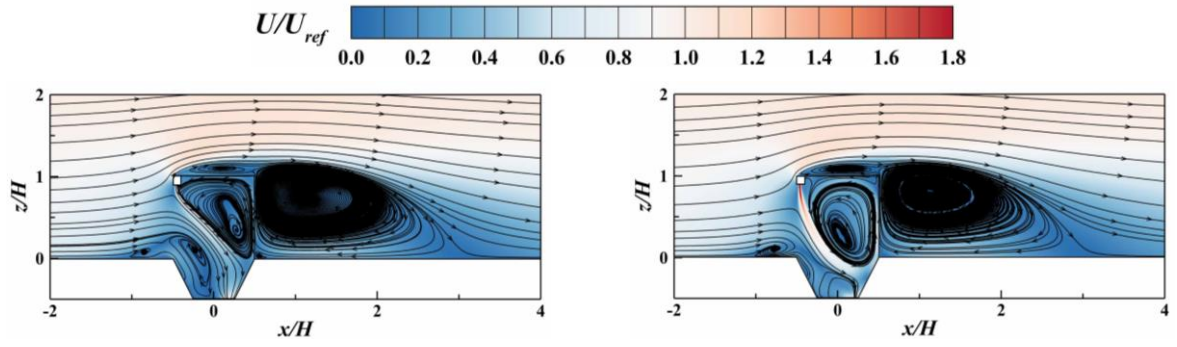
In the test cases, the inlet wind profile was described using a power-law equation: $u_z = u_{ref} \times (\frac{z}{z_{ref}})^{\alpha}$, where u_z was the mean wind velocity at height z (m/s), $u_{ref} = 4.5$ m/s was the

reference mean wind velocity at the building reference height z_{ref} = 0.2 m, and $\alpha = 0.1$ was the power-law exponent. The ground and building wall boundaries were specified as no-slip wall boundaries. Two near-wall treatment methods were used: enhanced wall treatment for grids with y+ values around 5, and the standard wall function for grids with y+ values above 35. The silo bottom opening and the computational domain outlet were set as pressure outlets, while the side and top boundaries were assigned symmetric boundary conditions, with a normal velocity of zero. Pollutant concentrations at different locations were scaled as the dimensionless concentration $K_c = \frac{c^* U_{ref}^* H^2}{C^* Q_l}$, where c was the pollutant concentration, U_{ref} was the reference mean wind velocity at the building height, H was the building height, C was the pollutant source concentration (1,000,000 ppm), and Q_l was the pollutant source release rate. Before further analysis of the simulated cases, the used turbulence model and numerical methods are compared with the wind tunnel experimental results (Yang et al.2019), which show the wind around the building, considering the interaction between the air curtain and outdoor wind. Slight differences are shown between the simulated and experimental results.

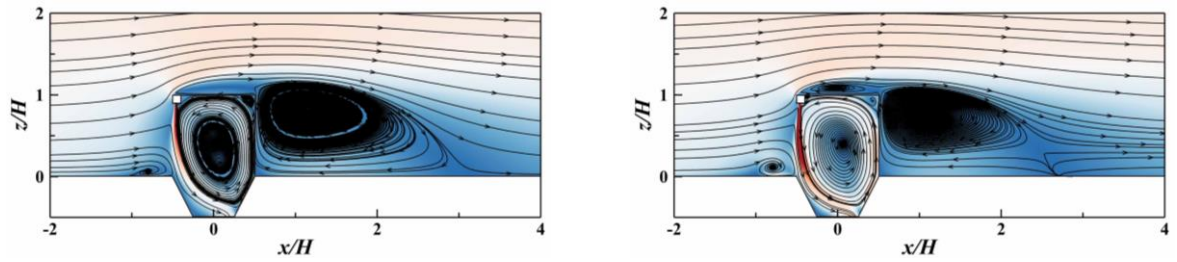
3. RESULTS

3.1 EFFECTS OF AIR CURTAIN JET VELOCITY

In Figure 2, both the dimensionless mean wind velocity and the time-averaged streamlines on the *x*-*z* plane are displayed for four distinct air curtain outlet velocities. The results reveal that as the air curtain velocity increases, the flow field distribution on the building's leeward side remains similar, with primary differences observed within the interior of the semi-open building. As shown in Figure 2(a), when the air curtain velocity is 6 m/s, the air curtain exhibits the weakest resistance to interference and cannot block the incoming flow. The air curtain airflow divides the interior space into two sections: an upper section with a counter clockwise vortex and a lower section with a smaller clockwise vortex. In Case 4 (Figure. 2(b)), when the air curtain velocity is increased to 10 m/s, the air curtain's resistance to interference improves somewhat, though it still does not fully prevent external airflow infiltration, and the vortex below the air curtain disappears. When the air curtain velocity increases from 10 m/s to 14 m/s (Figure. 2(c)), the velocity of the air curtain reaching the ground exceeds 5 m/s, enabling it to block most of the external airflow. Due to the Coanda effect, a large counter clockwise vortex forms inside the building. Further increasing the air curtain velocity to 18 m/s (Figure. 2(d)) does not produce significant changes in the internal flow field, though more airflow exits through the building's bottom opening.



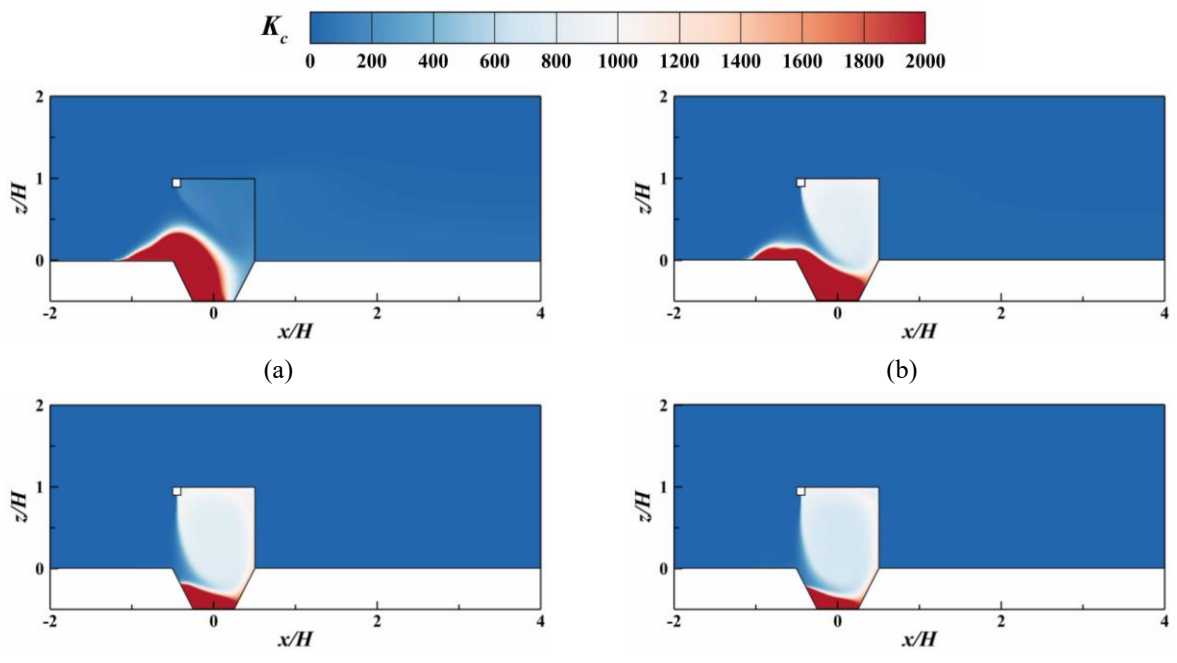
(a) (b)



(c) (d)

Figure 2. Normalized mean wind velocities of four typical jet velocities on the *x*-*z* plane at *y* = 0 for: (a) Case 2 (6 m/s), (b) Case 4 (10 m/s), (c) Case 6 (14 m/s) and (d) Case 8 (18 m/s).

Figure 3 displays the dimensionless mean concentration distribution contours on the *x*-*z* plane for four different air curtain outlet velocities. It is evident from the figure that the amount of pollutant escaping decreases as the air curtain velocity increases, indicating a negative correlation. Specifically, when the air curtain velocity is 6 m/s (Figure. 3(a)), high concentrations of pollutants still accumulate on the windward side of the building, promoting pollutant accumulation at the bottom of the silo. As the velocity increases to 10 m/s, the vertical dispersion of pollutants on the windward side of the building is significantly reduced, while the pollutant concentration within the building gradually extends to the roof level (Figure. 3(b)). Figure 3(c) illustrates the pollutant dispersion when the air curtain velocity is set to 14 m/s, where the air curtain effectively isolates the indoor and outdoor environments, with almost no pollutants diffusing outside through the building opening. When the velocity increases further to 18 m/s (Figure. 3(d)), the proportion of the high-concentration pollutant accumulation zone at the bottom of the silo continues to decrease, indicating that more pollutants are being directed toward the bottom opening and expelled by the air curtain.



(a) (b)

(c) (d)

Figure 3. Normalized pollutant concentration of four typical jet velocities on the *x*-*z* plane at *y* = 0 for: (a) Case 2

(6 m/s), (b) Case 4 (10 m/s), (c) Case 6 (14 m/s) and (d) Case 8 (18 m/s).

3.2 EFFECTS OF AIR CURTAIN JET ANGLE

The contours of the dimensionless mean concentration distribution on the *x*-*z* plane for air curtain velocities of 12 m/s (the intermediate jet velocity between the minimum and maximum values) and outlet angles of 5°, 10° and 15° (Case 9 – 11, Table 1) are illustrated in Figure 4. A comparison of the three cases reveals that all air curtain angles help to suppress pollutant dispersion. At an angle of 5° (Figure. 4(a)), the pollutant concentration inside the building is higher compared to 10° (Figure. 4(b)) and 15° (Figure. 4(c)), indicating that this setting does not direct most pollutants toward the bottom opening. Due to internal vortices, pollutants are contained within the building, circulating internally. When the angle increases to 10°, the airflow from the end of the air curtain aligns with the bottom opening of the silo, allowing some pollutants to exit through the opening and reducing the internal pollutant concentration. However, the air curtain with an angle of 15° fails to direct pollutants toward the bottom opening effectively, resulting in a slight increase in pollutant concentration within the building. Therefore, when the air curtain jet velocity is 12 m/s, the jet angle of 10° is a good choice to control pollutant effectively.

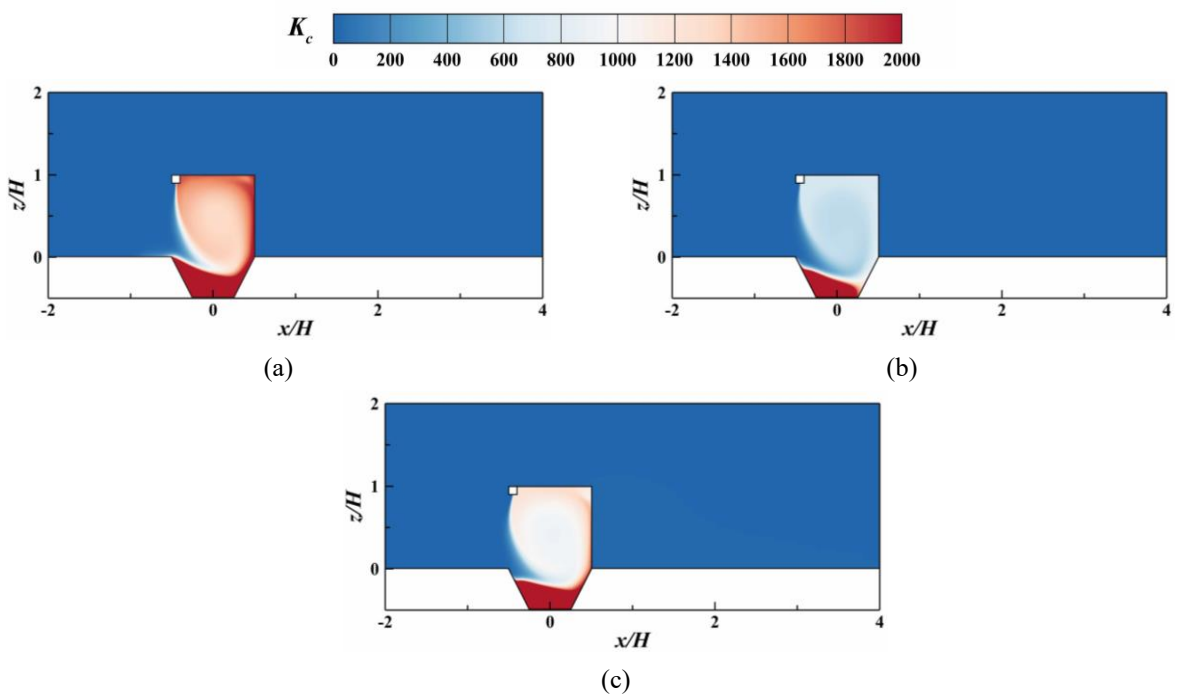


Figure 4. Normalized pollutant concentration of three jet angles on the *x*-*z* plane at $y = 0$ for: (a) Case 9 (5°), (b) Case 10 (10°) and (c) Case 11 (15°).

4.CONCLUSIONS

This study examined the effectiveness of air curtains in controlling pollutant dispersion during vehicle unloading in semi-open industrial buildings, and quantitatively assessed the influence of various air curtain parameters on the control performance. Based on the results presented in the previous analysis, the following conclusions can be drawn. Optimizing the air curtain's jet velocity and jet angle is crucial to its performance; however, this optimization effect can reach a saturation point. When the velocity exceeds a certain threshold (14 m/s) or the outlet angle exceeds a specific

range (10°), the control effect of the air curtain no longer significantly improves.

SUMMARY
Substantial waste heat generated by transportation and air-conditioning significantly increases urban temperatures, contributing to severe urban heat island effects. Although existing mitigation measures are limited, a novel smart-controlled Chilled Waterfall Wall (CWW), equipped with a heat pump, was developed to simultaneously reduce ambient temperature and humidity while filtering dust and particulate matter ($PM_{2.5}$). The system was pilot-tested within a practical prototype in the laboratory. In addition, it was integrated with a vegetative wall irrigated by cascading water, creating smaller, distributed cooling nodes strategically positioned throughout the urban area. A Building Integrated Photovoltaic (BIPV) folding panel installed atop the bus shelter captures solar energy, providing additional electrical support while maximizing natural daylight. The lower section of this panel includes a rainwater harvesting inlet, which collects rainwater after dust filtration and UV sterilization, storing the purified water in two insulated tanks beneath the bus shelter. Despite its effectiveness, the initial tests revealed notable challenges including water evaporation loss and biofilm maintenance concerns within the recycling system. A prototype measuring 1 m × 1 m × 2.1 m was constructed in a controlled environmental chamber to evaluate performance metrics. Results demonstrated that flow rates between 300 L/hr and 500 L/hr achieved an average temperature reduction of 4.2°C and a humidity reduction from 75% to 60% within 30 minutes. Furthermore, $PM_{2.5}$ concentration dropped significantly from 120 μg/m³ to 60 μg/m³, effectively halving airborne dust concentration compared to untreated control scenarios. Future studies will concentrate on enhancing water circulation efficiency and exploring durable photovoltaic materials suited for diverse climatic regions, further optimizing this innovative urban cooling technology

1. GENERAL INSTRUCTIONS

Waste heat emissions from urban traffic and air-conditioning systems, along with impermeable pavements, contribute significantly to the urban heat island effect (UHIE) and deteriorating air quality. During scorching summers, the frequent occurrence of heatstroke or dizziness among citizens waiting at bus stops has become a critical issue in tropical and subtropical metropolitan areas. To address this challenge, the Chilled Waterfall Wall (CWW) integrated with a water-source heat pump has been developed (Lee, 2023a). The CWW employs chilled water to create a waterfall that effectively reduces ambient temperature. Additionally, since the temperature of the chilled water is below the dew point, the CWW simultaneously removes moisture from the air, providing dehumidification. Furthermore, due to thermodynamic principles, hot air carrying particle matters naturally moves toward the cooler waterfall, where the particle matters are captured and flushed

down, thereby purifying the air. The captured particle matter is subsequently filtered, and the recycled chilled water is sterilized by UV light, ensuring continuous water quality within the system.

As the urban heat island effect (UHIE) becomes increasingly severe in tropical and subtropical metropolitan regions, the construction of large-scale infrastructure to reduce urban temperatures requires substantial financial investment. However, by connecting smaller cooling nodes dispersed through bus shelters in an urban area, it becomes possible to significantly improve the local microclimate, mitigating the urban heat island effect, air pollution, and sudden urban flooding by collecting and distributing heavy rainfall. This decentralized approach offers promising potential for the development of sustainable cities (Figure 1, Lee, 2023b). The design concept for integrating the Chilled Waterfall Wall (CWW) system with bus shelters has been developed and is illustrated in Figure 2 (Lee, 2023c). This study demonstrates the effectiveness of the CWW-integrated bus shelter system by highlighting its capacity for cooling, dehumidification, and dust removal.

Figure 1. Connect bus stops to solve troubles

Figure 2. The design concept for integrating the CWW system with bus shelters

2. PROTOTYPE TEST

The prototype was experimentally tested under four different flow conditions (no water flow, 300 liters/hour, 500 liters/hour, and 700 liters/hour) in a laboratory setting to evaluate optimal performance for controlling hygrothermal conditions and air quality in hot and humid environments. A Chilled Waterfall Wall (CWW) was installed on a surface measuring 1.00 m × 1.60 m, supplied with chilled water maintained at approximately 8–9°C by a water-source heat pump to reduce overall energy consumption, as illustrated in Figure 3. For experimental measurements, a closed, insulated test chamber with dimensions of 1 m (length) × 1 m (width) × 2.1 m (height) was established to examine the CWW's performance at varying water flow rates, as depicted in Figure 4.

The measure sensors were setup in the both sides of heat pump to measure the chilled water (T_{cw}) and heated water temperature (T_{Hw}), the water temperature in the sink (the bottom) of CWW (T_w), chilled water flow rate (Q_{cw}), heated water flow rate (Q_{Hw}), the chilled water pressure (P_{cw}), and heated water pressure (P_{Hw}). All sensors were connected to data logger to evaluate the efficiency of water flow rate between CWW and heat pump. Three different heights of measured points in 0.6m,1.1m, and 1.7m at 0.5m far from CWW for the air temperature and relative humidity referred by ASHRAE Standard 55 (ASHRAE, 2013). The particulate matter in diameter 2.5μm ($PM_{2.5}$) was measured by TSI Quest EVM-7 for air quality. A heat source (heater), a humidifier, and ten burning incenses were setup to check the performance at cooling, dehumidify, and the air cleaning

for testing the performance of CWW.

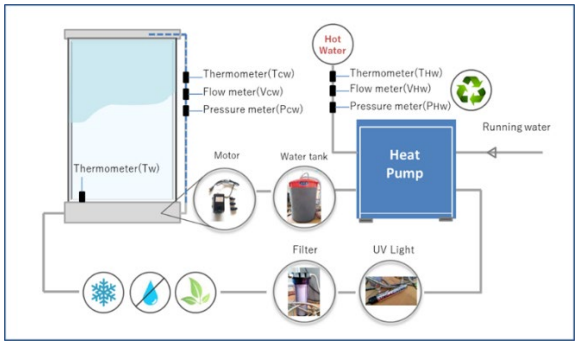

Figure 3. CWW as an air conditioner, air cleaner, dehumidifier and water heater with a heat pump

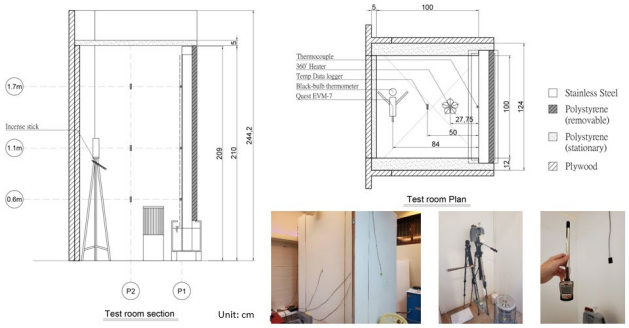

Figure 4. The experiment design scheme and the sensors setup in the test chamber

3. RESULTS AND DISCUSSION

As shown in Figure 5, the air temperature measured at a height of 1.1 m with a water flow rate of 300 L/hr demonstrated superior performance compared to other conditions, providing a similar cooling effect while consuming less energy in hot climates. Furthermore, as depicted in Figure 6, the chilled water temperature consistently decreased, stabilizing at approximately 16°C. This resulted in a significant ambient temperature reduction ranging from 6°C to 8°C.

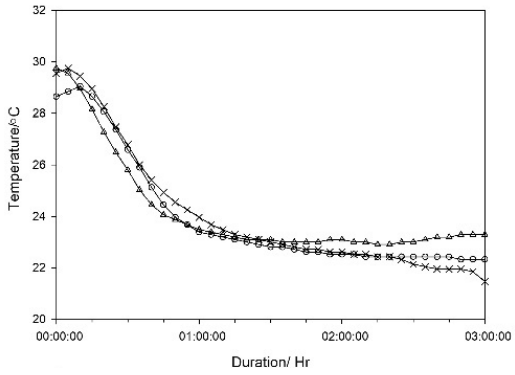

Figure 5. The ambient temperature various

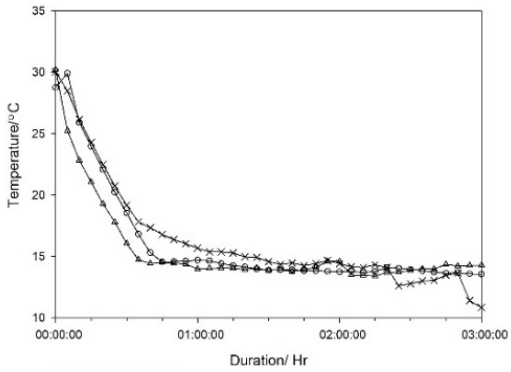

Figure 6. The chilled water temperature various

A humidifier vapored 100 ml moisture into the test chamber for 2 hours then turned on the heat pump for waterfall flowing on the CWW (marked as red line), the measured results in different height as shown in Figure 7. It presented the damp was slowly increasing in the begin 2 hours, the humidity was dropped when the chilled waterfall staring. However, the moisture still went up when the chilled water falling around the flow rate at 300 l/hour. The reason would be the chilled water suddenly raised the temperature to increase the ambient temperature and it could absorb more damp till the saturation.

The efficiency of particulate matter removal at different water flow rates was tested by burning a consistent quantity of incense inside the chamber, fully consumed in approximately 50 minutes. As shown in Figure 8, the concentration of PM2.5 (initially around 120 μg/m³) decreased more rapidly when the CWW was operational compared to when it was inactive.

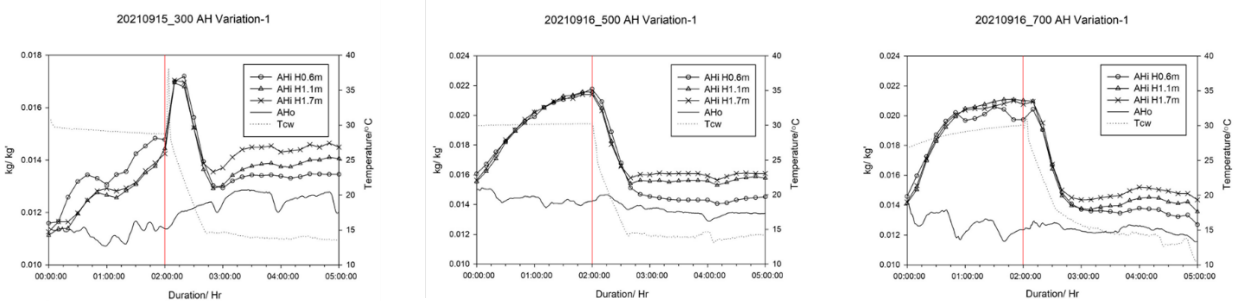

Figure 7. The dehumidify efficiency in each test

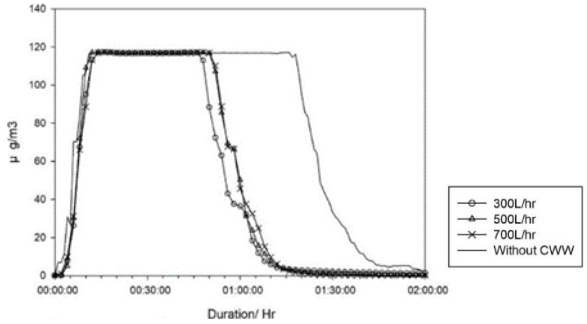

Figure 8. The concentration reduction of in each test

Overall, these test results clearly demonstrate the effectiveness of the CWW in cooling, dehumidifying, and removing airborne particulates. Integrating the CWW system into the design of bus shelters can effectively mitigate the urban heat island effect and improve air quality by efficiently removing airborne dust.

4. CONCLUSION

The test results confirmed that the CWW has effective performance in cooling, dehumidifying, and dust removal. Additionally, the use of a water-source heat pump enhances energy efficiency, enabling successful integration of the CWW with bus shelters. Besides the integrated design considerations, the control of water flow and the efficiency of the heat pump are crucial factors. Incorporating a solar-assisted heat pump system in the future could further improve energy savings.

SUMMARY
Maintaining indoor air quality in shared spaces requires understanding how ventilation, air purification, and human presence influence aerosol concentrations and CO_2 levels. This study examined these factors in a graduate student office (volume = 31.2 m³) across controlled scenarios with and without ventilation and air purification. Results show that occupancy led to a sharp increase in both $PM_{2.5}$ and CO_2, with the most pronounced rise occurring when ventilation was off. Ventilation effectively reduced CO_2 levels but introduced outdoor particles, leading to higher $PM_{2.5}$ concentrations compared to air purification alone. The air purifier significantly lowered aerosol concentrations, particularly for the smallest particles. Size distribution analysis confirmed a bimodal pattern, with a secondary peak around 2.5 µm when occupants were present. These findings reinforce the importance of combining ventilation and air purification, as filtration alone provided the most effective aerosol reduction while ventilation was essential for CO_2 removal.

Keywords: Indoor Air Quality, Aerosol Size Distribution, Ventilation, Air Purifying

1. INTRODUCTION

Indoor air quality (IAQ) is a key factor in maintaining the health and productivity of individuals working in shared spaces such as graduate student offices. Fine aerosols like $PM_{2.5}$ and gases such as carbon dioxide (CO_2) serve as important indicators of IAQ because they reflect both human activity and the effectiveness of ventilation systems. Previous research has shown that the presence of occupants can significantly influence aerosol levels through both direct respiratory emissions and the resuspension of settled particles (Chatoutsidou et al., 2015; Hussein et al., 2006). These processes can lead to fluctuations in particle levels throughout the day, affecting both air quality and exposure risks.

Understanding aerosol size distribution is as important as measuring their overall concentration. Smaller particles (particulate matter $PM_{0.1}$–PM_1) can stay suspended in the air for long periods and penetrate deep into the lungs, while larger ones ($PM_{2.5}$–PM_{10}) settle faster but can still contribute to indoor exposure. Indoor environments often show a bimodal size distribution, with one peak in the submicron range another at larger sizes due to resuspension from surfaces and occupant movement (Ogulei et al., 2006). Recognizing these patterns helps in designing better strategies to control exposure.

Effective IAQ management typically relies on a combination of mechanical ventilation and air purification. While ventilation is essential for maintaining acceptable CO_2 levels and reducing

airborne particles, in some cases, it can also introduce outdoor pollutants or fail to eliminate fine aerosols effectively (Felgueiras et al., 2022). Air purifiers equipped with high-efficiency particulate air (HEPA) filters can efficiently reduce particle concentrations but do not lower CO_2 levels, which are more directly linked to occupancy and air exchange rates (Aldekheel et al., 2022). This means that a combination of strategies is often necessary to maintain good air quality in occupied spaces.

This study investigates how ventilation rates, air purification, mask usage, and occupancy affect aerosol concentrations and size distributions in a graduate student office. By analysing $PM_{2.5}$ and CO_2 trends across different scenarios, this study aims to examine how these factors shape IAQ in real-world conditions.

2. METHODOLOGY

2.1. Experimental Setup

The study was conducted in a graduate student office at Burnside Hall, McGill University, with a volume of 31.2 m³ (4.3 m × 2.9 m × 2.5 m). The room was equipped with a displacement ventilation system, where air was supplied through floor vents and exhausted through ceiling outlets, providing an air change rate (ACH) of 8.1 h^{-1}. An air purifier with HEPA filtration was also used, operating at 7.0 h^{-1}.

Four graduate students participated, each submitting consent forms approved by the McGill University Ethics Committee. Experimental conditions varied based on ventilation status (on/off), air purifier usage (on/off), mask-wearing, and occupancy level (participants present or absent). Each scenario lasted 30 minutes, ensuring sufficient time to observe aerosol trends under different conditions. Aerosol concentrations were measured using a GRIMM 11D aerosol spectrometer, positioned centrally in the room to capture most representative values, while CO_2 levels were recorded using a TSI AirAssure 8144-6 sensor. Figure 1 illustrates the experiment setup and measurement configuration within the office space.

2.2. Data Analysis

Aerosol concentrations were continuously recorded at 6 s intervals using the GRIMM 11D spectrometer, with $PM_{2.5}$ and number concentrations extracted for analysis. Environmental parameters, including CO_2 concentrations, were measured every 1 minute using the TSI AirAssure 8144-6 sensor. To remove short-term fluctuations and retain long-term trends, a low-pass Butterworth filter was applied to both datasets.

For aerosol data, a cutoff frequency of 0.11 cycles per minute was selected, meaning variations occurring over periods shorter than ~9.1 minutes were filtered out. Given the 6 s sampling interval, this ensured that only gradual changes in $PM_{2.5}$ concentrations were retained, removing high-frequency noise. Similarly, for environmental data, a cutoff frequency of 0.23 cycles per minute was used, filtering out fluctuations shorter than ~4.35 minutes. Since CO_2 concentrations were recorded every 1 minute, this filtering method preserved meaningful long-term variations while eliminating transient fluctuations.

In addition to total $PM_{2.5}$ concentrations, aerosol size distributions were analysed across 31 size

bins ranging from 0.253 to 35.15 µm. By comparing size-resolved aerosol concentrations under different experimental conditions, we evaluated how ventilation, air purification, and mask usage influenced the distribution of fine and coarse particles in the indoor environment.

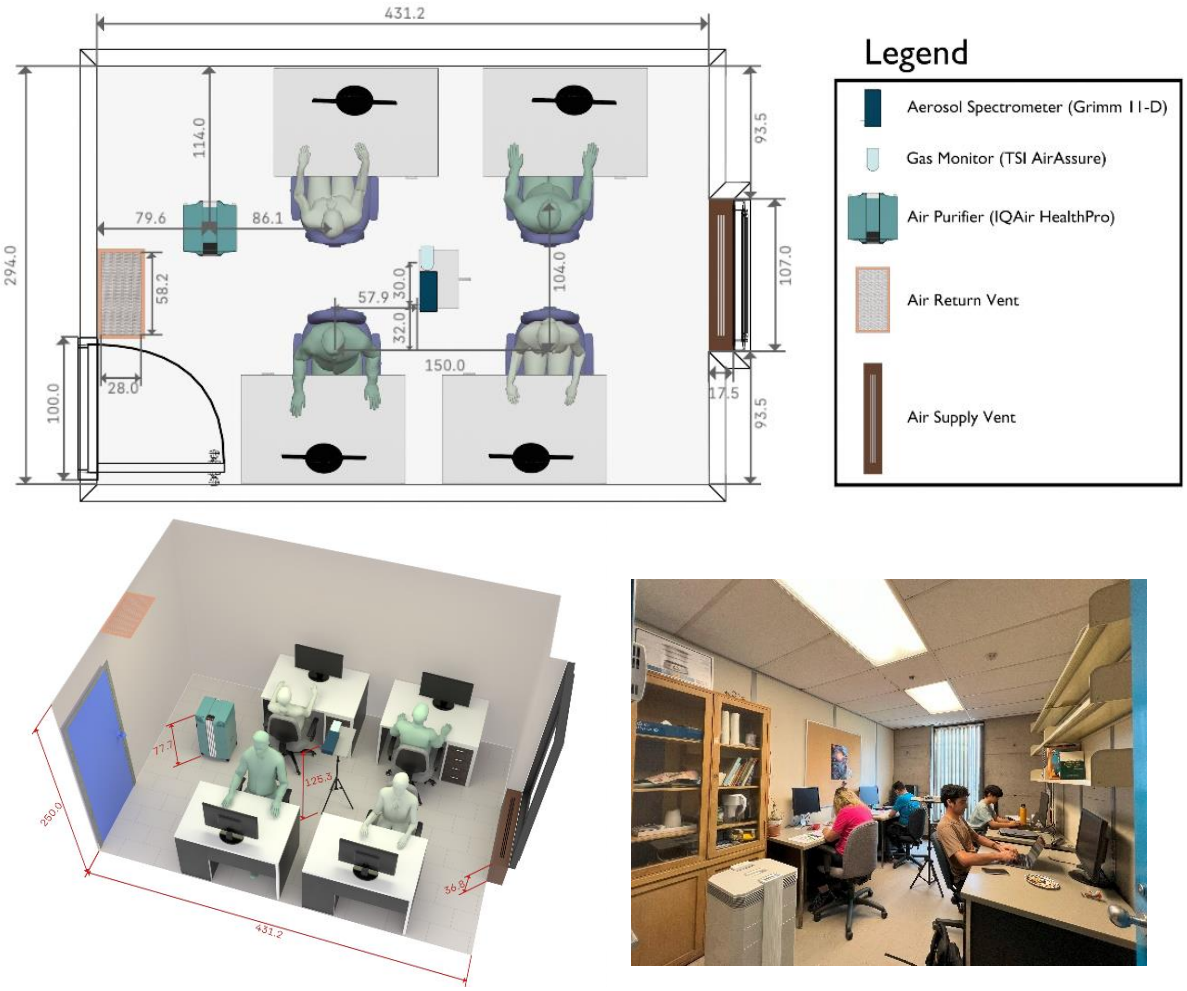

Figure 1. a) Experimental setup and plan view, b) sideview of the office and c) a photograph of the experiment. Dimensions are in cm.

3. RESULTS

3.1. Trends in $PM_{2.5}$ and CO_2 Concentrations

Figure 2 shows the temporal variation of $PM_{2.5}$ (top) and CO_2 (bottom) concentrations across different occupancy and mask conditions. The small spikes at the start of each segment correspond to door openings and closings, so the analysis focuses on the remaining 25 minutes of each period. During the initial unoccupied phase (red shading), both $PM_{2.5}$ and CO_2 remain stable, with CO_2 at approximately 450 ppm and $PM_{2.5}$ around 0.6 $\mu g/m^3$, representing background levels with minimal indoor sources.

When occupants enter without masks (green shading), both CO_2 and $PM_{2.5}$ begin to increase. CO_2 rises gradually due to respiration, reaching approximately 800 ppm in ventilated conditions and exceeding 1600 ppm when ventilation is off. $PM_{2.5}$ also increases, surpassing 1 $\mu g/m^3$ in the absence of ventilation, indicating a combination of respiratory emissions and resuspension of particles from activity in the room. The lower slope observed when masks are worn (blue shading) suggests that respiratory emissions play a significant role in aerosol accumulation.

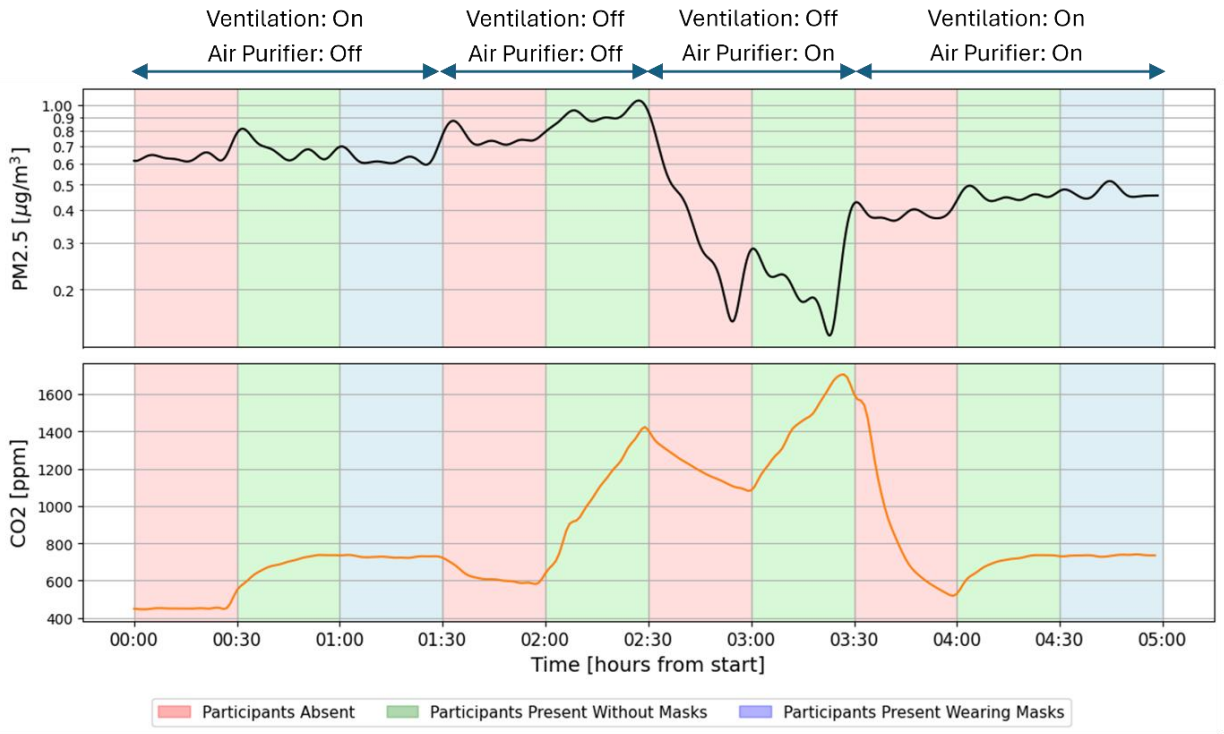

Figure 2. $PM_{2.5}$ ($\mu g/m^3$) and CO_2 (ppm) concentrations over time since the start of the experiment. The $PM_{2.5}$ scale is logarithmic. Periods when the ventilation and air purifier were on or off are indicated at the top of the figure. Occupancy is represented by colored highlights for each 30-minute period.

The air purifier significantly reduces $PM_{2.5}$ concentrations, bringing them below 0.2 $\mu g/m^3$. However, it does not affect CO_2 levels, emphasizing that filtration removes aerosols but does not affect exhaled gases. Notably, even when occupants remain in the room, the purifier lowers $PM_{2.5}$ although some particles persist.

A key observation is the effect of reintroducing ventilation after the air has been purified. While CO_2 concentrations return to background levels within approximately 30 minutes, $PM_{2.5}$ increases again, stabilizing around 0.45 $\mu g/m^3$, higher than with the purifier alone but lower than with ventilation alone. This pattern suggests that outdoor air introduces additional particles while simultaneously diluting CO_2. The results highlight the complementary roles of ventilation and air purification in controlling indoor air quality, with air purifiers more effective at reducing aerosols and ventilation critical for controlling CO_2 buildup.

3.2. Aerosol Size Distributions Across Different Scenarios

Figure 3 presents two heatmaps showing the temporal evolution of aerosol size distribution throughout the experiment based on number concentration (bottom) and mass concentration (top). These heatmaps highlight different aspects of aerosol dynamics: the number-based distribution (d*N*/dlog*D*) emphasizes smaller particles, which dominate in count but contribute less to total mass, whereas the mass-based distribution (d*M*/dlog*D*) reflects the greater influence of larger particles, which, despite being fewer, account for most of the particulate mass.

During the initial unoccupied period, both distributions remain relatively stable, with low concentrations across all size ranges. Once participants enter without masks, a gradual increase in particle concentrations is observed, particularly in the larger size range (>2.5 µm) in both the number-based and mass-based plots. This suggests that resuspension from movement is a primary contributor to coarse particle generation, rather than direct respiratory emissions. The buildup is more pronounced when ventilation is turned off, where accumulation occurs across the entire size spectrum, indicating reduced particle removal efficiency in the absence of air exchange.

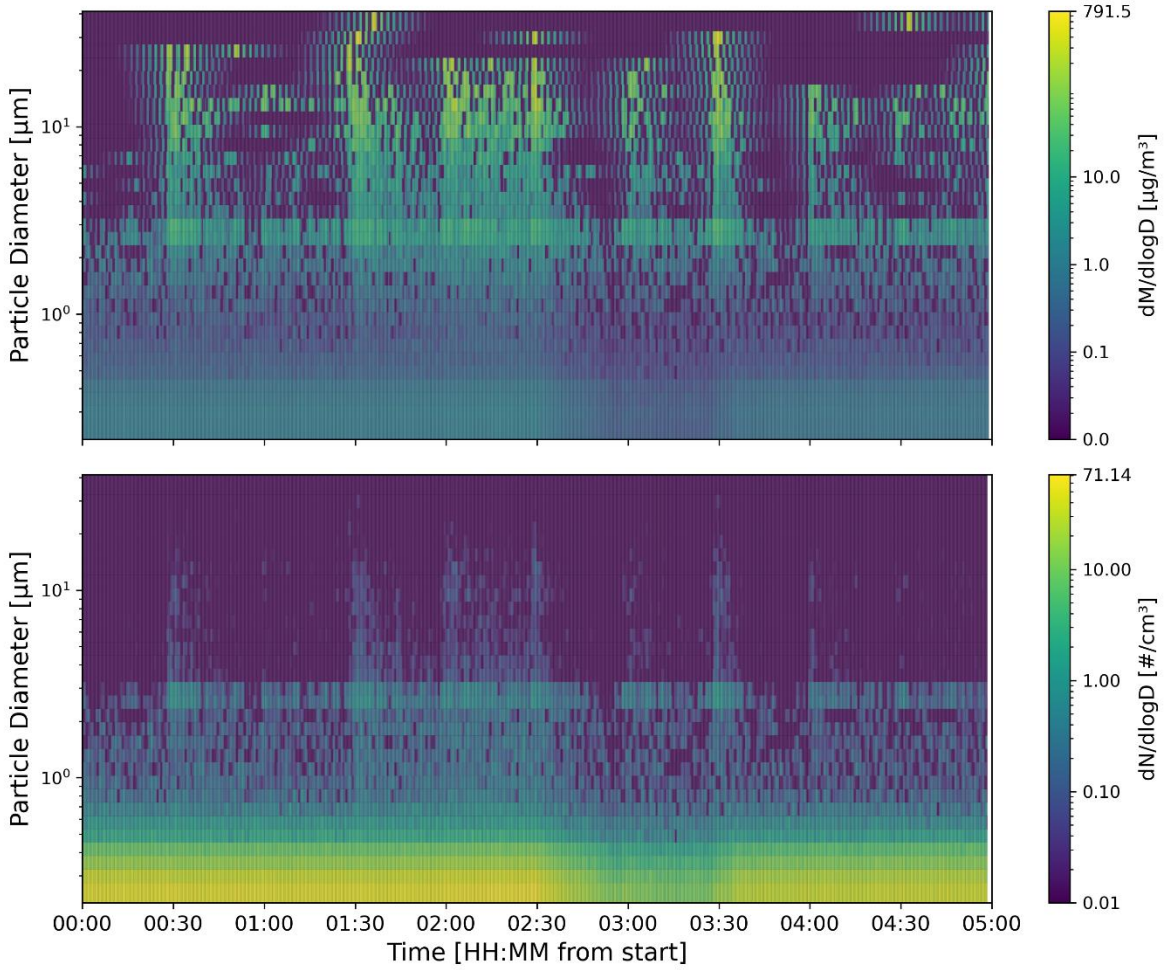

Figure 3. Temporal evolution of aerosol size distribution throughout the experiment in terms of (top) mass concentration (d*M*/dlog*D*) and (bottom) number concentration (d*N*/dlog*D*). The y-axis represents particle diameter (µm), divided into 31 logarithmically spaced bins ranging from 0.253 to 35.15 µm. Warmer colors indicate higher values.

When the air purifier is activated, a significant reduction in particle concentrations is observed across all sizes, but the effect is particularly strong in the submicron range. This suggests that HEPA filtration effectively removes finer particles, which remain airborne for longer periods, while larger particles settle more rapidly. After air purification, reintroducing ventilation leads to an increase in particle levels. This suggests that outdoor air intake is a source of additional particles, particularly in the smallest particle diameter range, counteracting the air purifier's effect.

A consistent feature throughout the experiment is the presence of a bimodal size distribution, with a primary peak in the submicron range and a secondary peak around 2.5 µm. These peaks are more pronounced in scenarios where occupants were present, reinforcing the role of human activity in shaping indoor aerosol dynamics. The persistence of these modes indicates that respiratory emissions primarily contribute to the finer fraction, while resuspension and environmental factors drive the coarser mode.

To better assess the impact of ventilation and air purification on aerosol size distribution, four specific scenarios were chosen, each representing different air controlling conditions while participants were present and unmasked, as shown in Figure 4. These scenarios were selected to isolate the effects of ventilation and air filtration separately, as well as in combination, and to compare them against a background condition where no participants were present. Size distributions were plotted based on the averaged data over the 25-minute period of each scenario.

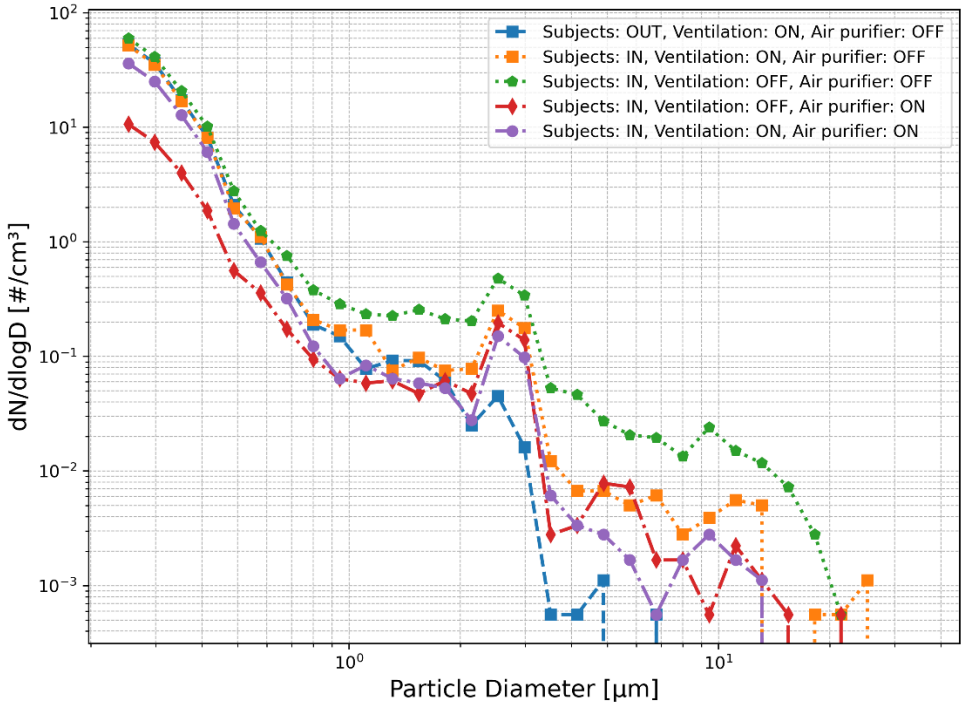

Figure 4. Number-based aerosol size distribution averaged over 25 minutes for five scenarios. The x-axis represents particle diameter (µm) on a logarithmic scale, and the y-axis shows dN/dlog$D$ on logarithmic scale.

The background scenario (blue line) serves as a reference, representing the particle concentrations when the room was unoccupied and the ventilation was on. The scenario where participants were

present with both ventilation and the air purifier turned off (green line) captures the maximum aerosol accumulation, as no removal mechanisms were active, allowing both respiratory emissions and resuspended particles to build up. The ventilation-only condition (orange line) isolates the effect of ventilation air exchange, showing how mechanical airflow influences particle removal without additional filtration. The air purifier-only scenario (red line) examines the impact of HEPA filtration without the potential particle influx from outdoor air. Finally, the combined ventilation and air purifier scenario (purple line) demonstrates the interaction between these two mitigation strategies.

A clear peak around 2.5 μm is present across all conditions with participants, while it is much less pronounced in the background scenario, highlighting that this size range is associated with human activity. The air purifier shows a strong effect in reducing submicron particles, while for particles larger than 1 μm, its performance aligns closely with the ventilation-only and combined scenarios. The green line, which represents the scenario where both air purifier and ventilation were off, consistently shows the highest particle concentrations at all sizes, particularly in the larger size range. This confirms that without ventilation or purification, aerosols build up and remain in the indoor environment, while using either strategy effectively reduces larger particles. These scenarios offer a clear comparison of the impact of different mitigation strategies.

4. Conclusions

This study demonstrates how occupancy, ventilation, and air purification influence aerosol concentrations and CO_2 levels in an indoor environment. $PM_{2.5}$ and CO_2 both increase with human presence, though their behaviours differ. CO_2 rises steadily due to exhalation, while $PM_{2.5}$ levels fluctuate more sharply, particularly when ventilation is off. The impact of masks is evident in reducing aerosol concentrations but does not affect CO_2. Air purification is highly effective at lowering aerosol levels, particularly for submicron particles, yet has no influence on CO_2. Notably, reintroducing ventilation after air purification results in a slight increase in $PM_{2.5}$ concentrations, likely due to outdoor air intake.

The size distribution analysis provides further insights into aerosol behaviour under different conditions. The bimodal nature of the distribution is consistent across scenarios, with a primary peak in the submicron range and a secondary peak around 2.5 μm, which appears in occupied periods. This suggests that fine aerosols originate primarily from respiratory emissions, while the larger peak likely results from resuspension and coarse respiratory droplets. The air purifier effectively reduces particle concentrations across all sizes but has the most pronounced effect on smaller aerosols. Ventilation plays a more complex role, effectively diluting CO_2 but also capable of introducing outdoor particle.

These results emphasize the importance of a balanced approach to indoor air quality management. Ventilation and air purification each address different aspects of air quality, and their combined use, along with wearing masks, provides the most effective strategy for minimizing harmful indoor air effects. Future research should explore how these mitigation strategies interact in indoor environments with varying ventilation rates and occupancy patterns.

SUMMARY
A key challenge in optimal performance-based design of ventilation systems is the need to accurately assess its performance under varying conditions, such as fluctuating weather patterns, occupancy behaviour, and the layout of the dwelling. Achieving this requires numerous evaluations, which are computationally unfeasible with traditional simulation-based methods.
This study addresses this challenge by exploring methods to reduce the computational load, specifically focusing on filtering and compressing input data using Fast Fourier Transform (FFT) analysis.
Typical input variables for building simulation models can be approximated using a limited set of frequencies, or by a distribution of discrete events. This principle is demonstrated using dry-bulb air temperature as a case study. By identifying and isolating dominant frequencies, the proposed method simplifies weather input data, thereby reducing simulation time while preserving the complexity of the underlying white-box building model. The approach increases simulation speed while maintaining appropriate accuracy in system performance evaluations.

Keywords: simulation, performance assessment, Fast Fourier Transform (FFT), indoor air quality

1. INTRODUCTION

This research is conducted within the framework of the NudgeFlow project, which aims to develop a decentralized ventilation system that leverages natural airflow within dwellings. By dynamically optimizing airflow patterns in response to real-time ventilation needs and environmental factors (e.g., wind, temperature gradients, and outdoor pollutants), the NudgeFlow system aims to minimize mechanical energy use. This represents a departure from conventional prescriptive ventilation designs, aligning with a global shift toward performance-based design methodologies.

This paradigm shift is evident in initiatives like the harm-based indoor air quality (IAQ) procedure proposed as an alternative compliance method for ASHRAE Standard 62.2, as well as the anticipated updates in European ventilation design standards (e.g., EN 16798-1-3 and EN 15665).

The primary challenge in developing performance-based ventilation systems, including the NudgeFlow system, lies in evaluating performance under variable conditions such as fluctuating weather patterns, diverse occupancy behaviours, and varied dwelling layouts. Performance-based workflows necessitate iterative assessments.

Traditionally the performance is assessed using Monte Carlo sensitivity analyses. It relies on running multi-zone airflow simulations, using an extensive number of fixed weather and occupancy profiles (Laverge et al., 2011). While effective for evaluating individual ventilation configurations, this approach is computationally intensive, requiring supercomputers to manage the high volume of variations involved. As a result, it is impractical for use in design optimization workflows. The main challenges include the lengthy computation times required for dynamic building simulations and the vast number of simulations necessary to achieve performance convergence.

Existing strategies to reduce computational loads have included optimizing solver choices, streamlining model structures, and minimizing events (Jorissen et al., 2018; Tiller, 2001). However, these approaches focus primarily on the simulation process itself. This paper takes a different approach by simplifying input signals, specifically weather data, to improve computational efficiency.

This study explores the application of Fourier Transform (FT) techniques to compress weather input data, with two primary objectives:

1. Signal Reconstruction: Using FT to reconstruct continuous input signals that minimize simulation events in variable timestep solvers, such as those used in Dymola (Modelica).
2. Frequency Filtering: Identifying and retaining dominant frequencies in weather patterns to streamline signal reconstruction while preserving the dominant dynamics of the input data.

2. METHODOLOGY

As a first step this research transforms the dry-bulb air temperature to the frequency domain. Since this data is commonly represented using time series without discrete changes, it is well suited for performing a discrete Fourier transform (DFT).

The accuracy and speed of simulations using the simplified signal input for the dry bulb temperature will be tested using Modelica in Dymola. The preprocessing of the weather data is done in python using the NumPy package. The results are then integrated into a Modelica model and tested using existing building models.

2.1. Weather data analysis with FFT

The Fast Fourier Transform (FFT) is an efficient algorithm to perform the Discrete Fourier Transform (DFT), that translates a finite sequence of data samples, in this case the dry-bulb air temperature measurements, into the frequency domain, using Equation 1. This transformation represents the original signal as a sum of sine and cosine waves, each with a specific frequency, amplitude, and phase.

$$F_k = \sum_{n=0}^{N-1} \left(f_n \cdot e^{-i2\pi \frac{k}{N} n} \right) \quad (1)$$

When applied to real-valued data, the FFT yields a series of complex coefficients that encode both amplitude and the phase of each frequency component. These complex numbers F_k, can be

decomposed into their real and imaginary parts as shown in Equation 2.

$$F_k = \mathrm{Re}(F_k) + \ Im(F_k) \tag{2}$$

Using the preprogrammed FFT function of NumPy, gives insight into the dominant frequencies present in the dry-bulb temperature. When assessing the power spectrum of the dry-bulb temperature of a typical meteorological year (TMY) for Brussels 2001-2020, two main frequencies stand out: 3.17E-8 Hz and 1.16E-5 Hz. These correspond to periodicities of one year and one day, respectively (Figure 1), reflecting the expected variations in outdoor air temperature.

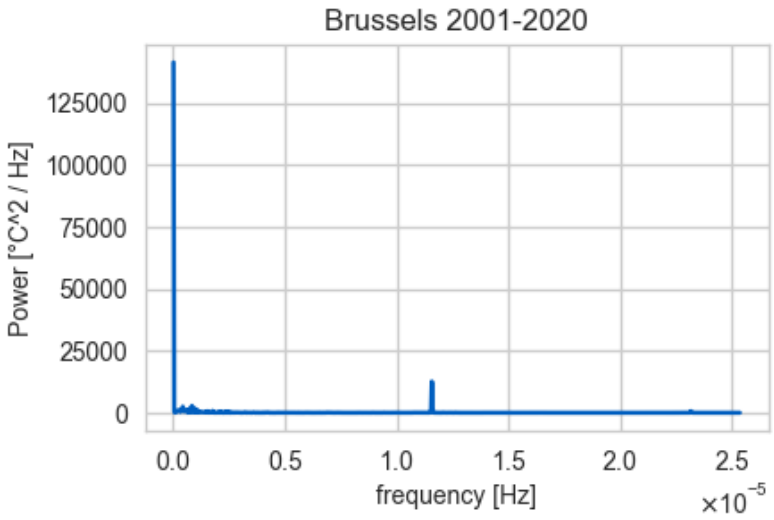

Figure 1 Power spectrum of dry-bulb temperature from TMY Brussels 2001-2020

A new model was developed in Modelica to reconstruct the temperature signal from the output of the FFT. This model reads the complex FFT output and uses it to reconstruct the original time-domain temperature signal based on Equation 3. Euler's formula (Equation 4) is applied to express the complex exponential terms as a sum of sines and cosines (Equation 5). This approach enables the generation of a continuous approximation of the original temperature time series, with the flexibility to incorporate a variable number of frequency components.

$$f_n = \frac{1}{N}\sum_{k=0}^{N-1}\left(F_k \cdot \ e^{i2\pi \frac{k}{T} n}\right) \tag{3}$$

$$e^{i\theta} = \cos\theta \ + i\sin\theta \tag{4}$$

$$f_n = \frac{1}{N}\cdot \sum_{k=0}^{N-1}(\mathrm{Re}(F_k) \ \cdot \cos(\frac{2\pi kn}{N}) \ - \ Im(F_k) \ \cdot \sin(\frac{2\pi kn}{N})) \tag{5}$$

2.2. Preliminary Impact on Simulation Speed and Accuracy

The proposed method was evaluated on six typical meteorological years (TMY) for two locations in Belgium: Brussels and Ghent. These TMYs were assembled in the context of the IEA EBC Annex 80, following the ISO EN 15927-4 standard (Machard et al., 2024). For each of the cities there are three TMY files spanning different time periods. The period 2001-2020 represents historical measured data while the periods 2041-2060 and 2081-2100 represent future climates under the Representative Concentration Pathway (RCP) 8.5.

The choice for TMY format weather data was made, as it aligns well with the IDEAS Modelica library, preventing the need to add additional information or extensive transformations on the file format. Secondly, in the generation of TMY files, the dry-bulb air temperature is considered as a primary parameter, as opposed to e.g. wind speed.

The dry-bulb temperature is reconstructed by progressively adding frequencies, starting with the one with the highest spectral power and sequentially including those with the next largest spectral powers in descending order. The Root Mean Square Error (RMSE) of each reconstructed signal follows a logarithmic relationship with the number of included frequencies.

The simulation speed of signal reconstruction is compared to reading the dry-bulb temperature time series using the 'CombiTimeTable' block from the Modelica Standard Library, which mimics how weather data is typically processed in an IDEAS simulation. The results show a reduction in CPU time for the reconstructed signal when using up to 86–100 frequencies. However, adding more frequencies slows down the simulation speed beyond the reference time series approach.

3. CASE: TWIN HOUSES

3.1. Model Description

The Twin Houses model, part of the IDEAS library, is used to test the impact of the proposed method. This model is based on the Twin House experiment conducted as part of the IEA EBC Annex 58 project (Strachan et al., 2016) and has been validated against experimental measurements. Additionally, the Twin Houses model was chosen because it has been extensively tested for validating the accuracy of the IDEAS library (Jorissen et al., 2018).

The experimental setup and corresponding model implementation follow a structured sequence. Initially, the indoor temperature is stabilized at a constant 30°C. This is followed by a phase in which a pseudo-random sequence of heat injections is applied. Subsequently, the system is re-initialized by restoring a stable indoor temperature. Finally, the experiment concludes with a free-floating period, allowing the building to cool down naturally without external interventions.

The model consists of seven thermal zones: the living room, corridor, bathroom, bedroom, kitchen, doorway, and parent bedroom. Each zone incorporates detailed representations of thermal and airflow dynamics, making it well-suited for evaluating ventilation system performance.

To enhance the applicability of this method for assessing ventilation system performance, a minor modification was made to the original model. Specifically, the supply air temperature was directly

linked to outdoor temperature profiles. In the initial configuration, the ventilation model used measured air temperatures for the ventilation air, while the rest of the model relied on a weather file. This adjustment created a more consistent approach to weather data integration, enabling a more accurate evaluation of the impact of simplified weather input data on indoor temperature conditions.

3.2.Testing Process

For the simulations, weather data is sourced from the six TMY files described above, with the option to substitute the dry-bulb temperature with a reconstructed signal using FFT. The number of frequencies that are included in the reconstructed signal varies between 2 and the maximum of 4380 on a logarithmic scale, as the initial testing showed drastic improvement in accuracy for the first additional frequencies. The simulations run using the original TMY input for the dry-bulb temperature are used to benchmark the accuracy and simulation speed of the simulations using the FFT-based reconstructions.

Experiment 1, building 1 is simulated from day 213 to day 297, encompassing all phases of the experimental setup: initialization, heating, re-initialization, and free-floating. The built-in Dassl solver was used with the standard 0.0001 tolerance (Petzold, 1982). The initial 14 days serve as an initialisation period for the simulation. During the heating and free-floating phases, the Root Mean Square Error (RMSE) and Mean Bias Error (MBE) are evaluated for the temperature of both the living room and the kitchen.

4. RESULTS

Figure 2 presents the RMSE values calculated for the free float period in both the living room and the kitchen across the six tested TMY files. The living room exhibits a higher RMSE compared to the kitchen, which can be attributed to its direct supply of outdoor air. This increased exposure to external temperature fluctuations leads to greater deviations in simulated indoor temperature, as reflected in the RMSE values.

The impact of the ventilation on the error is further validated by analysing the RMSE results from the original IDEAS simulation, where ventilation is not linked to outdoor air temperature but instead to measured temperatures. In these tests, RMSE values remain below 0.6K across all cases. This reinforces the observation that it is crucial to include the effects of a direct link to the outdoor air temperature through ventilation when opting for a filtered temperature input. When aiming for the same accuracy a simulation that includes ventilation will need a more detailed input, in this case more frequencies.

The heating period shows similar trends compared to the free float period, with slightly lower RMSE values recorded. In all cases the coefficient of variation of the RMSE (cvRMSE) remains within the limits outlined in ASHRAE Guideline 14-2002 across all tested frequency ranges. The mean bias error (MBE) for both periods remains consistently centered around zero, indicating no intrinsic bias in the model's predictions. Additionally, the normalized mean bias error (NMBE) consistently falls below the 10% threshold of the ASHRAE Guideline 14-2002 when more than 10 frequencies are considered. It is important to note that this ASHRAE guideline is designed for use in whole-year simulations, meaning that these results should be interpreted as an indication of

model performance rather than a definitive validation of compliance.

Overall, the results indicate that adding more frequencies initially has a significant impact on accuracy, but the effect diminishes as additional frequencies are introduced. This trend supports the approach of sequentially incorporating frequencies based on their respective power contribution.

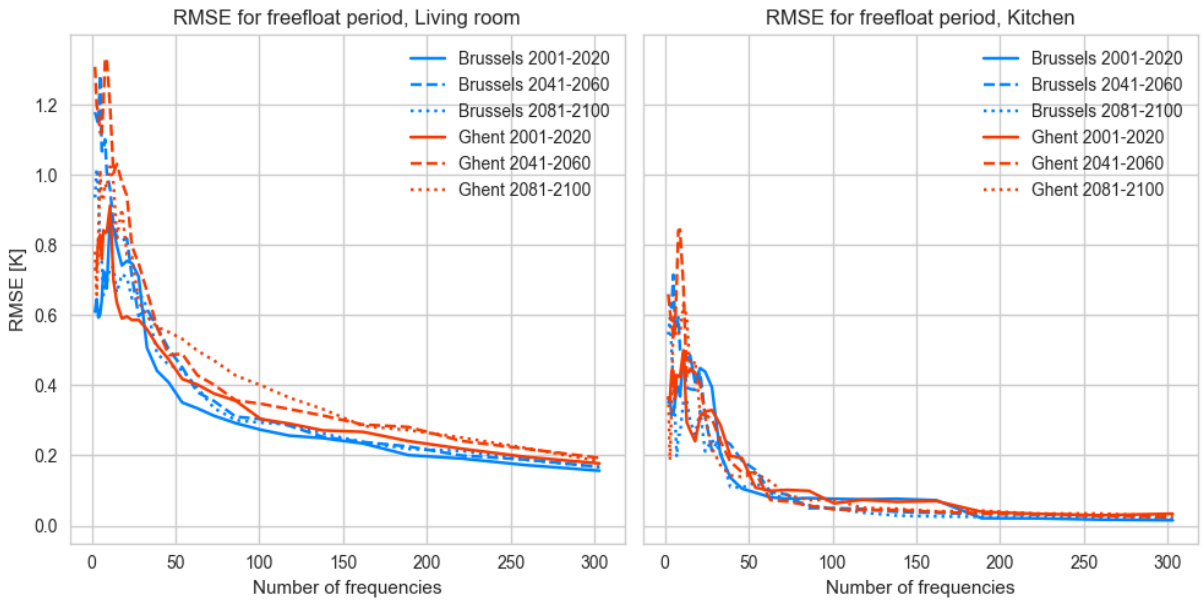

Figure 2 RMSE values computed between the default IDEAS model results and the model using reconstructed signals with varying frequency amounts, during the free float period (days 262 to 297), for both the living room and kitchen.

To evaluate computational efficiency, the CPU time for each simulation is recorded and averaged over five simulation runs. The speed of the baseline IDEAS simulation using TMY files is then compared to simulations using the reconstructed FFT signal. As illustrated in Figure 3, simulation speed decreases progressively as more frequencies are introduced. For the TMY Brussels dataset (2001–2020), no additional speed gains are observed beyond 101 frequencies, whereas for the TMY Ghent dataset (2041–2060), the tipping point occurs at 486 frequencies. The remaining cases fall within this range, demonstrating a varying impact of frequency count on computational performance.

When applying this method to enhance simulation speed, a trade-off must be considered between accuracy and computational efficiency. Using 21 frequencies, the RMSE falls below 1K across all tested cases, while simulation time is improved by 11.1% on average. Increasing the number of frequencies to 54, further reduces the RMSE below 0.5K while still maintaining a notable speedup of 9.6%. The most accurate results that can be achieved without compromising simulation speed occur at 259 frequencies, where the RMSE values range between 0.157K and 0.193K. This indicates that beyond this point, further improvements in accuracy come at the expense of increased computational cost, when compared to the default IDEAS simulation.

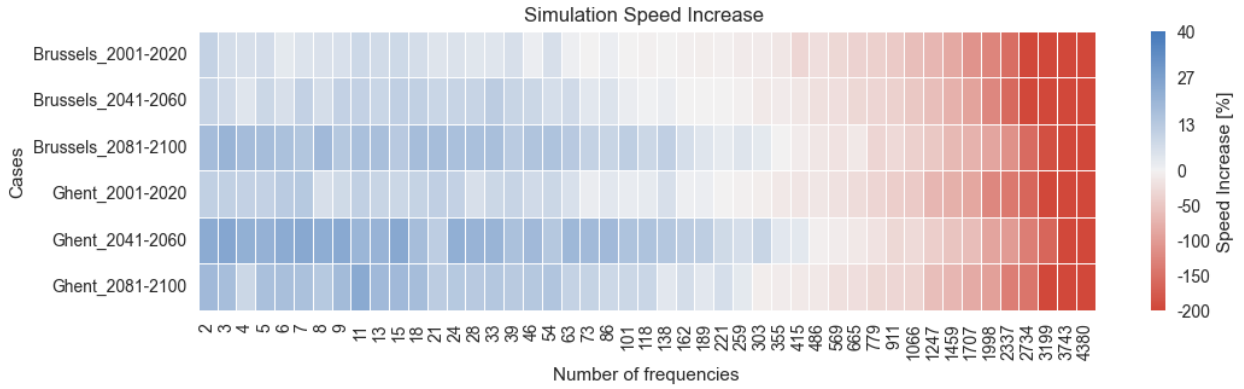

Figure 3 Simulation speed improvement with varying frequencies compared to the default IDEAS model, analyzed on a case-by-case basis.

5. DISCUSSION

When comparing the RMSE results from the simulation incorporating ventilation linked to outdoor air with the original simulation that used measured air temperatures for ventilation, the original simulations exhibited significantly lower RMSE values. This finding emphasizes the crucial role of ventilation in the accuracy of indoor climate modelling and highlights the necessity of incorporating higher frequency components when assessing the impact of ventilation on indoor temperature fluctuations. Neglecting these higher frequencies could lead to an oversimplification of the dynamic interactions within the indoor environment. However, the inclusion of higher frequencies also increases computational complexity, thereby partially limiting the potential for further acceleration of the simulations.

In this setup, only one input signal was considered: the dry-bulb temperature. Expanding this method to all weather data inputs could further enhance simulation speed. However, the simulation time is strongly influenced by the syntax and modeling methods used in Modelica. Additionally, different signals may require distinct filtering thresholds to ensure sufficient simulation accuracy. This would necessitate either further preliminary research into the reconstructed signals and the dominant frequencies affecting specific buildings or a reduction in overall filtering potential. Investigating which frequencies most influence the thermal dynamics of buildings, based on factors such as thermal mass, construction build-up, and ventilation strategy, could enable a more targeted filtering approach. These insights may lead to adaptive filtering strategies that preserve accuracy while enhancing simulation efficiency.

6. CONCLUSIONS

In conclusion, the results of this study demonstrate the effectiveness of using frequency-based signal filtering to enhance simulation speed while maintaining a high level of accuracy in indoor climate modeling. A reduction of 10% in simulation time is achievable with minimal impact on RMSE. The addition of more frequencies initially improves the model's performance, with significant reductions in RMSE and MBE as the number of frequencies increases. However, this improvement in accuracy diminishes as additional frequencies are added, highlighting the need to balance accuracy with computational efficiency.

These findings suggest that the method offers a viable approach for reducing simulation time without significantly sacrificing accuracy, making it a valuable tool for optimizing building performance simulations. However, careful consideration must be given to the trade-offs between accuracy and computational resources, especially when scaling the method to larger, more complex simulations. Expanding this approach to include additional weather data inputs and refining filtering thresholds may further enhance both simulation speed and accuracy, offering a promising direction for future research in this field.

[2]*Institue of Industrial Science, The University of Tokyo, Tokyo, Japan, jhy@iis.u-tokyo.ac.jp*

SUMMARY
Ensuring accurate indoor air pollution monitoring is essential for maintaining human health and comfort, especially as pollutant sources are often dynamic. This study proposes a method for optimizing the placement of a single air pollution sensor in an indoor environment. This method utilizes inverse analysis with adjoint concentrations, which enables efficient analysis of the spatially averaged concentration of a given evaluation area for arbitrary pollutant source locations. By leveraging this, we presented an optimal sensor location and an algorithm for exploration. A numerical experiment was conducted in an isothermal airflow field within a 2-dimensional indoor model to validate the applicability of the proposed method. A single optimal sensor was identified among the candidates as the position with adjoint concentration values highly correlated with the evaluation region's values. Furthermore, we discuss the optimal location of each sensor from the perspective of its sensitivity to pollutant emissions using adjoint concentration distributions.

Keywords: air quality, sensor placement, optimization, inverse analysis.

1. INTRODUCTION

Indoor air pollution significantly affects the health and comfort of occupants. In recent years, environmental sensors have been increasingly installed in indoor spaces to enable advanced monitoring and control of indoor air quality as well as the efficient operation of ventilation and air conditioning systems (Mylonas et al., 2019; Wang et al., 2023). However, the sensor's position significantly affects the monitoring quality (Yun & Licina, 2023). Studies have been conducted to identify the sudden generation of hazardous substances in indoor environments and optimize the placement of sensors (Chen & Wen, 2008; Zeng et al., 2020). However, enough consideration has not been given to monitoring substances that are always present in the environment but whose concentration distribution changes dynamically. Some studies have been proposed for optimal sensor placement utilizing CFD (computational fluid dynamics) simulation and heuristic optimization (Mousavi et al., 2017). However, these approaches often require prior knowledge or assumption of specific emission scenarios or involve high computational costs. Therefore, for spatially heterogeneous target variables such as pollutant concentration fields, methodologies are needed to assess how well sensor measurements represent the spatial characteristics and to guide sensor placement accordingly.

In addition, the locations and intensities of pollutant sources are diverse in the indoor environment, making it inefficient to perform a forward analysis for all possible scenarios. Conversely, adjoint concentrations enable the efficient analysis of pollutant concentrations within the evaluation area

and sensor measurements across various pollutant source conditions, and they have been applied to identify unknown pollutant sources outdoors and indoors (Jia & Kikumoto, 2022; Keats et al., 2007; Pudykiewicz, 1998; Wang et al., 2022). Therefore, in this study, we aim to develop a method for optimizing sensor placement for concentration monitoring for generally existing indoor pollutants based on inverse analysis using the adjoint concentration. The optimized sensor location is expected to be robust or, on average, closely matches the average concentration of the evaluation area under scenarios where pollutants are probabilistically generated from various places.

2. PROBLEM STATEMENT AND ASSUMPTIONS

Consider a single-ventilated indoor space (room) where a steady airflow is established through constant ventilation. Within this space, an air pollutant is generated, which is the subject of monitoring. The objective of this study involves evaluating the spatially averaged concentration of this pollutant within a designated evaluation area as a representative value of the air quality of the room. To realize this, a single concentration sensor is installed in the room, and its placement must be optimized such that the sensor's reading closely approximates the actual spatially averaged concentration within the evaluation area. We assume that although the pollutant emission rate is unknown, its intensity remains constant. Additionally, for simplicity, we exclude the effects of changes in airflow due to variations in pollutant source conditions or ventilation and focus on monitoring the pollutant concentration passively transported under constant airflow conditions.

3. SPATIALLY AVERAGED POLLUTANT CONCENTRATION FROM THE PERSPECTIVE OF ADJOINT CONCENTRATION

This section first introduces the concept of adjoint concentration and its mathematical foundation. Then, we explain how it is utilized to compute spatially averaged concentrations and guide sensor placement optimization under uncertain pollutant emission scenarios.

3.1. Overview of Adjoint Concentration and Duality Relationship

In a steady turbulent dispersion field, when the point source of a pollutant is located at $\mathbf{x}_\mathrm{s}$, its concentration at position $\mathbf{x}$ can be denoted as $C(\mathbf{x}|\mathbf{x}_\mathrm{s})$ and transport equation is expressed as:

$$\nabla \cdot (\mathbf{U}C - \Gamma \nabla C) = q_\mathrm{s}\delta(\mathbf{x} - \mathbf{x}_\mathrm{s}) \tag{1}$$

where $\mathbf{U}$ denotes the mean velocity vector, Γ denotes the effective diffusion coefficient of the concentration, and q_s denotes the emission intensity of the pollutant. In a steady turbulent field, the adjoint concentration is defined as the concentration $C^*(\mathbf{x}|\mathbf{x}_\mathrm{r})$ of a hypothetical tracer released at receptor location $\mathbf{x}_\mathrm{r}$ with an intensity of q_r in a reversed mean flow field, as shown in Fig. 1. The transport equation for the adjoint concentration is:

$$\nabla \cdot (-\mathbf{U}C^* - \Gamma \nabla C^*) = q_\mathrm{r}\delta(\mathbf{x} - \mathbf{x}_\mathrm{r}) \tag{2}$$

The pollutant and adjoint concentrations satisfy the duality relationship (Pudykiewicz, 1998):

$$q_\mathrm{r}C(\mathbf{x}_\mathrm{r}|\mathbf{x}_\mathrm{s}) = q_\mathrm{s}C^*(\mathbf{x}_\mathrm{s}|\mathbf{x}_\mathrm{r}) \tag{3}$$

This relationship implies that once the distribution of C^* is determined, concentration C at $\mathbf{x}_\mathrm{r}$

for any $\mathbf{x}_s$ and q_s can be immediately calculated as $C = q_s C^*(\mathbf{x}_s|\mathbf{x}_r)/q_r$, provided that the flow field remains unchanged. Typically, the number of potential pollutant source locations (N) is much larger than the number of receptor locations (e.g., person or sensor) (M), i.e., $N \gg M$. Therefore, using adjoint concentrations requires fewer analyses and is more efficient.

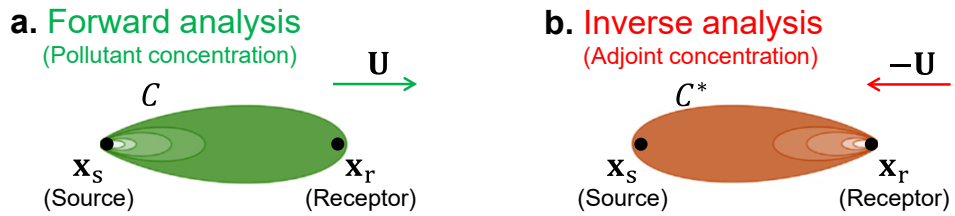

Figure 1. Conceptual diagram of forward (pollutant concentration) and inverse (adjoint concentration) analysis.

3.2. Spatially Averaged Pollutant Concentration Represented using Adjoint Concentration

In a target room noted as Ω_∞, one of the indicators representing the pollutant concentration to which occupants are exposed is the spatially averaged concentration within an evaluation region Ω_o ($\in \Omega_\infty$), such as a living area. Let the spatially averaged value f_o of any function $f(\mathbf{x})$ over Ω_o be defined as follows:

$$f_o = \frac{1}{V_o}\int_{\Omega_\infty} \phi_o f \mathrm{d}\mathbf{x} = \frac{1}{V_o}\int_{\Omega_o} f \mathrm{d}\mathbf{x} \quad \text{where} \quad \phi_o(\mathbf{x}) = \begin{cases} 1 & \mathbf{x} \in \Omega_o \\ 0 & \mathbf{x} \notin \Omega_o \end{cases}, \; V_o = \int_{\Omega_\infty} \phi_o \mathrm{d}\mathbf{x} = \int_{\Omega_o} \mathrm{d}\mathbf{x} \tag{4}$$

Here, let $\mathbf{x}_r$ be an arbitrary position within Ω_o. If a pollutant source with strength q_s is located at $\mathbf{x}_s$, the spatially averaged concentration $C_o|_{\mathbf{x}_s}$ of the pollutant in Ω_o can be expressed as:

$$C_o|_{\mathbf{x}_s} = \frac{1}{V_o}\int_{\Omega_o} C(\mathbf{x}_r|\mathbf{x}_s)\mathrm{d}\mathbf{x}_r \tag{5}$$

Applying the duality relationship in Eq. (3), $C_o|_{\mathbf{x}_s}$ in Eq. (5) can also be expressed using the adjoint concentration as:

$$C_o|_{\mathbf{x}_s} = \frac{q_s}{q_r V_o}\int_{\Omega_o} C^*(\mathbf{x}_s|\mathbf{x}_r)\mathrm{d}\mathbf{x}_r = \frac{q_s}{q_r} C_o^*(\mathbf{x}_s) \quad \text{where} \quad C_o^*(\mathbf{x}) = \frac{1}{V_o}\int_{\Omega_o} C^*(\mathbf{x}|\mathbf{x}_r)\mathrm{d}\mathbf{x}_r \tag{6}$$

The transport equation for $C_o^*(\mathbf{x})$ can be derived by applying an averaging operation, as shown in Eq. (4), with respect to $\mathbf{x}_r$ on both sides of Eq. (2) yields:

$$\nabla \cdot (-\mathbf{U}C_o^* - \Gamma \nabla C_o^*) = \frac{q_r}{V_o}\phi_o(\mathbf{x}) \tag{7}$$

Thus, once distribution $C_o^*(\mathbf{x})$ of the adjoint concentration with the source term $q_r/V_o \cdot \phi_o(\mathbf{x})$ is calculated using Eq. (7), the spatially averaged concentration $C_o|_{\mathbf{x}_s}$ in the evaluation region can be obtained from Eq. (6) for any point source ($\mathbf{x}_s$, q_s), as long as the flow field remains constant.

4. OPTIMIZATION METHOD FOR SINGLE SENSOR PLACEMENT USING ADJOINT CONCENTRATION

4.1. Definition of Optimal Sensor Location

In this study, we consider a scenario in which a single sensor is installed in a room to measure the concentration of a target pollutant. The goal involves identifying the sensor position that provides measurements that closely match the spatially averaged concentration $C_o|_{\mathbf{x}_s}$ within the evaluation region, considering probabilistic pollutant emissions from various locations $\mathbf{x}_s$.

The concentrations in the evaluation region and sensor location are proportional to q_s. Thus, q_s does not influence the optimal sensor position for passively transported pollutants. From Eq. (6), $C_o|_{\mathbf{x}_s}$ can be replaced with $C_o^*(\mathbf{x}_s)$. Furthermore, for a specific sensor location $\mathbf{x}_{r'}$, the adjoint concentration $C^*(\mathbf{x}|\mathbf{x}_{r'})$ can be evaluated using Eq. (2) (with $\mathbf{x}_r$ replaced by $\mathbf{x}_{r'}$). Therefore, if the potential emission region of the contaminant is Ω_s ($\in \Omega_\infty$), the optimal sensor location $\mathbf{x}_{opt}$ can be defined as:

$$\mathbf{x}_{opt} = \arg\max_{\mathbf{x}_{r'}} \mathrm{cor}(C^*(\mathbf{x}|\mathbf{x}_{r'}), C_o^*(\mathbf{x})|\mathbf{x} \in \Omega_s) \tag{8}$$

This implies that the adjoint concentration $C^*(\mathbf{x}|\mathbf{x}_{r'})$ at the sensor placed at $\mathbf{x}_{opt}$ exhibits the highest spatial correlation (cor) with $C_o^*(\mathbf{x})$ within Ω_s. Based on the duality relationship, this is equivalent to ensuring a high correlation between the sensor's measured concentration and spatially averaged concentration in the evaluation region. Additionally, by performing correlation analysis and obtaining a linear regression line (with slope α and intercept β) to estimate $C_o^*(\mathbf{x})$ from $C^*(\mathbf{x}|\mathbf{x}_{r'})$, the spatially averaged concentration C_o in the evaluation region can be accurately estimated from the sensor measurement C_{opt} at the optimal location as follows:

$$\hat{C}_o = \alpha \cdot C_{opt} + \beta \tag{9}$$

4.2. Algorithm for Searching the Optimal Sensor Location

Based on the approach presented in the previous section, we propose an algorithm for identifying the optimal sensor location, as outlined in Table 1. The optimal sensor location is selected from a predefined set of discrete and finite candidate positions (Steps 4 and 7 of Table 1) for practical considerations.

5. OVERVIEW OF CASE STUDY

A case study was conducted to evaluate the effectiveness of the proposed sensor location optimization method introduced in the previous section. As an initial investigation, the problem is simplified by employing an isothermal airflow field within a two-dimensional indoor space model termed the IEA Annex 20 model, which has been widely used as a benchmark for CFD analyses (Ito et al., 2015; Lemaire et al., 1993; Nielsen, 1990). As shown in Fig. 2, the indoor space model (Ω_∞) has a height of H (= 3.0 m) and a width of $3H$. It is continuously ventilated through an inlet with a height of $0.056H$ and an outlet with a height of $0.16H$, maintaining a steady airflow.

Two scenarios are considered for the pollutant concentration evaluation region (Ω_o). Scenario 1: The evaluation region covers the entire indoor space ($\Omega_{o1} = \Omega_\infty$). Scenario 2: The evaluation region is restricted to the central part of the room ($\Omega_{o2} = \{x \in [H, 2H], z \in [H/3, 2H/3]\}$), representing the breathing zone of an occupant situated near the center of the room.

Table 1. Algorithm for searching the optimal sensor location and constructing the estimation model for spatially averaged concentration.

Step 1. Definition of the target indoor space: Define room Ω_∞.
Step 2. Definition of the evaluation region for pollutant concentration: Define the evaluation region $\Omega_\mathrm{o}(\in \Omega_\infty)$, such as the living area, where pollutant concentration will be monitored.
Step 3. Analysis of adjoint concentration in the evaluation region: Using CFD analysis and following equation (Eq. (7)), obtain distribution of $C_\mathrm{o}^*(\mathbf{x})$ in Ω_∞: $\nabla\cdot(-\mathbf{U}C_\mathrm{o}^* - \Gamma\nabla C_\mathrm{o}^*) = q_\mathrm{r}/V_\mathrm{o}\cdot\phi_\mathrm{o}(\mathbf{x})$
Step 4. Definition of candidate sensor locations: Define M candidate sensor locations $\{\mathbf{x}_{\mathrm{r}',i}\vert i=1,\dots,M\}$.
Step 5. Analysis of adjoint concentration at candidate sensor locations: For each candidate sensor location $\mathbf{x}_{\mathrm{r}',i}$, use CFD analysis and the following equation (Eq. (2)) to obtain the distribution of $C_i^*(\mathbf{x}) = C^*(\mathbf{x}\vert\mathbf{x}_{\mathrm{r}',i})$: $\nabla\cdot(-\mathbf{U}C_i^* - \Gamma\nabla C_i^*) = q_\mathrm{r}\delta(\mathbf{x}-\mathbf{x}_{\mathrm{r}',i})$
Step 6. Definition of potential pollutant emission region: Define the potential emission region Ω_s $(\in\Omega_\infty)$.
Step 7. Selection of the optimal sensor location: Among the M candidate locations, identify $C_i^*(\mathbf{x})$ that shows the highest correlation with $C_\mathrm{o}^*(\mathbf{x})$ in its spatial distribution over Ω_s. The corresponding sensor location is designated as the optimal location $\mathbf{x}_\mathrm{opt}$.
Step 8. Construction of the estimation model for spatially averaged concentration: Using the least squares method, construct a linear regression model (slope α, intercept β) to estimate $C_\mathrm{o}^*(\mathbf{x})$ from $C^*(\mathbf{x}\vert\mathbf{x}_\mathrm{opt})$ in Ω_s.
Step 9. Estimation of spatially averaged concentration in the evaluation region: Estimate the spatially averaged concentration $\hat{C}_\mathrm{o}$ in the evaluation region using the sensor measurement C_opt at $\mathbf{x}_\mathrm{opt}$ and the following equation (Eq. (9)): $\hat{C}_\mathrm{o} = \alpha\cdot C_\mathrm{opt} + \beta$

Schmidt number	Schmidt number = 1.0; Turbulent Schmidt number = 0.7

Fig. 3 shows the candidate positions for sensor placement ($\mathbf{x}_{\mathrm{r}',i}$). A total of 16 (= M) candidate positions were considered, including areas near the ceiling, walls, and center of the room. As potential pollutant emission regions, $\Omega_\mathrm{s} = \Omega_\infty$ (pollutants are emitted uniformly from the entire room) is assumed for simplicity. The CFD analysis of airflow and concentrations in the indoor space model (Fig. 2) was conducted using OpenFOAM v2106 with transport equations for the adjoint concentrations and other implemented variables. To perform dispersion analysis in a

steady-state turbulent field, the standard k–ε turbulence model was used. Further details of the CFD analysis are listed in Table 2.

6. RESULTS OF CFD ANALYSIS

First, the mean flow field within the room was calculated using CFD. The velocity streamlines are shown in Fig. 4. Air entering through the inlet flowed along the ceiling, struck the right wall, and exited through the outlet. This indicates that a primary ventilation pathway was formed near the ceiling, whereas a recirculation flow developed on the right side of the room. Dispersion analysis is conducted based on the flow field, and the resulting average concentration distributions are shown in Fig. 5. Low concentrations are observed along the ventilation pathway near the inlet.

The adjoint concentration fields for the pollutant concentration evaluation region and candidate sensor locations were calculated. The adjoint concentration represents the pollutant concentration response in the evaluation region or sensor location if a point source of pollution is present at that location. The results for the evaluation regions Ω_{o1} (entire room), Ω_{o2} (central part of the room), and selected sensor positions (No. 2, 9, 15) are shown in Fig. 6. In Ω_{o1}, the averaged concentration is highly sensitive to the influence of sources located in the left lower part of the space, while Ω_{o2} is more susceptible to concentrations from central emissions. Pollutants in ventilation pathways are rapidly transported, limiting the response of Ω_{o1} and Ω_{o2} to sources appearing in these areas. Sensors located near the walls (No. 1–3, 14, and 16) in the ventilation pathways constantly receive fresh air and are influenced only by nearby sources. However, sensors in the room's central area, such as No. 9, primarily detect emissions originating from the center. Moreover, given the low ventilation efficiency in the lower-left corner of the room, the response area of sensor No. 15 is restricted to a small range, making it less sensitive to emissions from other locations.

7. OPTIMIZATION RESULTS FOR SENSOR PLACEMENT

In scenarios where emission conditions are unknown, the spatial correlation between the adjoint concentration fields of each candidate sensor location and monitoring evaluation region were calculated using the following equation (refer also to Eq. (8)), where subscript i denotes the i-th candidate sensor location.

$$R_{\Omega_o}(i) = \mathrm{cor}(C_i^*(\mathbf{x}), C_o^*(\mathbf{x}) | \mathbf{x} \in \Omega_s) \tag{10}$$

The results of the correlation calculations are presented in Table 3. Based on these results, under the assumption that emission conditions are unknown in advance, optimal sensor locations corresponding to evaluation regions Ω_{o1} (entire indoor space) and Ω_{o2} (central area of the room), were determined as No. 11 and No. 9, respectively. Furthermore, it was observed that the results for the sensors in the central region (No. 5–13) were similar. In Fig. 6, it can be inferred that the responsiveness of sensors located in well-ventilated areas (No. 2 and 14) is low, resulting in lower $R_{\Omega_{o1}}$ and $R_{\Omega_{o2}}$ values. Furthermore, due to the high concentration of the adjoint concentration field around the sensor in the corner (No. 15), its relationship with Ω_{o2} was found to be negligible. Although sensors are often placed near exhaust outlets to monitor indoor air environments, the results in Table 3 indicate that sensor No. 16 has a correlation coefficient of approximately 0.3 with any of the evaluation regions.

8. CONCLUSIONS

This study proposed a method to optimize single-sensor placement for indoor air pollution monitoring using CFD-based inverse analysis with adjoint concentrations. The method identifies sensor locations that robustly estimate the average pollutant concentration in a target area under uncertain emission conditions. A case study in a two-dimensional indoor space demonstrated its effectiveness: Sensor No. 11 (entire room) and Sensor No. 9 (central area) achieved high correlation coefficients of 0.81 and 0.97, respectively. Conversely, Sensor No. 16 near the exhaust outlet showed a low correlation of 0.29 (entire room) and 0.28 (central area), highlighting the limitations of typical placement strategies. Future work will extend this approach to more diverse emission scenarios, three-dimensional spaces, multi-sensor systems, etc., toward practical applicability in real buildings.

SUMMARY
Ventilation may lead to a deterioration in indoor air quality in urban environments located close to roads. Comprehending the disparities in chemical compositions of size-resolved particulate matter (PM) between indoor and outdoor settings is crucial for evaluating associated health effects. In this study, indoor and outdoor size-resolved PM was collected from an office in Beijing in summer and winter. The levels of $PM_{2.1}$ and $PM_{2.1–9}$ mass were higher outdoors than they were indoors. The size distributions of mass concentrations were shown to be bimodal, peaking at 0.43–0.65 μm and 4.7–5.8 μm, respectively. The most abundant chemicals were organic matter, nitrate, and sulfate for $PM_{2.1}$ and organic matter, crustal materials, and nitrate for $PM_{2.1\text{-}9}$. We found higher percentages of sulfate, nitrate, ammonium, elemental carbon, and heavy metals in smaller-size fractions of PM. Additionally, positive matrix factorization showed that biomass burning, secondary inorganic aerosol, coal combustion, dust, traffic, and industrial pollution were the main sources of PM during the study period. The greatest non-carcinogenic and carcinogenic hazards were found at 0.43–0.65 μm in summer and 2.1–3.3 μm in winter. Our results indicate that size-resolved PM of ambient origin may infiltrate buildings near roads to varying degrees, resulting in negative health effects.

Keywords: indoor and outdoor; health risk assessment; size distributions

1. INTRODUCTION

Particulate matter (PM) is a significant air pollutant with adverse health impacts. Studies have associated short-term PM exposure with increased morbidity and mortality (Weber, 2020). Understanding its size distributions and chemical compositions is essential for health effect assessment (Tian el al., 2014), as large particles influence deposition in the respiratory tract and chemical components contribute to toxicity, with heavy metals being of particular concern. The determination of chemical species in size-resolved fractions of PM is central in evaluating the health impacts associated with exposure to airborne particles (Enyoh et al., 2020).

For urban dwellers, indoor environments are a major source of PM inhalation, yet the relationship between outdoor and indoor air quality remains unclear. In urban environments, researchers have investigated PM sources and associated health risks outdoors, but the possible impacts of outdoor air pollution on indoor air quality are not yet well understood. Regarding the potential health risks associated with the ventilation of outdoor air pollution (Liu et al., 2024), two questions should be addressed separately. Firstly, we must distinguish the differences in the size fractions and chemical components of indoor and outdoor PM, as they may originate from different sources (Morawska et al., 2017). Then, since the size fractions for indoor and outdoor

PM may vary, assessments of potential health effects can guide the development of air pollution control policies for indoor and outdoor environments (Nassikaset al., 2024).
Quantifying source contributions to size-resolved PM aids in emission management. While outdoor pollution is regulated, indoor pollution control is lacking (Huang et al., 2014). The receptor model, such as PMF, has been widely used worldwide to estimate the source contributions of PM in the absence of inputs from a local source profile (Dao et al., 2022). Prior studies have focused on the estimation of source contributions to indoor and outdoor PM in single-size fractions (Huang et al., 2023), but there have been an inadequate number of quantitative studies on source contributions to size-resolved PM collected from indoor and outdoor air.
This study evaluates mass concentrations, chemical compositions, sources, and health implications of indoor and outdoor size-segregated aerosols in Beijing, aiming to provide insights into the outdoor-indoor air quality relationship and support emission remediation strategies.

2. MATERIALS AND METHODS

2.1 Sample collection

This study focused on an office in Beijing, located near a residential area close to the 3rd Ring Road. The outdoor sampling site was positioned at approximately 15 m above the ground on the office building roof, while the indoor site was within a 10-square-meter office furnished with four computers, a printer, a refrigerator, and an air conditioner. Four people worked in the office on weekdays. In summer, the windows were open, and the air conditioner was operational during the day. The area had no neighboring industrial pollution sources, and sampling was conducted during two periods: 5 - 25 July 2020 (summer) and 5 - 31 January 2021 (winter).
Two nine-stage particle samplers (Andersen Series 20-800, USA) were utilized to simultaneously collect indoor and outdoor size-segregated airborne particles at a flow rate of 28.3 L min^{-1}, targeting nine particle sizes (0.43 - 9.0 μm). Quartz fiber filters were used for water-soluble ions, organic carbon, and elemental carbon analysis, while cellulose filters were for elemental concentration quantification. Samples were collected for 24 - 48 h, yielding 14 sets in summer and 18 sets in winter.

2.2 Chemical Analyses

For water-soluble ion analysis, a quarter (7 cm^2) of each quartz filter was added to 25 mL of de-ionized water and ultrasonically extracted for 30 min at room temperature. The extract was then filtered through a 0.22 μm filter before measuring the levels of water-soluble ions including Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, NO_3^-, and SO_4^{2-} using an ICS-90 ion chromatograph. The ions' limits of detection were less than 0.02 μg m^{-3} when the injection volume was 100 μL. The thermal/optical carbon aerosol analyzer (DRI Model 2001A) was used to determine organic carbon and elemental carbon levels. For trace element measurement, 7 cm^2 of the cellulose membrane was digested with a mixture of HNO_3, H_2O_2, and HF, and the levels of 19 trace elements included Na, Mg, Al, K, Ca, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Mo, As, Cd, Sb, Ba, and Pb, were measured using an Agilent 7500ce inductively coupled plasma mass spectrometer.

2.3 PMF Model

EPA-PMF 5.0 was employed to apportion sources for PM, with concentrations and uncertainty of the above chemical species in size fractions of <0.43, 0.43–0.65, 0.65–1.1, 1.1–2.1, 2.1–3.3, 3.3–4.7, 4.7–5.8, and 5.8–9 μm as input. We calculated the uncertainty of the concentration data using the following equations.

We used Equation (1) to calculate the uncertainty when the measured level was lower than or equal to the detection limit (MDL) for the analytical method.

$$\text{Uncertainty} = 5/6 \times \text{MDL} \quad (1)$$

We used the following calculation Equation (2) when the concentration was higher than the detection limit (MDL) for the analytical method.

$$\text{Unc} = \sqrt{(Errorfraction \times concentration)^2 + (0.5 \times MDL)^2} \quad (2)$$

3. RESULTS AND DISCUSSION

3.1. Mass Concentrations

Fine particles (<2.1 μm) and coarse particles (2.1-9.0 μm) were considered as proxies for $PM_{2.5}$ and PM_{10}, respectively, due to sampler limitations. A significant linear correlation was observed between $PM_{2.1}$ and $PM_{2.5}$ ($R^2 = 0.89$, $p < 0.05$), and between PM_9 and PM_{10} ($R^2 = 0.87$, $p < 0.05$). $PM_{2.1}$ and $PM_{2.1–9}$ concentrations were generally lower indoors, except for $PM_{2.1–9}$ in summer, indicating that major indoor sources different from those outdoors were responsible for the coarse particles in summer offices. Winter had higher $PM_{2.1}$ but lower $PM_{2.1–9}$ compared to summer. During haze days (defined as PM2.5 > 35 μg m^{-3}), both indoor and outdoor particle levels substantially increased compared to clear days.

The size distribution of mass concentration (Fig. 1) showed a bimodal pattern, with peaks at 0.43–0.65 μm (fine mode) and 4.7–5.8 μm. Notably, for outdoor particles, the fine-mode peak shifted to larger sizes on haze days in both seasons. The indoor/outdoor (I/O) ratios were generally below 1 across most size ranges in both seasons, except for some coarse fractions (2.1–3.3 μm and 3.3–4.7 μm). The I/O ratio was highest in the 2.1–4.7 μm range, potentially due to elevated human activity indoors. This ratio was also affected by the penetration efficiency of particles and the protection of the building envelope from coarser outdoor particles.

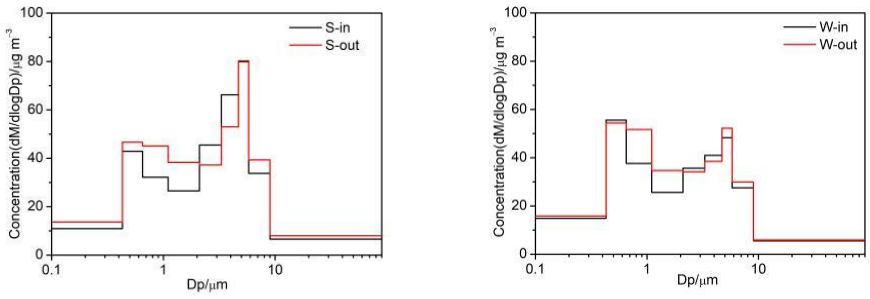

Figure 1. Size distributions of the mass concentrations of both inside and outside particles.

3.2 Chemical components of PM

PM chemical components were grouped into eight categories (Fig. 2): sulfate, nitrate, ammonium, chlorine, organic matter (OM), elemental carbon (EC), crustal materials (CM), and heavy metals (HM). OM and sulfate-nitrate-ammonium (SNA) dominated the $PM_{2.1}$ mass, accounting for over 76.6% of the total. The fraction of SNA was higher in outdoor $PM_{2.1}$, suggesting more secondary particle formation outdoors. In contrast, the fraction of OM was lower outdoors, indicating indoor sources of OM. High contributions of CM and OM were observed in $PM_{2.1–9}$, accounting for 30.3%~40.2% and 24.3%~54.0% of the total $PM_{2.1-9}$ mass, respectively. The undetermined fraction for $PM_{2.1}$ and $PM_{2.1–9}$ ranged from 1.4% to 8.8%, potentially due to oxide species, heteroatoms, water molecules, and undetermined mineral components.

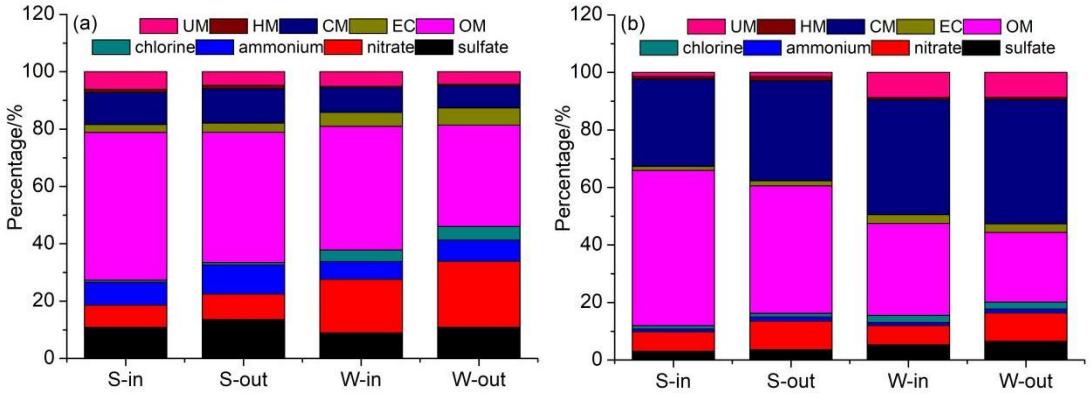

Figure 2. Average mass closure for the indoor and outdoor samples of (**a**) $PM_{2.1}$ and (**b**) $PM_{2.1–9}$.

The mean concentrations of water-soluble ions were higher in winter (28.8 μg m^{-3} indoors and 36.9 μg m^{-3} outdoors) compared to summer (18.8 μg m^{-3} indoors and 25.0 μg m^{-3} outdoors). SNA contributed to 69.5% - 74.4% of water-soluble ions in $PM_{2.1}$ and 25.7% - 48.4% in $PM_{2.1-9}$. The concentrations of SO_4^{2-}, NO_3^-, and NH_4^+ were higher in indoor $PM_{2.1}$ and $PM_{2.1–9}$. During haze days, the accumulation of SNA occurred both indoors and outdoors. The sulfur oxidation ratio (SOR) and nitrogen oxidation ratio (NOR) were positively correlated with relative humidity (RH) in winter. The size distribution of SNA was bimodal, with the fine-mode maximum shifting to larger sizes on haze days for outdoor particles.The acidity and alkalinity of PM, evaluated by the equivalent ratio of cations to anions ($R_{C/A}$), showed that outdoor PM was more acidic. The $R_{C/A}$ values ranged from 0.9 to 3.3, with the lowest ratios in the 1.1–2.1 μm size fraction.

OC and EC concentrations varied seasonally and between indoor and outdoor. In summer, indoor OC and EC in $PM_{2.1}$ and $PM_{2.1–9}$ were slightly lower than outdoors, while the opposite was true for OC in $PM_{2.1–9}$. In winter, indoor OC was slightly higher, and EC was lower than outdoors. During haze days, the average concentrations of OC and EC in $PM_{2.1}$ and $PM_{2.1–9}$ increased. The size distribution of carbonaceous constituents was bimodal or trimodal, with the fine-mode maximum shifting to larger sizes on haze days for outdoor OC, likely due to the hygroscopic growth of ultrafine particles and the secondary formation of secondary organic carbon.

I/O ratios for CM and HM were <1 in both $PM_{2.1}$ and$PM_{2.1–9}$, indicating dominant outdoor contributions. Haze days showed higher CM and HM concentrations than clear days, with fine-mode CM ($R_{H/C}$: 1.28–2.30) accumulating more than coarse-mode (1.11–1.84), while HM exhibited accumulation in both modes ($PM_{2.1}$: 1.30–1.61; $PM_{2.1–9}$: 1.35–2.11). Size distributions

of CM and HM displayed bimodal peaks: fine mode (0.43–1.1 μm) and coarse mode (3.3–5.8 μm). Outdoor HM fine-mode peaks shifted from 0.43–0.65 μm (clear days) to 0.65–1.1 μm (haze days), suggesting hygroscopic growth or secondary formation, but indoor particles showed no such shift. These findings highlight outdoor sources as major contributors to indoor pollution, with haze enhancing fine-particle accumulation.

3.3 Source Apportionment

Six sources of PM were identified through positive matrix factorization (PMF) analysis: biomass burning, secondary inorganic aerosols (SIA), coal combustion, dust, traffic, and industrial pollution. These sources accounted for 91.3%- 99.0% of $PM_{2.1}$ and 90.7% - 98.4% of $PM_{2.1–9}$ (Fig. 3).

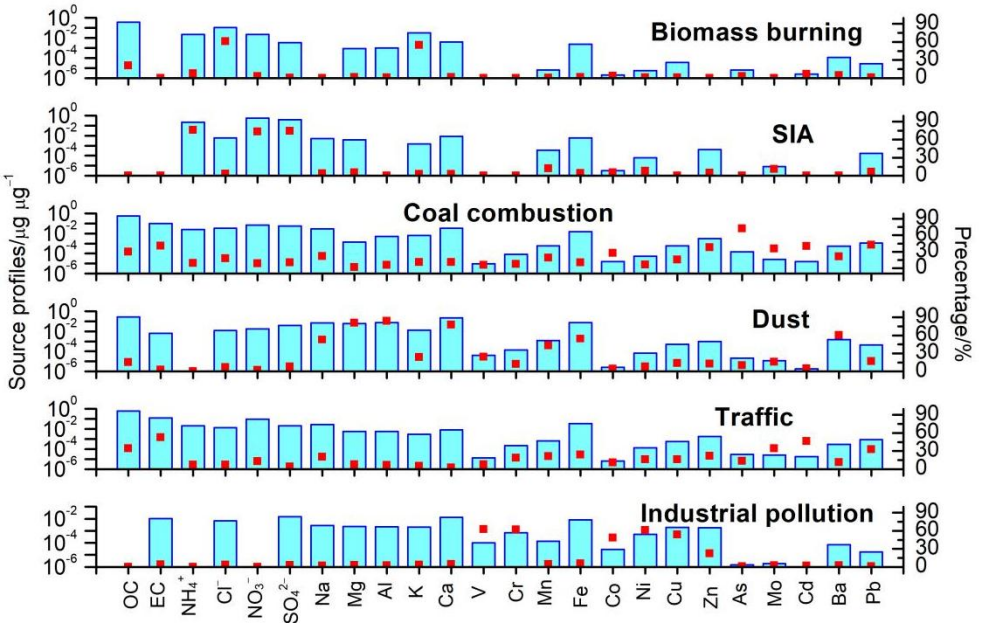

Figure 3. The profiles of each source and the apportioned percentages of species for each source.

The first source, biomass burning, was represented by the high Cl^- (61.1%), K (54.7%), which is an excellent tracer of aerosols from biomass burning, and OC (20.6%) contents. Their contributions to indoor and outdoor $PM_{2.1}$ in winter were 4.9% and 5.2%, which were slightly higher than their 3.6% and 3.3% contributions to $PM_{2.1–9}$. This finding is consistent with previous studies (Cheng et al., 2014). The greater contributions to $PM_{2.1}$ and $PM_{2.1–9}$ were found in summer (6.6% and 6.9% to indoor and outdoor $PM_{2.1}$ and 7.5% and 7.7% to $PM_{2.1–9}$), demonstrating an obvious seasonality.

The second source was SIA, which was characterized by significant amounts of SO_4^{2-} (74.4%), NO_3^- (73.1%), and NH_4^+ (75.7%). SNA represented the dominant composition of secondary inorganic aerosols. SNA was mainly formed through the photochemistry and heterogeneous processes of gaseous precursors (SO_2, NO_x, and NH_3). Their contributions to indoor and outdoor $PM_{2.1}$ in winter were 32.1% and 39.2%, which were significantly greater than their 13.7% and 18.6% contributions to $PM_{2.1–9}$. The contributions of SIA to both $PM_{2.1}$ and $PM_{2.1–9}$ revealed

significant seasonal trends, with lower concentrations observed in summer (27.8% and 34.2% to indoor and outdoor $PM_{2.1}$ and 13.0% and 15.4% to $PM_{2.1–9}$).
The third source, coal combustion, was represented by elevated As (72.4%), Pb (42.2%), Cd (40.1%), EC (40.5%), Zn (37.8%), Mo (35.8%), Co (27.5%), and OC (30.0%) concentrations . As is an excellent tracer of aerosols from coal combustion. Coal combustion is one of the main sources of primary OC and EC. Moreover, Pb, Cd, Zn, Mo, and Co are present in coal combustion. The contributions of this source to indoor and outdoor $PM_{2.1}$ in winter were 19.3% and 20.6%. Besides the contribution to $PM_{2.1}$, coal combustion contributed significantly to $PM_{2.1–9}$ (21.4% and 21.9% to indoor and outdoor $PM_{2.1-9}$). The contributions of coal combustion to $PM_{2.1}$ and $PM_{2.1–9}$ showed the obvious seasonal pattern of winter > summer (17.2% and 17.4% to indoor and outdoor $PM_{2.1}$ and 20.1% and 20.5% to $PM_{2.1–9}$).
The fourth source was dust, which were characterized by significant amounts of crustal elements, such as Al (83.9%), Mg (80.9%), Ca (77.9%), Ba (60.4%), Fe (54.3%), Na (52.7%), and Mn (40.3%). The OC content was close to 15.2%, and these high levels suggest resuspended dust. Thus, this source possibly mixes desert/loess dust, anthropogenic construction dust, fugitive dust, and resuspended road dust. The contributions of this source to indoor and outdoor $PM_{2.1}$ in winter were 8.6% and 7.8%, which were significantly lower than the 32.0% and 35.2% contributions to $PM_{2.1–9}$. Its fraction of both $PM_{2.1}$ and $PM_{2.1–9}$ showed significant seasonal trends, with lower concentrations found in summer (9.2% and 9.9% to indoor and outdoor $PM_{2.1}$ and 26.3% and 29.8% to $PM_{2.1–9}$).
The fifth source, traffic, was characterized by elevated EC (52.7%), Cd (46.3%), Mo (34.4%), OC (34.2%), Pb (32.7%), Fe (23.9%), Zn (21.9%), and Mn (21.2%) concentrations. The contributions of this source to indoor and outdoor $PM_{2.1}$ in winter were 22.6% and 21.8%. These aerosol species are all enriched in vehicular and/or waste incineration emissions. EC primarily arises from engines; Zn, Fe, and Mn are found in tailpipe emissions; and OC, Pb, Cd, and Mo are present in motor and fuel oil combustion. In addition to its contributions to $PM_{2.1}$, traffic significantly contributed to $PM_{2.1–9}$ (17.5% and 16.6% to indoor and outdoor $PM_{2.1–9}$). The contributions of traffic to $PM_{2.1}$ and $PM_{2.1–9}$ exhibited the similar seasonal pattern of winter < summer (24.5% and 22.9% to indoor and outdoor $PM_{2.1}$ and 19.2% and 18.7% to $PM_{2.1–9}$).
The sixth source was industrial pollution, which were characterized by significant amounts of V (62.6%), Cr (61.8%), Ni (61.1%), Cu (53.6%), Co (48.6%), and Zn (22.6%); this source may be related to smelters and the metallurgical industries. The contributions of this source to indoor and outdoor $PM_{2.1}$ in winter were 4.2% and 4.4%, which were slightly higher than the 2.5% and 2.8% contributions to $PM_{2.1–9}$. Its fractions of both $PM_{2.1}$ and $PM_{2.1–9}$ indicated significant seasonal trends, with higher contributions found in summer (5.9% and 6.2% to indoor and outdoor $PM_{2.1}$ and 4.6% and 3.9% to $PM_{2.1–9}$).

3.4 Possible human health implications

The non-carcinogenic and carcinogenic risks of toxic elements were calculated, considering both indoor and outdoor exposures. The total HQ values in PM_9 and TSP during both summer and winter were higher than unity, indicating notable non-carcinogenic risks from these elements. For estimating the risks of individual elements, the HQ values for Ni were found to be greater than those of other elements, and the HQ values for Ni in PM_9 and TSP in winter were higher than 1. This indicates that Ni in PM_9 and TSP poses significant non-carcinogenic risks to human health during winter. Similarly, the total CR values in $PM_{2.1}$, PM_9, and TSP during both summer and winter were greater compared with the acceptable limit of 1.0×10^{-6}, indicating the potential

carcinogenic risks caused by these elements. Additionally, the CR values of Co in PM_9 and TSP in summer, Co and Ni in PM_9 and TSP in winter, and Pb in $PM_{2.1}$, and PM_9 and TSP during winter were located between 1.0×10^{-6} and 1.0×10^{-4}, indicating potential the carcinogenic risks caused by these elements.

Fig. 4 shows the non-carcinogenic and carcinogenic risks and relative proportions of toxic elements in different size fractions. The HQ values of different elements follow the order Ni > Mn > Al > Cd > Co in both summer and winter. Generally, the highest non-carcinogenic risks were observed at 0.43–0.65 μm in summer and 2.1–3.3 μm in winter. The CR values of different elements follow the order Co > Pb > Ni > Cd in both summer and winter. The highest carcinogenic risks were also observed at 0.43–0.65 μm in summer and 2.1–3.3 μm in winter. These results indicate that we cannot ignore the non-carcinogenic and carcinogenic risks caused by coarse particles.

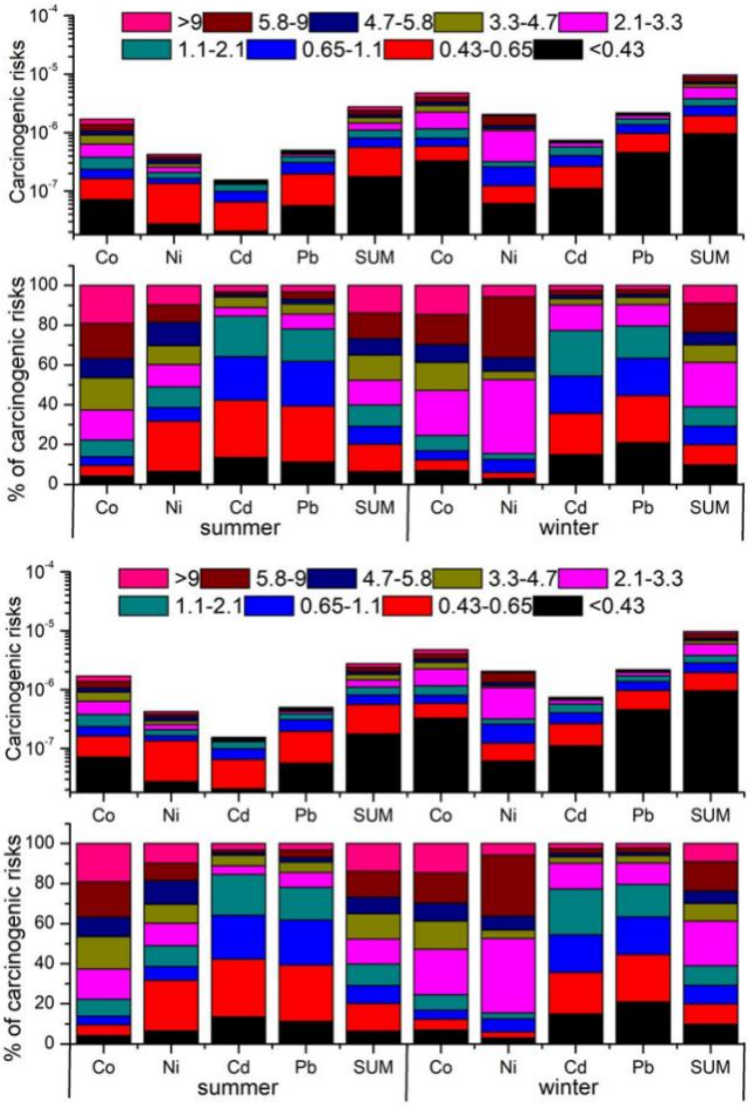

Figure 4. Non-carcinogenic and carcinogenic risks and relative proportions of toxic elements in different size fractions.

4. CONCLUSIONS

This study compared indoor and outdoor size-resolved particles in urban Beijing. Results showed that $PM_{2.1}$ and $PM_{2.1–9}$ concentrations were usually lower indoors but increased during haze. The size distribution was bimodal. OM and SNA dominated $PM_{2.1}$, while CM and OM were significant in $PM_{2.1–9}$. The source apportionment results indicated that biomass burning (4.9%~6.9% to $PM_{2.1}$ and 3.3%~7.7% to $PM_{2.1-9}$), SIA (4.9%~6.9% to $PM_{2.1}$ and 3.3%~7.7% to $PM_{2.1–9}$), coal combustion (4.9%~6.9% to $PM_{2.1}$ and 3.3%~7.7% to $PM_{2.1–9}$), dust (4.9%~6.9% to $PM_{2.1}$ and 3.3%~7.7% to $PM_{2.1–9}$), traffic (4.9%~6.9% to $PM_{2.1}$ and 3.3%~7.7% to $PM_{2.1–9}$), and industrial pollution (4.9%~6.9% to $PM_{2.1}$ and 3.3%~7.7% to $PM_{2.1–9}$) were the main sources of PM during the study period. Toxic elements in PM_9 and TSP exhibited non-carcinogenic risks, and those in $PM_{2.1}$, PM_9, and TSP had potential carcinogenic risks. The highest non-carcinogenic and carcinogenic risks were observed at 0.43–0.65 μm in summer and 2.1–3.3 μm in winter. However, the study had limitations, such as a single sampling location and small volume. Future studies should further explore the associations between indoor and outdoor particles.

SUMMARY
Formaldehyde is a prevalent indoor pollutant with well-documented adverse health effects. Recent advancements in metal-organic frameworks (MOFs) have demonstrated their ability to efficiently and reversibly capture formaldehyde, with minimal energy penalties for subsequent regeneration. In this study, we evaluated the formaldehyde removal efficiency of a newly developed MOF (Al-3.5-PDA/MOF-303), activated carbons, and MnOx catalysts in a 500 L airtight environmental chamber. The removal efficiencies were found to be 96.0% for Al-3.5-PDA, 44.8% for activated carbons, and 92.6% for MnOx catalysts. Additionally, formaldehyde emissions from medium density fiberboard (MDF) were measured in a 100 L environmental chamber both in the presence and absence of Al-3.5-PDA. Under continuous emission conditions, the average removal rate of Al-3.5-PDA was approximately 66%, which is lower than that observed under static conditions. Notably, Al-3.5-PDA exhibited consistently stable performance for formaldehyde removal over a 150-hour testing period.

Keywords: dynamic environmental chamber, material emissions, activated carbons, MnOx catalysts, Al-3.5-PDA

1. INTRODUCTION

Maintaining optimal indoor air quality (IAQ) is crucial due to its significant impact on human health, productivity, and overall well-being (Lizana et al., 2020; Oh et al., 2019). Among the various indoor pollutants, formaldehyde is of particular concern. Formaldehyde is released from a wide array of sources, including building materials, furniture, and household products (Salthammer, 2019). Prolonged exposure to formaldehyde has been associated with numerous adverse health effects, such as respiratory irritation, nasal cancer, and leukemia (IARC, 2012; Tang et al., 2009). Consequently, research into formaldehyde and effective mitigation strategies is essential for enhancing indoor air quality and safeguarding public health.

Purification techniques have been widely utilized for formaldehyde removal (Wang et al., 2023). The effectiveness of purification in reducing formaldehyde levels is primarily due to its ability to significantly decrease indoor formaldehyde concentrations through advanced air purification technologies, such as activated carbon adsorption, photocatalysis, manganese oxides (MnOx), and negative ion generation (Law et al., 2024; Zhao et al., 2022). Despite their widespread use, these conventional purification methods are constrained by limitations in efficiency, selectivity, and energy consumption (Zhang et al., 2017). Recent developments in metal-organic frameworks (MOFs) have highlighted their potential for reversible formaldehyde capture. Nevertheless, existing MOFs still face challenges, including inadequate water stability, competitive adsorption under humid conditions, and high energy requirements for regeneration (Vikrant et al., 2019;

Wang et al., 2016). For example, amine-functionalized MOFs like UiO-66-NH_2 require regeneration temperatures above 130°C (Vikrant et al., 2019). These limitations emphasize the necessity for designing MOFs with optimized architectures that ensure high selectivity, stability, and energy-efficient regeneration processes.

More recently, a novel pyrazole-based aluminum MOF, Al-3.5-PDA (MOF-303), has shown remarkable potential for efficiently capturing formaldehyde in a reversible manner with minimal energy requirements for regeneration (Sadovnik et al., 2024). Unlike traditional MOFs, Al-3.5-PDA exhibits a hybrid architecture consisting of infinite Al(III)-hydroxyl chains and 3,5-pyrazoledicarboxylate ligands, forming one-dimensional microporous channels (6 Å) with accessible pyrazole groups (Fathieh et al., 2018; Sadovnik et al., 2024). This unique structure enables synergistic chemisorption via dual hydrogen bonding between formaldehyde and the framework's μ_2-OH and pyrazole moieties, achieving an unprecedented adsorption capacity of 5 $mmol \cdot g^{-1}$ under humid conditions (90% RH). Notably, Al-3.5-PDA demonstrates negligible formaldehyde desorption below 50 °C and can be regenerated through water washing at ambient temperature, thereby eliminating energy-intensive thermal processes. Furthermore, its hydrophobic pores and tailored active sites provide exceptional selectivity against co-contaminants such as toluene and CO_2, surpassing amine-functionalized MOFs and activated carbons (Sadovnik et al., 2024).

However, comparative studies assessing the effectiveness of different purification technologies remain scarce. Furthermore, since building materials are major sources of formaldehyde emissions, it is essential to evaluate whether newly developed Al-3.5-PDA can effectively remove formaldehyde under continuous emissions from these materials. Herein, we first compare the performance of Al-3.5-PDA with activated carbons and MnOx catalysts in a 500 L airtight environmental chamber under static conditions. Subsequently, formaldehyde emissions from medium density fiberboard (MDF) were measured in a 100 L environmental chamber both in the presence and absence of Al-3.5-PDA to assess its removal efficiency under continuous emission scenarios. The results of this study offer significant insights into the formaldehyde removal capabilities of the newly developed Al-3.5-PDA material when applied in indoor environments.

2. MATERIAL AND METHODS

2.1 The tested materials

The activated carbon utilized in this study was procured from Nanjing Wanqing Chemical Glass Instrument Co., Ltd., with a particle size of 20−50 mesh. The active manganese decomposition sheets were sourced from Nanjing Yujie Environmental Technology Co., Ltd., under the product patent number ZL 2013 1 0139928.3. These sheets are composed of high-molecular-weight polyethylene terephthalate fibers serving as the carrier, onto which MnOx crystals are loaded. The fiber diameter is approximately 15−20 μm, and the specific surface area of the MnOx particles is 202.89 m^2/g, with pore diameters predominantly ranging from 4 to 6 nm. Each sheet measures 125 mm × 180 mm. The Al-3.5-PDA was synthesized using cellulose fibers and nano-fibrillated cellulose (NFC) as carriers, impregnated with MOF particles Al-3,5-PDA. This material comprises helical AlO4(OH)2 chains and 3,5-pyrazoledicarboxylate ligands, forming one-dimensional channels with a diameter of approximately 0.7 nm, a specific surface area (BET) of about 1343 m^2/g, and a porosity of 0.49 cm^3/g. Detailed information regarding the preparation method of this

Al-3.5-PDA can be found in US Patent US 20230001380A1. The paper membrane has dimensions of 200 mm × 200 mm and a mass of 12.0 g. Images of each material are presented in Figure 1.

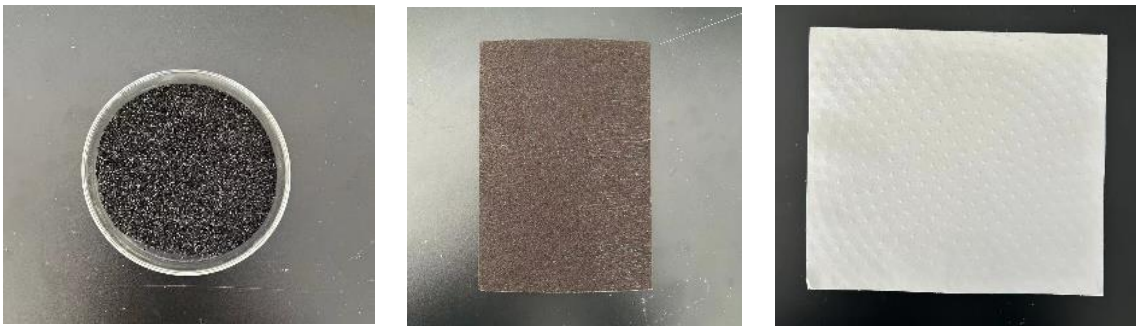

Figure 1. The images of the (a) activated carbons, (b) MnOx catalysts, and (c) Al-3.5-PDA materials used in the experiments.

Prior to the experiment, both the Al-3.5-PDA and activated carbon samples must undergo activation in a vacuum drying oven. By applying heat and vacuum extraction, impurities adsorbed within the pores of the samples are effectively desorbed. Specifically, the Al-3.5-PDA was activated at 102°C under a vacuum of 800-850 mbar for 5 hours. For the activated carbon particles, the activation process involved exposure to 102°C under a vacuum of 500 mbar for 16 hours. When reused after adsorption, the Al-3.5-PDA needs to be regenerated at 102°C under a vacuum of 500 mbar for 16 hours. In all experiments, a consistent mass of 12 grams was used for each material.

2.2 The static tests

The formaldehyde removal efficiency of the three materials under static conditions was evaluated in a 500 L (780 mm × 800 mm × 800 mm) airtight environmental chamber maintained at a constant temperature of 25°C. The natural decay rate of formaldehyde in the chamber, in the absence of any test materials, was determined to be 0.013 h^{-1}. To achieve a high initial formaldehyde concentration, 2.5 mL of a 1000 mg/L formaldehyde standard solution was evenly dispensed into a glass dish positioned centrally within the chamber. A small heating pad placed beneath the glass dish was activated for 30 minutes to expedite the evaporation of the formaldehyde solution. Subsequently, the circulating fan within the chamber was turned on, and the formaldehyde solution was allowed to volatilize for an additional 2 hours. Once complete volatilization was confirmed, the initial formaldehyde concentration in the chamber was measured using the 3-methyl-2-benzothiazolinone hydrazide (MBTH) spectrophotometric method as recommended by Chinese national standard (GB/T 18204.26, 2002). The chamber door was then opened, and the test material was promptly placed on the stainless steel shelf at the center of the chamber before closing the door again. Formaldehyde concentrations were periodically sampled at the chamber outlet using a QC-3 pump (Beijing Institute of Labor Protection) operating at a flow rate of 0.3 L/min for 5 minutes. Measurements were conducted twice for each material to validate the robustness of the results.

2.3 The environmental chamber tests

A medium-density fiberboard (MDF) sample measuring 200 mm × 200 mm × 30 mm was initially evaluated in a 100 L dynamic environmental chamber at 23°C, 50% relative humidity, and an air

exchange rate of 1 h^{-1} for 150 hours to investigate the dynamic emission characteristics of the material. Subsequently, a second sample from the same MDF batch was tested under identical conditions in the presence of Al-3.5-PDA. By comparing formaldehyde concentrations between these two scenarios, the dynamic formaldehyde removal efficiency of Al-3.5-PDA in response to continuous emissions from building materials could be assessed.

2.4 Quality control and assurance

To determine formaldehyde concentrations, 0.4 mL of a 10 g/L ferric ammonium sulfate solution was added to the sampling tube. The tube was shaken and then incubated for 15 min, during which formaldehyde reacted with MBTH to form a blue cationic dye. The absorbance was measured at 630 nm using a spectrophotometer (Unic 7200, China). Formaldehyde quantification was performed based on standard calibration, yielding a calibration curve with ten data points and $R^2 > 0.99$. The detection limit of this method was 0.056 μg, and the recovery rate of formaldehyde ranged from 90% to 105%.

3. RESULTS AND DISCUSSIONS

3.1 Results of the static tests

The decay pattern of formaldehyde concentration and the removal efficiency of activated carbons, MnOx catalysts, and Al-3.5-PDA in static testing conditions are shown in Figure 2. There were some differences in concentrations between repeat measurements due to variations in the initial formaldehyde concentration in the chamber and the sampling time points throughout the measurement process. However, by comparing the removal rates at the same time points, the differences remained within 5% for most of the measurements, indicating the good repeatability of the experimental results.

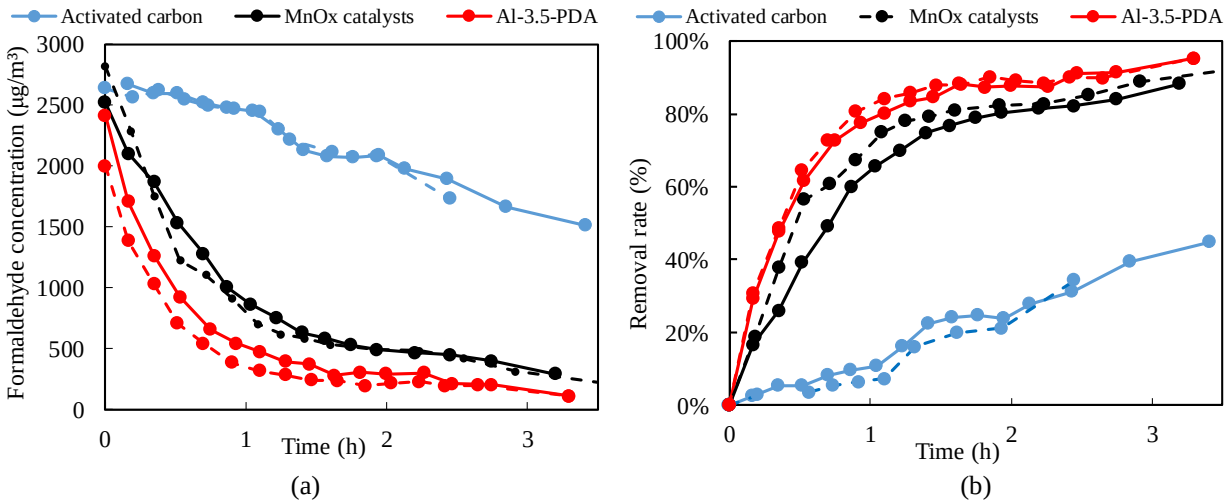

Figure 2. (a) The decay pattern of formaldehyde concentration and (b) the removal efficiency of activated carbon, MnOx, and Al-3.5-PDA in static testing conditions. The dashed and solid lines represent the two repeated measurements for each material.

In the presence of MnOx catalysts and Al-3.5-PDA, the formaldehyde concentration within the chamber decreased rapidly before stabilizing at a relatively low level. Specifically, one hour after introducing Al-3.5-PDA, the formaldehyde concentration dropped from an initial 2416.0 μg/m³ to

477.4 μg/m³, representing a reduction of 1938.6 μg/m³ (79.8%). The concentration then gradually decreased further, reaching 112.78 μg/m³ after 3.3 hours. Similarly, in the presence of MnOx catalysts, the formaldehyde concentration also decreased rapidly; one hour after introduction, it fell from an initial 2818.3 μg/m³ to 704.3 μg/m³, representing a reduction of 2114.0 μg/m³ (75.0%). After 3.6 hours of MnOx catalysts introduction, the concentration had further decreased to 208.0 μg/m³. In contrast, the rate of decrease was more gradual with activated carbons. The initial formaldehyde concentration was 2741.9 μg/m³ and decreased to 2449.9 μg/m³ one hour after introducing the activated carbons, representing a reduction of only 292.0 μg/m³ (10.6%). By 3.4 hours into the test, the concentration had decreased to 1513.78 μg/m³.

The removal rate of the materials was determined by comparing the concentration decay to the initial concentration. As illustrated in the figure, both Al-3.5-PDA and MnOx catalysts exhibited rapid increases in formaldehyde removal rates at the onset of the experiment, followed by gradual stabilization. Among the three materials, Al-3.5-PDA achieved the highest formaldehyde removal rate of 96.0% at 3.3 hours, demonstrating its superior performance in formaldehyde purification under static conditions. The trend for MnOx catalysts was similar to that of Al-3.5-PDA, with a removal rate of 92.6% at 3.6 hours, indicating effective purification albeit at a slightly slower rate compared to Al-3.5-PDA. In contrast, the formaldehyde removal rate of activated carbons increased steadily but at a relatively slower pace throughout the entire testing period, reaching 44.8% at 3.4 hours.

3.2 Results of the environmental chamber tests

Formaldehyde concentration in the dynamic environmental chamber of MDF with and without Al-3.5-PDA is illustrated in Figure 3. The presence of Al-3.5-PDA did not significantly alter the overall trend of formaldehyde concentration changes within the chamber, although it notably influenced the concentration levels. In both cases, formaldehyde concentration initially increased rapidly before stabilizing at a relatively constant level. However, during the later stages of emission, the formaldehyde concentration without Al-3.5-PDA exceeded 600 μg/m³, while with Al-3.5-PDA, it was maintained at approximately 200 μg/m³. This indicates that Al-3.5-PDA demonstrates effective formaldehyde adsorption capacity under dynamic testing conditions, maintaining a consistently stable adsorption rate. The removal rate of Al-3.5-PDA under this scenario was calculated by the concentration decay to that without Al-3.5-PDA. It could be figured out that the removal rate was between 60−70% during the dynamic testing, with an average value of 66%.

Overall, the formaldehyde removal rate of the Al-3.5-PDA in dynamic testing is lower than that observed in static testing. In static conditions, the environmental chamber remains sealed, enabling the Al-3.5-PDA to achieve prolonged and thorough contact with formaldehyde, thereby maximizing adsorption. Conversely, in dynamic testing, formaldehyde emission and adsorption occur concurrently. When the adsorption rate of the Al-3.5-PDA for formaldehyde is slower than the emission rate from the MDF, it becomes challenging to effectively reduce the formaldehyde concentration within the chamber, leading to a reduced removal rate in dynamic testing.

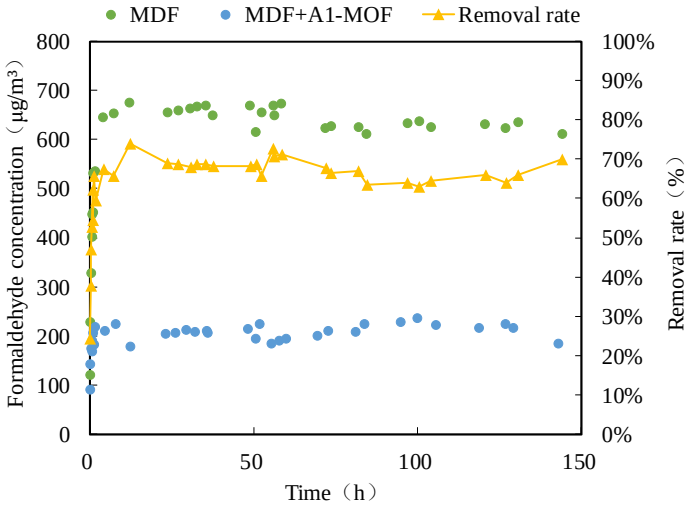

Figure 3. The variations of formaldehyde concentration and the removal efficiency of Al-3.5-PDA in dynamic environmental chamber testing conditions.

3.3 Limitation

While this study confirms the superior formaldehyde removal performance of Al-3.5-PDA, several limitations must be acknowledged to guide future research and practical deployment. First, the synthesis of Al-3.5-PDA depends on hydrothermal conditions and pyrazole dicarboxylate ligands, which may result in higher material costs compared to conventional activated carbons. Therefore, scalable production methods should be investigated to reduce manufacturing expenses. Second, although laboratory tests have shown high efficiency in controlled environments, integrating Al-3.5-PDA into real-world applications such as heating, ventilation, and air conditioning (HVAC) systems or portable air purifiers presents challenges, including optimizing pressure drop for MOF-coated filters and ensuring stability under fluctuating humidity and temperature conditions. Third, while Al-3.5-PDA demonstrates regenerability through water washing, its long-term cyclability (>10 cycles) in complex indoor environments—exposed to mixed pollutants such as volatile organic compounds (VOCs) and particulate matter—has yet to be tested. Future studies should focus on conducting field trials and performing cost-benefit analyses compared to commercial adsorbents to bridge the gap between laboratory innovation and industrial adoption. Addressing these limitations will enhance the potential of Al-3.5-PDA as a sustainable and energy-efficient solution for indoor air purification.

4. CONCLUSION

In this study, we assessed the formaldehyde removal efficiency of a newly developed MOF, activated carbons, and MnOx catalysts within a 500 L sealed environmental chamber. The results indicated that Al-3.5-PDA and MnOx catalysts achieved a removal efficiency of 96.0% and 92.6%, markedly higher than the 44.8% for activated carbons. Additionally, formaldehyde emissions from MDF were measured in a 100 L environmental chamber both in the presence and absence of Al-3.5-PDA. Under continuous emission conditions, Al-3.5-PDA maintained an average removal rate of approximately 66%, which is relatively lower compared to its performance under static conditions.

SUMMARY
This study investigates the impact of VPD regulation strategies on energy consumption in a commercial tomato greenhouse in Quebec, Canada. Three scenarios are simulated: Natural ventilation (NV) only, combined NV and mechanical dehumidification (MD), and MD only. Results show that while MD significantly improves VPD stability (75.27% satisfaction), it substantially increases energy consumption (1878.15 kWh/m²) compared to NV only (427.31 kWh/m²). The combined NV and MD strategy achieves a balance, improving VPD satisfaction (61.19%) with a moderate energy increase (1320.76 kWh/m²). This study highlights the critical trade-off between VPD control precision and energy efficiency, emphasizing the need for optimized control strategies and renewable energy integration for sustainable greenhouse operations in cold climates.

Keywords: VPD control, TRNSYS, Greenhouse, Regulation

1. INTRODUCTION

In recent years, controlled environment agriculture, particularly in greenhouses, has become a key strategy for optimizing crop productivity, especially for high-value crops like tomatoes. By controlling parameters such as temperature, humidity, ventilation, and vapor pressure deficit (VPD), greenhouses can create optimal growing conditions that enhance both crop quality and yield (Kempkes et al., 2017). However, while greenhouse environments are designed to support crop growth, balancing these environmental parameters can be energy-intensive, especially in cold-climate regions such as Quebec. Maintaining VPD within its optimal range, around 0.5 to 1.2 kPa is critical for maximizing plant transpiration and nutrient transport (Rahman et al., 2021; Shamshiri et al., 2018), while reducing disease risks that arise from excessive humidity or low VPD conditions (De Halleux & Gauthier, 1998).

Recent studies highlight the importance of VPD control in enhancing crop productivity and optimizing resource use in greenhouse environments. Gates et al. (Gates et al., 1998) developed strategies to implement VPD control for plant propagation, demonstrating how simultaneous manipulation of air temperature and humidity could be effectively achieved using low-cost chambers, with methods and logic applicable to broader systems. Lu et al. (Lu et al., 2015) studied the effects of a fogging system for VPD control during the winter season in greenhouses, showing that reducing VPD from 1.4 to 0.8 kPa enhanced tomato plant growth, stomatal function, and photosynthetic rates, ultimately increasing biomass and yield by 17.3% and 12.3%, respectively. Similarly, Zhang et al. (Zhang et al., 2017) explored VPD regulation to reduce plant water stress and improve water productivity in tomato plants, finding a 19.9% reduction in cumulative transpiration and significant improvements in irrigation water use efficiency, with yield gains of

up to 39.1% under low-VPD treatments. Noh and Lee (Noh & Lee, 2022) investigated VPD regulation with automated fogging systems, observing significant improvements in total yield, fruit count, and commercial yield—up to 89%—especially in crops grown in coconut fiber. These works collectively underscored the critical role of precise VPD management in achieving better plant growth, resource efficiency, and crop yield, forming the basis for advancing VPD-focused climate control strategies in modern greenhouses.

Despite advances in greenhouse climate control technologies, gaps remain in understanding the influence of VPD management on energy consumption. Existing research has often overlooked the direct impact of enhanced VPD control strategies on energy use. This gap is especially evident in cold regions, where greenhouse operations must contend with both extreme external temperatures and the challenge of maintaining humidity levels without excessively increasing heating energy demands.

Addressing these concerns, the present research focuses on evaluating the impact of VPD regulation on energy consumption, particularly through the development of a user-defined TRNSYS type for VPD control. This paper aims to fill this gap by analyzing and comparing different scenarios of VPD regulation in greenhouses, providing insights into both the energy demands and the cost implications of improving climate control precision.

2. METHODOLOGY

2.1. Greenhouse description

The data utilized in this study were obtained from a commercial greenhouse located in Saint-Jérôme, Quebec, Canada (45.77° N, 73.96° W). This facility, “Serres Royales”, is a specialized tomato-growing greenhouse consisting of eight connected spans. Each span measures 7.62 m in width, 121.92 m in length, and 6.40 m in height, resulting in a total cultivated area of approximately 5200 m^2 and a volumetric capacity of 50,000 m^3 (Fig. 1). The plant density is maintained at 2.8 plants per square meter to optimize growth conditions.

Dedicated to tomato production, the greenhouse operates from January to late November, capturing data across a range of climatic variations. To maintain a consistent and controlled temperature, radiant heating pipes are installed between each pair of plant rows within every span. This placement allows for uniform heat distribution and ensures optimal growing conditions throughout the cultivation period.

The greenhouse’s structure integrates a thermally efficient design, including a double-layer polyethylene roof with a 10 cm insulating air gap, enhancing energy conservation. The side walls combine polycarbonate panels for high light transmission and durability, while the lower portions consist of a polyurethane core enclosed between two metal sheets, offering superior insulation and mechanical strength.

For natural ventilation (NV) and humidity management, the greenhouse employs a mid-roof ventilation system. Each span is equipped with two automated roof panels that open partially or fully based on specific temperature and relative humidity thresholds. This ventilation setup ensures cooling and dehumidification when internal conditions exceed preset limits.

2.2. TRNSYS Model

The simulation framework for this study builds on a previously validated TRNSYS model developed to replicate the microclimatic dynamics of the studied greenhouse. The model considers one span out of eight to reduce computational time, with validation confirming satisfactory results

for this approach. It incorporates critical processes such as heating, CO_2 enrichment, condensation, and crop evapotranspiration, with the latter implemented using a custom TRNSYS type based on the Stanghellini model (Stanghellini, 1987). NV was integrated into the system through coupling with CONTAM, enabling precise modeling of airflow dynamics. The model's validation, performed in accordance with ASHRAE guidelines (Garrett & New, 2016), demonstrated its ability to accurately predict greenhouse environmental conditions under various scenarios.

Figure 1. Greenhouse dimensions.

For this study, the TRNSYS model was enhanced by integrating new features to assess VPD regulation. A new user-defined type was developed to implement a control strategy prioritizing NV over mechanical dehumidification (MD), combining energy efficiency with effective VPD control. A cooling coil system was added to represent a dehumidifier, selected with an airflow rate of 21 000 cfm, corresponding to the maximum ventilation rate in greenhouses of 0.01 $m^3/s/m^2$ (Jackson & Darby). The optimal temperature range, encompassing both day and night conditions, was set dynamically by agronomists between 14°C and 26°C which aligns with (Ruiz-Nieves et al., 2021). Fogging needs were evaluated and incorporated directly into the Type 56 model as a humidity gain, eliminating reliance on a separate humidifier type.
All simulations were conducted using hourly experimental weather data collected for the year 2022. This dataset provided a comprehensive representation of ambient conditions for the studied greenhouse, capturing the variability of environmental parameters across a complete annual cycle. By leveraging this extended and validated TRNSYS model, the study investigates the performance of the proposed control strategy across three scenarios, as detailed in the subsequent sections.

2.3 VPD control strategy Type development

The developed control strategy for this study operates based on a hierarchical logic designed to manage VPD effectively in the greenhouse while optimizing energy use. The strategy dynamically adjusts NV and MD depending on both indoor and outdoor environmental conditions, incorporating a precise interaction between temperature, humidity, and the operational states of the greenhouse systems. The Type controller takes as parameters VPDmin (0.5 kPa), VPDmax (1.2 kPa), Lock-ON (15 min) and Lock-OFF (15 min) which are the minimum and maximum optimal VPD values and the minimum run times for the ON and OFF operation cycles of the dehumidifier, respectively. Parameters have fixed values during the simulation but can be changed

by the user prior to the simulation. The Type considers as inputs, indoor parameters such temperature, relative humidity, absolute humidity, VPD, and the predefined ventilation setpoint set by agronomists. Outdoor parameters, such as temperature, relative humidity, and absolute humidity, serve as real-time inputs influencing the control logic. The outputs from the Type are ventilation signal, dehumidifier signal, relative humidity setpoint for dehumidifiers, and absolute humidity difference used for fogging.

The control process begins by assessing whether NV can be used to reduce humidity. The logic works as follows:
The vents are first activated if the indoor temperature exceeds the predefined ventilation setpoint and if outdoor conditions are suitable (i.e., outdoor temperature and VPD fall within an acceptable range). Vents open incrementally by 10%. The temperature is monitored for 1 hour following this opening (this duration can be adjusted by the user). If, after one hour, the temperature has not decreased or if the external temperature remains higher than indoor conditions, the vents are closed, and the dehumidifier signal is activated. To avoid "cold ventilation", the rapid entry of cold air causing temperature drops that affect plant transpiration, NV is avoided when the indoor temperature falls below 8°C, and vent opening is limited to 10% when the temperature is below 12°C. If NV is deemed ineffective, dehumidifiers are switched on to maintain the optimal indoor conditions.

An important aspect of this strategy is the dynamic adjustment of the relative humidity setpoint for the dehumidifier, based on the VPD. The strategy uses TRNSYS's moist air properties function to calculate the relative humidity at each timestep (5-minute step for simulation accuracy):

$$\begin{Bmatrix} if\ \ VPD < VPDmin\ \ \ Then\ RH_{set} = f(T_{in}, VPDmin) \\ \\ if\ VPD > VPDmax\ \ Then\ \ AH_{diff} = AH_{set} - AH_{int} \\ with\ \ AH_{set} = \ f(T_{in}, VPDmin) \end{Bmatrix}$$

The resultant humidity gain is added to Type 56 in the TRNSYS model, reflecting an increase in humidity within the greenhouse.

For accurate simulation of indoor climate dynamics, the model operates at a time-step of 5 minutes. This provides sufficient resolution for tracking rapid changes in temperature, humidity, and VPD, as well as for effective control of both NV and MD.

To evaluate the performance of the developed control strategy and its impact on maintaining optimal VPD, three distinct scenarios were simulated:

1- Scenario (a): NV only;
2- Scenario (b): Combined NV and MD;
3- Scenario (c): MD only;

3. RESULTS

3.1 Controller performance

Table 1 presents the monthly average, standard deviation, and minimum values of VPD across the three scenarios. While the average VPD remains within the optimal range ([0.5–1.2 kPa]) for all scenarios, the standard deviation is highest in Scenario (a) and decreases progressively in Scenarios (b) and (c). This trend highlights the increasing effectiveness of the control strategy in stabilizing VPD.

The minimum VPD values frequently reach 0 kPa, indicating periods of high relative humidity and potential condensation. However, in months where minimum VPD is above 0, the values increase noticeably with Scenarios (b) and (c), suggesting the positive impact of dehumidification in preventing saturation.

Additionally, the monthly percentage of time where VPD = 0 is relatively low across all scenarios but shows a clear decline in Scenarios (b) and (c). This further emphasizes the role of the control strategy and dehumidification in reducing excessive humidity and mitigating condensation risks.

Table 1. Monthly VPD Average (± standard deviation) and minimum.

Fig. 2 illustrates psychrometric behavior across three scenarios. Scenario (a), relying solely on NV, achieves 43.85% VPD satisfaction but lacks precision, leading to high variability. Scenario (b), combining NV with MD, improves satisfaction to 61.19% by mitigating NV's limitations, particularly when external air is unsuitable for dehumidification or cooling. MD enhances control, reducing VPD fluctuations. Scenario (c), using only MD, achieves the highest satisfaction at 75.27%, as cooling coils precisely regulate moisture independent of external conditions. While MD minimizes thermal stress and eliminates "cold ventilation" risks, it demands more energy, bypassing NV’s passive dehumidification potential. The data clustering below 26°C in (b) and (c) further highlights MD’s effectiveness in stabilizing VPD and reducing plant stress.

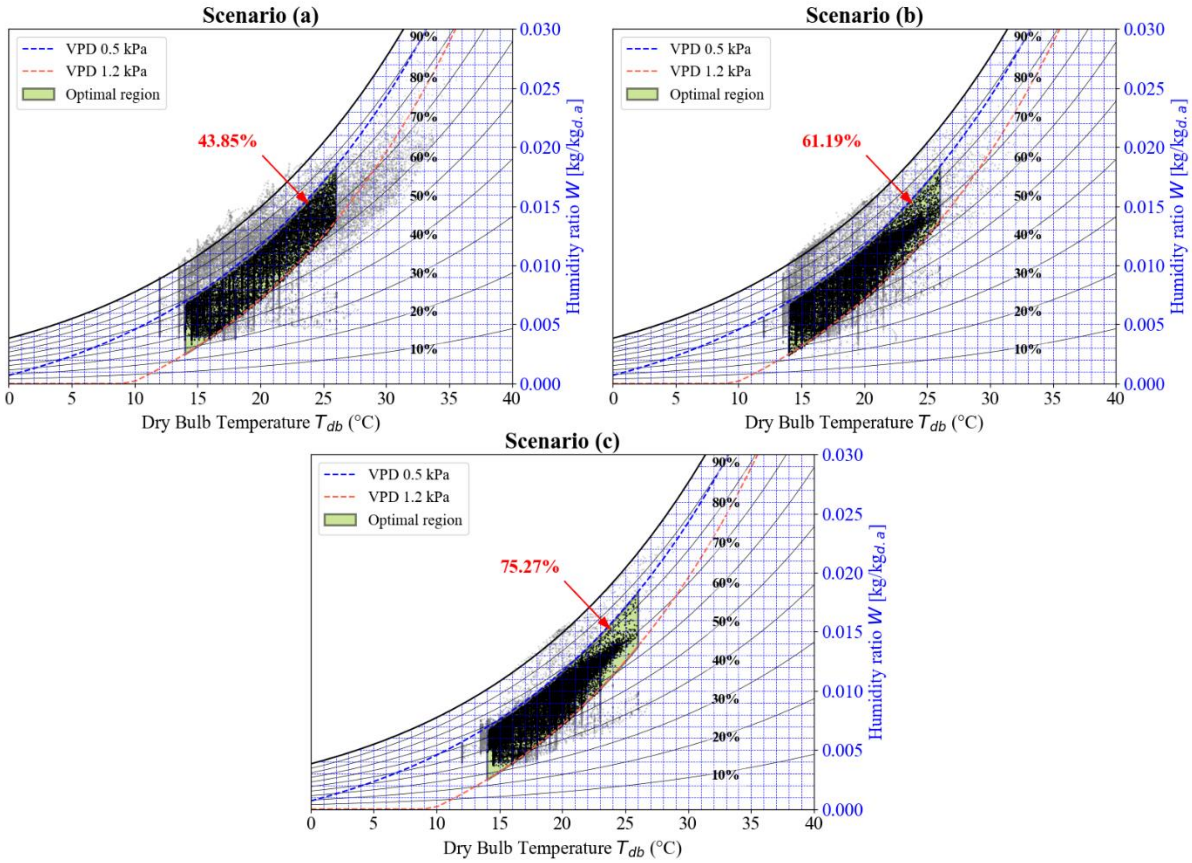

Figure 2. VPD distribution and optimal ranges for the 3 scenarios.

3.2 Energy use

Fig. 3 presents the energy consumption breakdown for heating and dehumidification across scenarios. In scenario (a), energy use is solely for heating, as no MD is involved. Despite lower total consumption, the lack of precise moisture control results in fewer optimal VPD values, potentially impacting yield and quality.

Scenario (b) introduces MD, increasing energy demand compared to (a), but remains more efficient than (c) by prioritizing NV when conditions allow. The dynamic RH setpoint ensures MD operates only as needed, reducing unnecessary energy use while improving environmental stability.

Scenario (c) has the highest energy consumption, relying entirely on MD for humidity control. While this ensures optimal VPD, it eliminates passive energy savings from NV, increasing operational costs and sustainability concerns. The rise in heating demand in (b) and (c) stems from MD's cooling effect, which requires additional heating to maintain suitable temperatures.

The energy use outlined in Table 2 shows that introducing mechanical dehumidifiers (as in scenarios b and c) drastically increases energy consumption, primarily due to the associated cooling and reheating demands to counter the dehumidification process. Transitioning from scenario (a) to scenario (b) increases energy consumption from 427 kWh/m² to 1320 kWh/m², tripling the energy use. Moving from scenario (b) to scenario (c) raises energy use further to

1878.15 kWh/m², an additional 42.3% increase. This suggests that improving VPD control leads to higher energy consumption, with diminishing returns in energy efficiency, thus resulting in increased operational costs. Based on the calculated energy use per percentage of VPD satisfaction, using Scenario (a) as the baseline, Scenario (b) shows 11.83 kWh/m²/%, while Scenario (c) uses 15.2 kWh/m²/%. This highlights that both Scenario (b) and Scenario (c) result in considerably higher energy consumption compared to Scenario (a), which relies solely on NV.

When estimating the operational costs based on Hydro-Québec's Tarif général G, the costs are 1267.2 $/ % for scenario (b) and 1627.7 $/ % for scenario (c).

This reinforces the finding that while precision control strategies like dehumidification and heating improve VPD satisfaction, they come at a significantly higher operational cost.

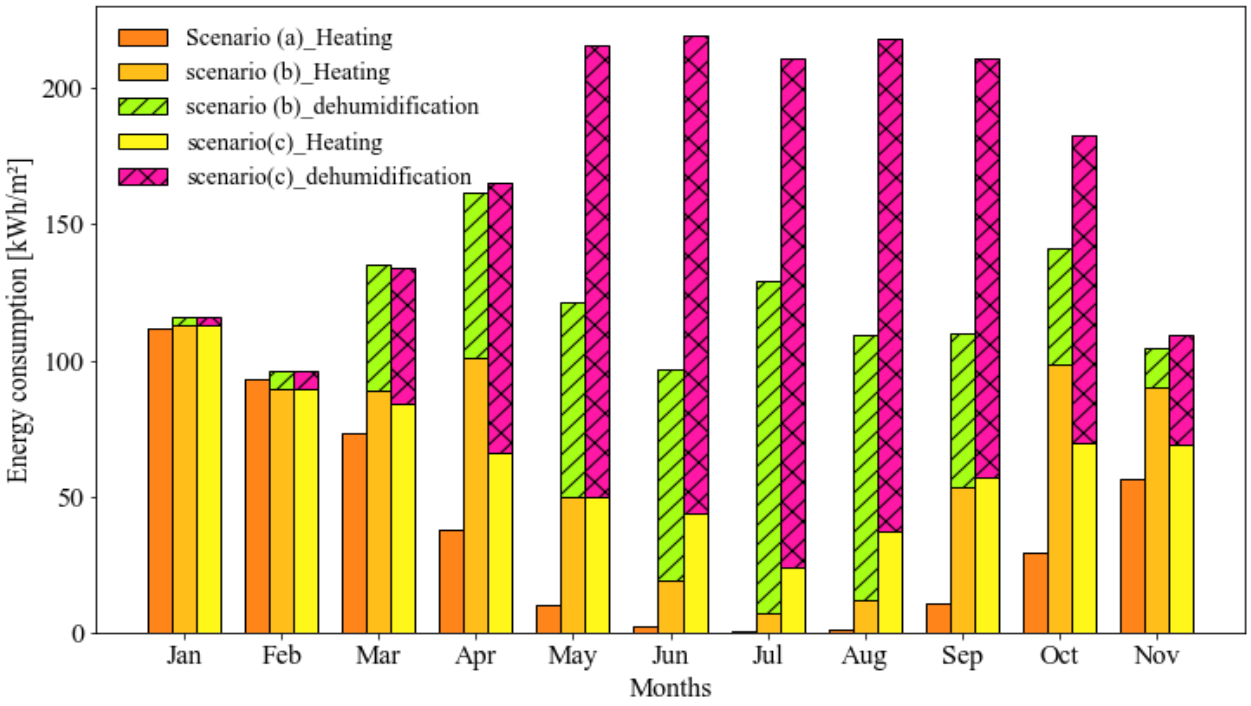

Figure 3. Monthly heating and dehumidification energy use comparison.

Table 2. Monthly and total energy consumption for the 3 scenarios.

	Energy consumption [kWh/m²]		
Month	Scenario (a)	Scenario (b)	Scenario (c)
January	111.65	115.90	116.10
February	93.39	95.87	95.87
March	73.22	135.12	134.05
April	37.88	161.51	165.00
May	10.28	121.47	215.68
June	2.30	96.49	219.12
July	0.63	129.17	211.09
August	1.26	109.30	218.08
September	10.82	110.15	211.07
October	29.21	141.29	182.88
November	56.68	104.50	109.20
Total	**427.31**	**1 320.76**	**1 878.15**

4. CONCLUSION

This study investigated the impact of VPD regulation on energy consumption in a commercial greenhouse. Three scenarios were simulated: NV only (43.85% VPD satisfaction), combined NV and MD (61.19% VPD satisfaction), and MD only (75.27% VPD satisfaction). While MD significantly improved VPD stability, it substantially increased energy consumption. The combined NV and MD strategy, prioritizing NV, achieved a balance, tripling energy use compared to NV only (427 kWh/m²) to 1320 kWh/m², while MD further increased it to 1878.15 kWh/m². This translates to operational costs of 1267.2 $/% and 1627.7 $/% for scenarios (b) and (c), respectively, compared to scenario (a).

Implementing advanced control algorithms, such as predictive control, could further refine the balance between energy use and environmental stability, reducing unnecessary dehumidification and heating demands.

SUMMARY
Due to climate change, extreme hot and cold weather events are becoming more frequent, intense, and prolonged. Pre-cooling has been suggested as a feasible solution, few studies have explored its potential to mitigate indoor overheating during heatwaves coinciding with power outages. In this study, an optimized pre-cooling strategy was developed using Bayesian Optimization to thermostat setpoint schedule by minimizing electricity cost and thermal discomfort. Two rule-based pre-cooling strategies and one baseline cooling strategy with no pre-cooling were compared. A prototype residential building was used to evaluate the performance of precooling strategies under a five-day heatwave scenario in Chengdu in 2022, coinciding with scheduled power outages. The results demonstrate that the optimized pre-cooling strategy can reduce approximately 78% of PMV exceedance hours compared to the rule-based strategies. Although its total electricity consumption was higher than that of the baseline and rule-based strategies, the optimized strategy achieved comparable or even lower electricity costs. This study highlights the potential of cost-effective pre-cooling strategies to enhance thermal resilience under extreme weather coincided with power outage.

Keywords: heatwave, pre-cooling, Bayesian Optimization, thermal resilience

1. INTRODUCTION

With climate change, extreme heatwaves have become more frequent, longer, and intense. The frequency of extreme heat events is projected to increase by 5–10 times by the end of the twenty-first century (Luber et al., 2008). The heatwave events have significant adverse effects on human health, energy consumption, and the economic, especially in light of projections indicating that the intensity and severity of climate change-related events will continue to escalate (Seneviratne et al. 2021). In addition, when a heatwave event occurs, the sustained abnormally high temperatures will lead to a surge in cooling electricity demand, resulting in power supply shortages and even grid failures. In the summer of 2022, the southwest region of China experienced unprecedented and prolonged heatwave, exceeding any observed in at least the past 63 years (Liang et al. 2024). This led to a historical peak in electricity demand. Due to power outages, many residential buildings had to suspend or limit air conditioning (AC) usage due to power outage, significantly increasing the heat risks for building occupants.

To enhance thermal resilience during heatwaves, pre-cooling can be an effective strategy to mitigate indoor overheating and reduce peak cooling electricity demand in buildings. This approach is typically implemented within the context of demand response (DR), achieved by lowering the thermostat setpoint below the conventional cooling setpoint before peak hours (Yin et al. 2010). During this period, the building's thermal mass stores cooling energy, which is then

gradually released during peak hours. This process allows for an increase in the cooling setpoint, helping to reduce peak cooling demand.

Numerous studies have been conducted to explore the performance of pre-cooling techniques in reducing power consumption and energy costs in buildings. Turner et al. evaluated the potential of pre-cooling to shift peak electricity loads during peak periods in residential buildings across 12 US climate zones (Turner et al., 2015). In their study, the optimal pre-cooling result was achieved with a 5-hour pre-cooling time and a setpoint temperature of 23.3°C, which shifted more than 75% of the peak load. Chen et al. conducted an experimental study to investigate the effects of a pre-cooling strategy, with the indoor temperature set to 22°C from 1:00 a.m. until it reached 26°C when DR occurred (Chen et al. 2020). The results indicated that chillers could be turned off for approximately 90 minutes without affecting thermal comfort. More recently, several studies have developed optimized pre-cooling control strategies to determine the optimal cooling setpoint schedule, aiming to maximize the trade-off between thermal comfort and energy costs (Wang et al. 2023; Zeng et al. 2022).

Previous studies have primarily focused on the effectiveness of pre-cooling strategies within the context of DR programs, aiming to reduce electricity load during peak hours, with air conditioning systems always in operation. Few studies, however, have explored the use of pre-cooling strategies in residential buildings to enhance thermal resilience during heatwave coincided with a power outage. In this context, pre-cooling is defined as lowering the indoor air temperature a few degrees below the conventional cooling setpoint prior to a power outage. The objective of this study is to mitigate the indoor overheating risks without increasing energy cost burden by implementing pre-cooling strategy. An optimized precooling strategy was developed using a Bayesian Optimization algorithm to determine the optimal setpoint and the starting time for pre-cooling. A prototype residential building located in Chengdu, China, was selected as the case study to evaluate the effectiveness of the proposed strategy based on simulation work.

2. METHODOLOGY

The aim of this study is to investigate the effect of pre-cooling strategies on reducing indoor overheating during extreme heatwaves combined with a power outage in a residential building. An optimized strategy is developed using Bayesian Optimization, which determines the optimal cooling setpoint and precooling start time by minimizing a composite objective function. The overview of methodology is shown in Fig. 1.

2.1. Weather data

In 2022, Chengdu experienced a long duration and intense heat wave from August 8 to August 24, marking the most severe heat wave events since 1961. To explore the impact of pre-cooling strategies under heat waves conditions, hourly weather data from August 8 to 12 were collected, when the daily maximum temperature exceeds 35℃. The meteorological data are from the ERA5 (the European Center Reanalysis version 5) dataset, which is the fifth generation of the Global Climate Reanalysis dataset produced by the European Centre for Medium-Range Weather Forecasts (ECMWF 2024). This dataset includes meteorological parameters such as atmospheric variables, radiative variables, precipitation variables, and offers meteorological information with a spatial resolution of 0.25° × 0.25° (about 31 km × 31 km) and an hourly temporal resolution.

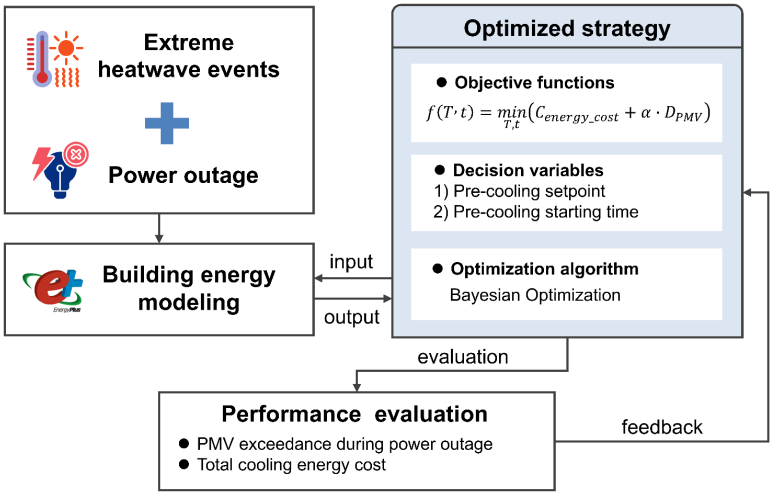

Figure 1. Overview of the methodology.

2.2. Building energy model

This study used a prototype high-rise residential building in Chengdu, China, where the climate zone is hot summer and cold winter. The building has a total floor area of 10,261 m^2 and includes 24 floors. The building geometry model is shown in Fig. 2. The case building consists of several types of zones, including residential bedrooms, living rooms, kitchen, and bathrooms. However, only the bedrooms and living rooms are equipped with air conditioners. In this study, a test living room located in the northwest corner of the standard floor was selected to evaluate the performance of the pre-cooling strategies. Solar radiation can enter into the room through exterior windows. The building envelope thermal properties were set based on the national standard of building energy efficiency of residential building released in 2010. The operating schedules of each household were determined based on the prototype building introduced in a previous study (Liu et al. 2024). Table 1 lists the key simulation parameters.

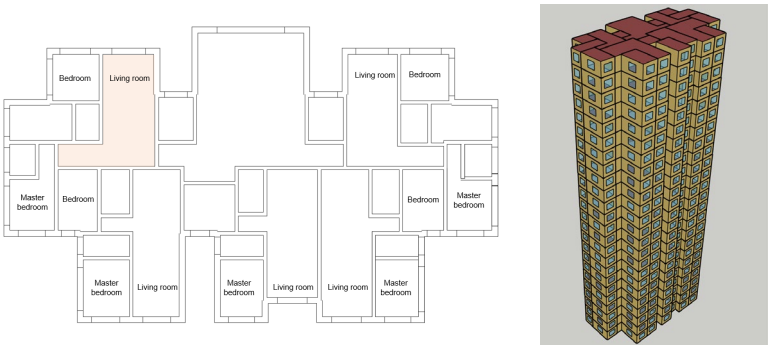

Figure 2. Building geometric model.

Table 1. Key parameters for building energy modeling.

Parameters	Value
Average window-to-wall ratio	0.27
U-value of exterior wall /W/(m^2·K)	0.8
U-factor exterior window /W/ (m^2·K)	3.0
U-value of roof /W/ (m^2·K)	1.0
Window SHGC	0.3

Lighting power density /W/m^2	5.0
Equipment power density /W/m^2	9.0
Air conditioner COP	2.75
Infiltration /ACH	0.6

The AC capacity for each conditioned room was autosized using the EnergyPlus model, as actual equipment capacity data was unavailable. Once the AC capacities were determined, pre-cooling strategies were implemented based on these capacities. Furthermore, the internal thermal mass was set by using *InternalMass* object and *ZoneCapacitanceMultiplier:ResearchSpecial* object recommended by a previous study (Chen et al. 2022). The setting of internal thermal mass was 196 kJ/(m^2·K), and the surface area was 2 times of the floor area. The Zone Capacitance Multiplier C_T was set as 2.

To calibrate the building energy model, the hourly indoor air temperature of a living room in Chengdu was recorded from October 15th to November 15th, during which the room operated in free-running mode. The root mean square error (RMSE) of the calibration was 0.8°C, which is below the required 1.5°C threshold (Donovan et al., 2019).

2.3. Pre-cooling strategies

The pre-cooling strategies were applied to a real five-day heatwave event that coincided with a power outage in 2022. The power outage during the heatwave occurred from 7:00 a.m. to 1:00 p.m., which was reported by the website of Sichuan Power Grid Corporation and sourced from its official website.

2.3.1. Optimized strategy

To optimize the pre-cooling strategy of a residential thermal zone during summer mornings, a multi-objective optimization problem was formulated aimed at minimizing energy costs and thermal discomfort. The decision variables include the pre-cooling setpoint temperature and the pre-cooling start time. Once pre-cooling began, the air conditioner operated continuously until the power outage began, maintaining a constant thermostat setpoint to maximize thermal storage. The optimization was implemented using a simulation-based approach integrated with EnergyPlus. The objective function is defined as:

$$f(T,t) = \min_{T,t}(C_{energy_cost} + \alpha \cdot D_{PMV}) \quad (1)$$

Where T and t are decision variables; T denotes the pre-cooling temperature setpoint (°C), constrained between 20.0°C and 26.0°C, with a resolution of 0.5°C; t represents the start time of pre-cooling, ranging from 1:00 a.m. to 7:00 a.m., with a resolution of 0.5 hour; C_{energy_cost} is the total electricity cost (in CNY) during the heatwave event, calculated based on hourly time-of-use (TOU) pricing; D_{PMV} is the accumulated thermal discomfort defined as the sum of the predicted mean vote (PMV) exceedances above 0.7 during 7:00 a.m. – 1:00 p.m.; α is a weighting factor to normalize the discomfort penalty relative to energy cost. In this study, α was set to 0.1, as the typical magnitude of D_{PMV} was approximately ten times greater than that of C_{energy_cost}. Regarding the cooling electricity cost, it is calculated based on the real-time TOU tariff in Chengdu during the summer of 2022. The off-peak rate of 0.239 CNY/kWh is applied from 23:00 to 7:00. A mid-peak rate of 0.497 CNY/kWh is used during 7:00–14:00 and 21:00–23:00. The on-peak period, corresponding to the highest rate of 0.754 CNY/kWh, occurs between 14:00 and 21:00.

Given the high computational cost of dynamic building energy simulations, Bayesian Optimization (BO) was adopted to efficiently search for the optimal decision variables. BO is well suited for problems involving expensive black-box functions, as it builds a probabilistic surrogate model of the objective function. This study employed BO algorithm using Gaussian Process regression as the surrogate model and the Expected Improvement acquisition function for sampling. In this study, BayesianOptimization Python package was utilized for implementing BO algorithm. The BO process was initialized with 20 randomly sampled points to fit the initial surrogate model. Subsequent iterations used the EI acquisition function to propose the next input combination, which was then evaluated by running an EnergyPlus simulation and calculating the corresponding objective value. This study conducted 100 iterations in total to determine the decision variables.

2.3.3. Benchmarking of the optimized precooling strategy

Two rule-based setpoint temperature scenarios were designed as benchmarks for evaluating the optimized precooling strategy, as illustrated in Fig. 3. Scenario 1 adopted a rule-based pre-cooling schedule in which the AC operated from 0:00 a.m. to 7:00 a.m. with a cooling setpoint of 24°C. Scenario 2 used a schedule from 3:00 a.m. to 7:00 a.m. with a setpoint of 20°C. The Baseline scenario represents a situation with no pre-cooling, where the AC operates from 1:00 p.m. to 9:00 p.m. with a cooling setpoint of 25°C. The optimized strategy identified through BO algorithm operated AC from 0:00 a.m. to 7:00 a.m., with a cooling setpoint of 21.5°C.

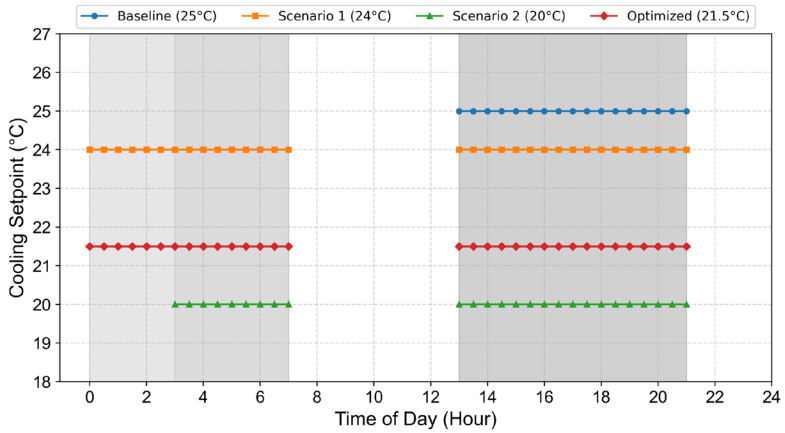

Figure 3. The schedules of four cooling strategies. The gray shade areas indicate the periods when AC is on, while unshaded areas indicate it is off.

3. RESULTS AND DISCUSSION

3.1. Indoor air temperature and overheating

Fig. 4 demonstrates the indoor air temperature profiles under four different cooling strategies during the heatwave. During each day, a power outage occurred from 7:00 a.m. to 1:00 p.m., during which no active cooling was available. As shown in the figure, the baseline strategy results in a significant temperature rise during the outage period, with peak indoor temperatures exceeding 28°C. In contrast, the optimized strategy successfully mitigates this temperature rise through effective the nighttime pre-cooling, maintaining indoor temperatures below 27°C during the outage periods. Scenario 1 and Scenario 2, which represent rule-based pre-cooling strategies, provide partial mitigation but are less effective than the optimized approach. These results indicate the potential of the optimized pre-cooling strategy in enhancing thermal resilience during heatwave coinciding with power outages.

It can also be noted that, although the pre-cooling setpoint for Scenario 2 was 20°C, the indoor air temperature did not consistently reach this setpoint and only approached approximately 22°C. This is mainly because the room air conditioning equipment was selected based on a set temperature of 25°C under typical meteorological conditions, without considering heatwave scenarios. As a result, during the heatwave events in this study, the capacity of the room air conditioning equipment was insufficient to quickly cool the living room.

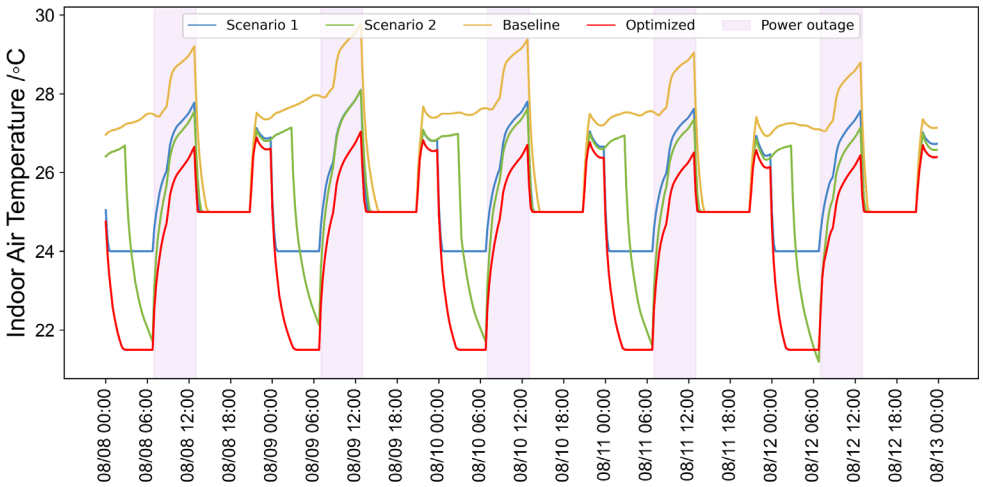

Figure 4. The indoor air temperature of the four cooling strategies during the heatwave.

Table 2 summarizes the accumulated thermal discomfort during the heatwave, measured as the total number of hours in which the predicted mean vote (PMV) exceeded the comfort threshold. The baseline scenario exhibits the highest level of discomfort, with 32 hours of exceedance. In contrast, Scenario 1 and Scenario 2 reduces the exceedance hours to 19 and 17, respectively, indicating an improvement in indoor thermal comfort. Notably, the optimized strategy demonstrates the best performance, reducing PMV exceedance to only 3 hours, which corresponds to an approximate 78% reduction compared to the rule-based strategies and 87% reduction compared to the baseline. This result highlights the effectiveness of the optimization-based approach in significantly enhancing indoor thermal conditions during extreme heat events.

Table 2. Indoor overheating risks of the four strategies.

Strategy	Hours of PMV exceedance
Scenario 1	19
Scenario 2	17
Baseline	32
Optimized	3

3.2. Energy consumption and cost

The hourly cooling electricity consumption profiles of the four cooling strategies was shown in Fig. 5, and the total electricity consumption and cost during the heatwave were also calculated and given in Table 3. In pre-cooling scenarios, two peaks in electricity consumption occur: one during the night and the other during the daytime. The night peak corresponds to the start of the pre-

cooling process, while the daytime peak marks the initiation of cooling after the power outage. The baseline strategy shows the highest cooling electricity during afternoon hours, primarily due to the accumulation of indoor heat gain. Scenario 1 and Scenario 2 achieve partial load shifting to earlier hours, thereby reducing peak demand during outage recovery periods. The optimized strategy has the lowest electricity consumption during the afternoon, indicating a more effective utilization of building thermal inertia.

Regarding cooling electricity consumption, although the baseline scenario exhibits the lowest total energy use of 21.8 kWh, its electricity cost is not the lowest due to the concentration of AC operating during more expensive mid- and peak-price periods. In contrast, the electricity cost of Scenario 1, 2 and optimized strategy are 14.9, 16.2 and 15.0CNY, respectively, indicating that the implementation of pre-cooling strategies does not lead to a significant increase in cooling electricity expenses. This is because the optimized strategy takes advantage of lower TOU electricity prices by shifting the cooling load to nighttime hours.

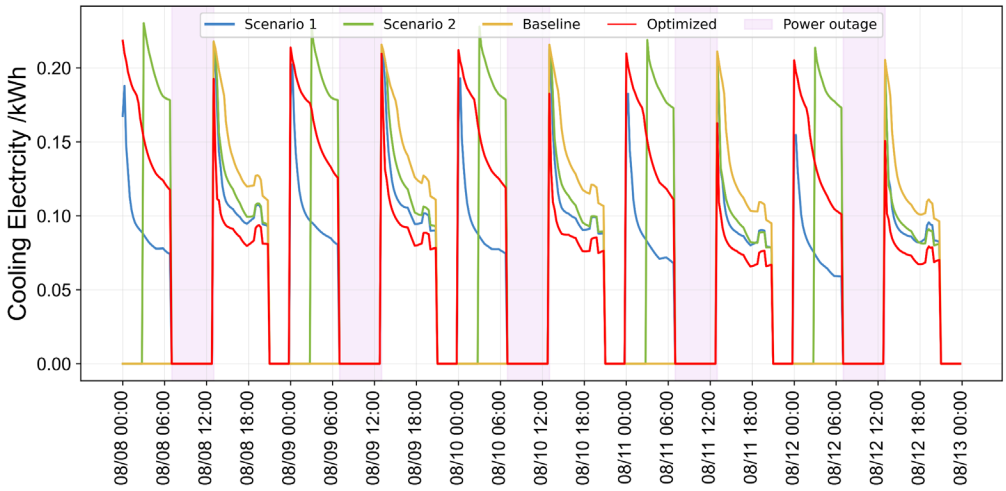

Figure 5. The cooling consumption of the four cooling scenarios during the heatwave.

Table 3. Electricity consumption and cost of the four strategies.

Scenario	Electricity consumption (kWh)	Electricity cost (CNY)
Scenario 1	30.0	14.9
Scenario 2	33.2	16.2
Baseline	21.8	15.4
Optimized	35.4	15.0

4. CONCLUSIONS

This study evaluated the performance of the optimized pre-cooling strategy developed by Bayesian Optimization algorithm, focusing on their impacts on indoor thermal comfort, electricity consumption, and cost. Two rule-based pre-cooling strategies and one baseline strategy with no pre-cooling were used as benchmarks. A prototype residential building in Chengdu, under a real five-day heatwave coincided with a power outage, was selected as a case study. Results showed

that the optimized strategy significantly outperformed the other cooling strategies, reducing PMV exceedance hours by approximately 78% compared to the rule-based precooling strategies and by 87% compared to the baseline, without increasing the energy cost burden. Although its total electricity consumption was higher than that of the baseline and rule-based strategies, the optimized strategy achieved comparable or even lower electricity costs by shifting cooling load to nighttime hours. These findings highlight the potential of the optimized pre-cooling strategy in improving the thermal resilience of residential cooling systems under extreme heatwaves.
Future work will explore the integration of passive design strategies with pre-cooling to further enhance and evaluate its potential for mitigating indoor overheating.

URBAN GENERATION: optimising the design of NBS for climate change adaptation

Francesca Mosca [1], Katia Perini [2]

[1]*University of Genoa, Genoa, Italy, francesca.mosca@edu.unige.it*

SUMMARY
Urban areas are facing different challenges related to the increase in population, land use and greenhouse gases emissions. The subsequent environmental degradation requires the implementation of a new set of planning and design strategies to improve liveability and reduce the vulnerability of cities. Nature-based Solutions (NBS) constitute one of the most promising strategies among the regenerative tools currently available. The occurrence of the urban heat island effect is one of the most relevant challenges, due to the direct impact on ecosystems and on human health. NBS can play a key role in improving urban microclimatic conditions due to their capacity to provide shade and the evapotranspiration processes, driven by the radiative properties of plants. The URBAN GENERATION project aims to develop a computational design approach to optimise the definition of mitigation and adaptation to climate change, particularly concerning the reduction of the urban heat island effect.

Keywords: climate adaptation, nature-based solutions, design optimisation.

EXTENDED ABSTRACT

Introduction

The urban environment is characterized by several challenges due to anthropic activities, on top of which climate change is widely recognized as one of the most critical aspects (Rosenzweig et al., 2018). In addition, the effects of climate change are constantly increasing over time, resulting in extreme events and related high vulnerability for urban infrastructures and citizens (Füssel et al., 2017). Urban areas main challenges include vulnerability to climate change effects and the increase in the frequency and entity of extreme events, as well as reduced ecosystem health and related ecosystem services production, and the environmental harm they themselves cause (Thomas et al., 2019). The urban heat island effect and the increase in global temperatures is particularly relevant, due to the consequent increase in energy consumption for cooling and the heat-related risks for human health (Jain et al., 2022).
Given the relevance of the topic, design and planning solutions should focus on the implementation of adaptation strategies to improve the liveability of urban areas. Nature-based solutions (NBS), defined as solutions inspired by nature and its processes (Castellar et al., 2021), play a crucial role in climate change adaptation and enhancing the overall environmental quality of densely populated urban areas (Mosca et al., 2023). In order to ensure the effectiveness of NBS, it is particularly important to measure and quantify their site-specific performances (Kamari et al., 2021). Different methods can be applied, such as field measurement, however, computational tools constitute one of the most promising methods, due to the potential application at early design stages and without

the need for real mock-ups, allowing the quantification of the performance before the construction of the design solution (Peters & Peters, 2018).
Several simulation and computational tools have been developed during the last years to allow designers to assess the performances of buildings and NBS in terms of energy consumption but also in terms of impact on microclimate (Manso et al., 2021; Perini et al., 2022). However, a systematic approach to understand and evaluate the synergies and trade-offs between the urban context and different design solutions in terms of climate change mitigation and adaptation is still missing.
The URBAN GENERATION project aims at developing a comprehensive design approach to include both mitigation and adaptation strategies into urban and building design processes to optimise the performance of different design solutions.
Focusing on the support of NBS in achieving climate change adaptation in terms of microclimate regulation, an operative methodology has been defined, to provide designers and policy makers knowledge and tools to optimise the performance of their solutions (Perini & Mosca, 2024).

Methodology
In order to develop and test the design approach, we simulate a wide range of NBS in different urban contexts/scales, being able to quantify the effects of vegetation on microclimate to improve thermal comfort (adaptation action) and, consequently, reduce the energy consumption of buildings (mitigation action). Firstly, we focus on urban canyon to generalize the results; it is defined as a theoretical flat site, with two standard buildings and an empty area in between. Secondly, a set of NBS well-known for their microclimatic performance are selected and modelled (Fig. 1): in particular, groups of trees with different crown shapes (spherical, conical, vase, columnar and vertical oval crowns) and dimensional order (1st class height >16m, 2nd class height 10m<h<16m, 3rd class height h<10m). Specifically, trees have been selected as the most relevant land-media NBS in terms of microclimate regulation according to literature (Mosca et al., 2025).

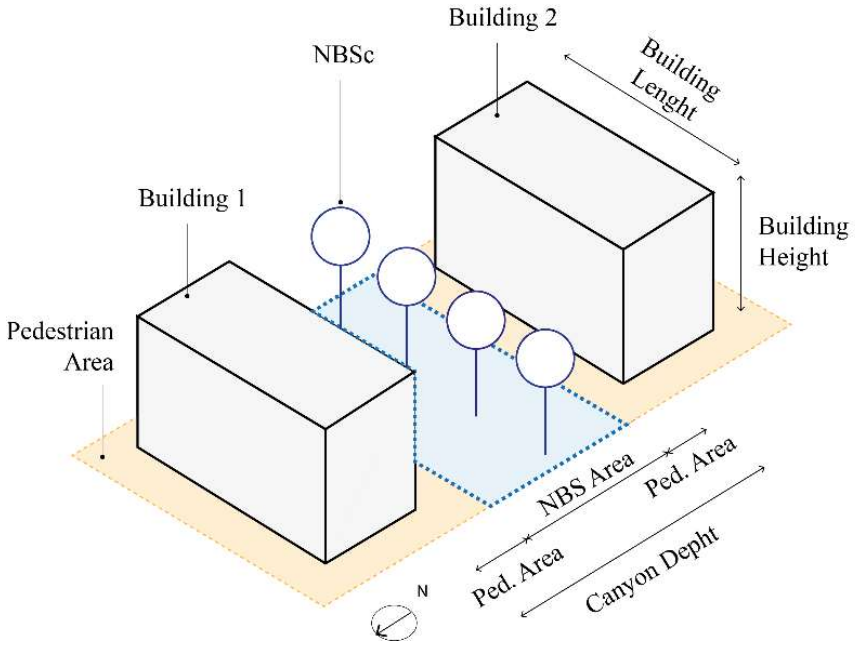

Figure 1. Definition of Urban Canyon and NBS parameters for the simulations.

By varying the geometrical parameters and NBS types, we can identify correlations between NBS performances and urban canyon configuration. To do so, the methodology includes an optimization process running on a wide range of simulations to support the design process focused on microclimate regulation. The workflow takes into account also the role of NBS cooling capacity in reducing energy consumption for air conditioning.

Results and future developments

Currently, 16 configurations of NBS type and trees typologies are simulated for two case studies cities in Italy, considering different geographical and climatic conditions (Genoa and Turin). The NBS and urban canyon configurations simulated are the same for both locations, while latitude and weather parameters vary. Fig. 2 shows the operative workflow and the related application on one of the configurations defined. The results from each package of simulations are exported as .csv files, collecting output data related to each configuration. In particular, the most relevant parameters are related to the NBS features (e.g. type and number of trees) and microclimatic conditions (e.g. Mean Radiant Temperature and percentage of shading provided on the urban canyon). Based on the results, a database made of the output data is build and used for a multi-objective optimization process, which aims at identifying the most performing NBS configuration in relation to the urban canyon geometry.

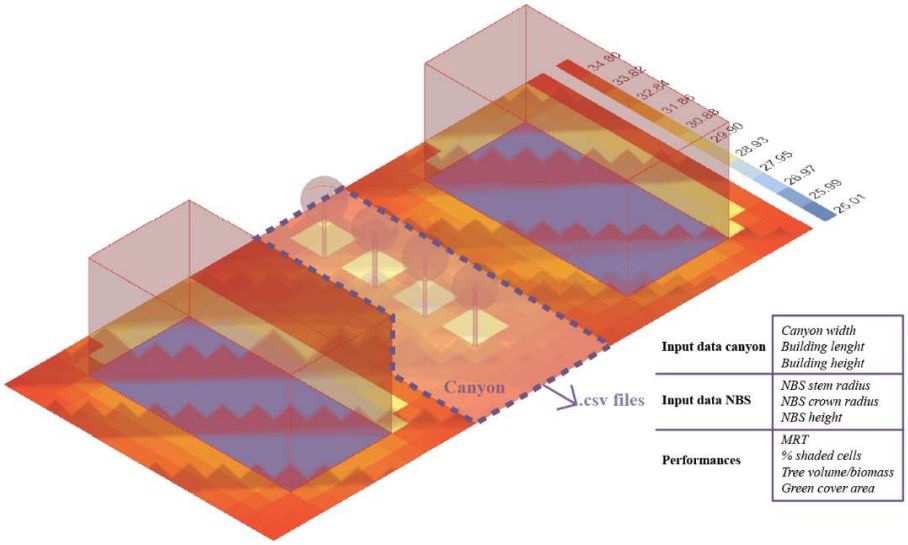

Figure 2. Example of simulation output and related data for the optimization.

The potentials and limitations of the selected tool has been widely deepen in literature, however, the main aim of this experiment is to reduce the need for CFD simulations at early design stages, allowing the definition of the best-performing NBS configuration depending on geographical and climatic conditions. Future developments include the application of the methodology to more sites/cities to acquire data on the microclimatic performances of NBS in relation to different geographical and climatic conditions. Based on the results from this study, a set of correlations

between urban conditions and NBS can be derived and generalized, through the use of machine-learning methodologies (linear regression, random forest). This approach will allow informing the urban design process without the need to run specific microclimatic simulations, supporting urban policies for climate change adaptation.

ACKNOWLEDGEMENTS

The presented research is part of the URBAN GENERATION project (PRIN PNRR 2022 program - CUP D53D23020090001), funded by the Italian Research Ministry. The project consortium consists of researchers from University of Genoa, Polytechnic School of Turin and the CIMA Research Foundation.

Numerical risk assessment of first and second-hand exposure to group 1 hazardous chemicals generated by e-cigarette smoking using coupled CFD-PBPK model

Kazuki Kuga [1], Kazuhide Ito [2]

[1]*Kyushu University, Kasuga, Japan, kuga@kyudai.jp*
[2]*Kyushu University, Kasuga, Japan, ito@kyudai.jp*

SUMMARY
Electronic cigarettes (e-cigarettes) are considered less harmful than conventional cigarettes due to the absence of combustion; however, harmful chemical substances are generated during vaporization. This study employed a numerical airway model replicating the geometry from the nasal and oral cavities to the 13th bronchial bifurcation, integrating computational fluid dynamics (CFD) with a physiologically based pharmacokinetic (PBPK) model. The study quantitatively analyzed first-hand exposure during inhalation, the dispersion of exhaled chemicals in indoor environments, and second-hand exposure to non-smokers. Formaldehyde, acetaldehyde, acrolein, benzene, toluene, glycerol, and nicotine were examined. The findings revealed varying deposition rates in the upper airways, with nasal exhalation increasing absorption by 4-9%. Second-hand exposure was affected by spatial positioning and airflow patterns, emphasizing the need for further assessment of e-cigarette-related health risks.
Keywords: CFD, PBPK, e-cigarette, numerical airway model.

1. INTRODUCTION

Electronic cigarettes (e-cigarettes) have gained significant attention worldwide due to the misconception that they are safe for human health in terms of first-, second-, and third-hand exposure to smoking. E-cigarettes are portable devices designed to vaporize "e-liquid," which contains various chemicals. While they do not rely on tobacco combustion, they are often perceived as less harmful than traditional smoking. However, despite the non-combustion process, the vapor they produce can still contain pollutants resulting from chemical reactions in the e-liquid. Beyond the direct inhalation associated with first-hand smoking, the exhaled vapor from e-cigarette users introduces a new source of pollutants that can impact indoor air quality. As a result, developing a numerical prediction method to assess the health risks of e-cigarette vapor exposure in both the human respiratory tract (first-hand exposure) and indoor environments (second-hand exposure) is critical. This study aims to provide a qualitative and quantitative evaluation of e-cigarette vapor exposure in the human respiratory tract using coupled CFD–PBPK analysis.

2. METHODOLOGY

2.1. Numerical Airway model and Room model

A numerical airway model was developed based on the CT data of a 30-year-old male, accurately replicating the geometry from the nasal and oral cavities to the 13th bronchial bifurcation (Corley et al., 2021, Kabilan et al., 2016). The model consisted of 273 bronchial outlets, ensuring detailed anatomical representation. A high-resolution mesh was created to maintain wall unit y+ values

below 1, optimizing accuracy in CFD simulations. To simulate e-cigarette inhalation, a circular opening with 8.0 mm diameter was placed at the mouth opening. The model enabled the analysis of inhaled pollutant distribution and deposition dynamics, providing a foundation for integrating the PBPK model. A scenario involving secondary exposure was simulated by integrating the numerical airway model into a simplified indoor environment. This indoor space was modeled as a room with a volume of 27 m^3, where two numerical human models (Computational Simulated Persons, CSPs) were positioned facing each other to replicate a typical face-to-face interaction scenario. This setup allowed for the evaluation of pollutant transport from the initial inhalation of e-cigarette vapor through exhalation and dispersion within the indoor space and finally to the secondary exposure of the non-smoking individual. The room was designed with displacement ventilation, featuring two openings: an inlet at the upper front wall and an outlet at the lower rear wall, both measuring 0.3 m × 0.3 m.

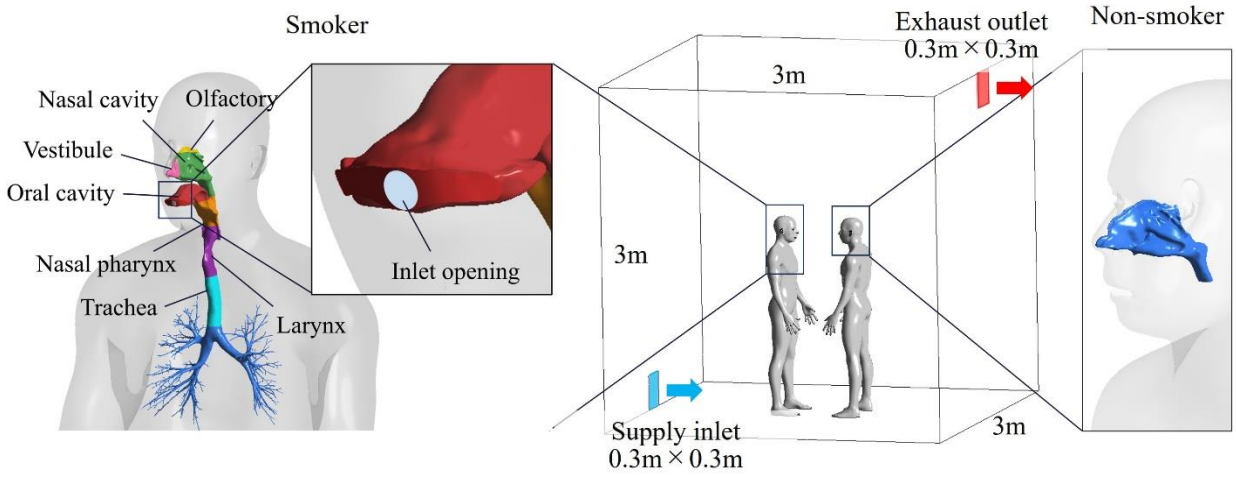

Figure 1. Numerical airway model and room model

2.2. Coupled CFD-PBPK model

The PBPK model was incorporated to simulate the diffusion of inhaled pollutants across the mucus layer, epithelial cells, and subepithelial tissues. Seven key pollutants—formaldehyde, acetaldehyde, acrolein, benzene, toluene, glycerol, and nicotine—were analyzed. The model accounted for chemical absorption through airway walls, enhancing the understanding of pollutant retention and translocation within respiratory tissues. The PBPK model was integrated into the airway geometry, allowing coupled CFD-PBPK simulations to evaluate pollutant behavior under different inhalation and exhalation conditions. The concept and governing equations of the coupled CFD-PBPK analyses are shown in Figure 2.

2.3. Setup for Numerical Simulation of First and Second-hand Exposure

Primary exposure analysis was conducted using only the numerical airway model to simulate the inhalation and exhalation of e-cigarette aerosols. The inhaled concentrations of the selected pollutants were set as follows: formaldehyde (0.70 μg/mL), acetaldehyde (0.22 μg/mL), acrolein (0.02 μg/mL), benzene (1.6 × 10 μg/mL), toluene (3.1 × 10 μg/mL), glycerol (33.2 μg/mL), and nicotine (0.27 μg/mL). During exhalation, it was assumed that the air returning from the lungs to the bronchial region was completely free of pollutants. The CFD-PBPK model was applied to the

airway walls, and simulations were performed for two exhalation methods: oral exhalation and nasal exhalation. The spatial distribution of pollutant concentrations within the airway during exhalation was analyzed accordingly. For the second-hand exposure analysis in the room, fresh air was supplied at a velocity of 0.05 m/s. To account for human thermal effects, each CSP was equipped with Fanger's thermo-regulation model. Furthermore, PBPK models were applied not only to the airway walls but also to the skin and ocular surfaces of the CSPs to evaluate the absorption of pollutants through these additional exposure pathways. Simultaneous simulations of inhalation, dermal, and ocular exposure were performed to provide a comprehensive assessment of the diffusion and absorption dynamics of e-cigarette vapor in the room.

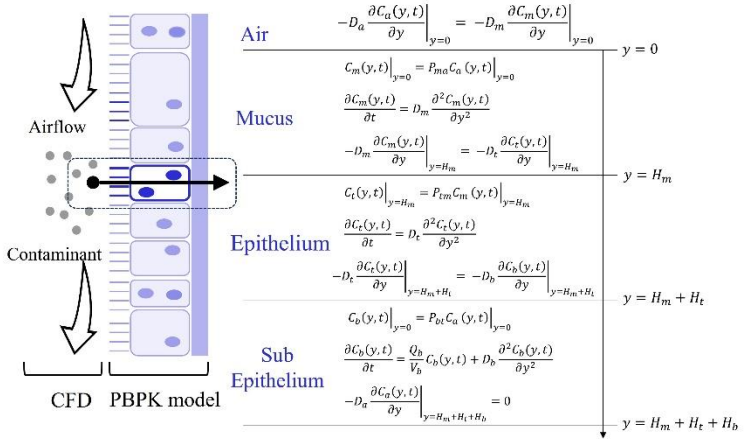

Figure 2. Concept of coupled CFD-PBPK model

3. RESULTS AND DISCUSSIONS

Fig. 3a shows the normalized concentration distributions of formaldehyde, nicotine, and acrolein within the airway model at the end of inhalation. The concentration distributions were found to be heterogeneous, with noticeable differences in deposition near the oral cavity and pharyngeal region depending on the pollutant. This indicates that each pollutant exhibited distinct upper airway distributions due to variations in adsorption along the mucosal surfaces. The absorption rates of all pollutants into the airway walls, calculated as the ratio of absorbed mass to inhaled mass, are shown in Fig. 3b. The results reveal that nasal exhalation led to an increase in absorption rates by approximately 4–9% for all pollutants compared to oral exhalation. This increase is attributed to the elevated absorption flux into the nasal mucosal surfaces during exhalation, which enhances retention within the nasal cavity. The initial indoor airflow field in the exposure risk analysis incorporating the CSPs is shown in Fig. 3c. Since displacement ventilation was assumed in this analysis, thermal plumes formed around the human body. This thermal environment significantly influenced the transport and dispersion of exhaled pollutants in the indoor space. The temporal variation of formaldehyde concentration exhaled by the smoker is illustrated in Fig. 3d. The exhaled pollutants were diluted in the ambient air and reached the chest area of the facing nonsmoker within approximately 2.5 seconds. Subsequently, the pollutants were lifted into the breathing zone of the nonsmoker due to the thermal plume generated by body heat. Previous studies on secondary exposure have often assumed that pollutants exhaled from the oral cavity travel directly from the smoker's mouth to the nonsmoker. However, in this study, by incorporating realistic oral cavity geometry and conducting a continuous analysis from primary to secondary exposure, it was observed that the exhaled pollutants were initially transported diagonally downward due to the specific shape of the oral cavity.

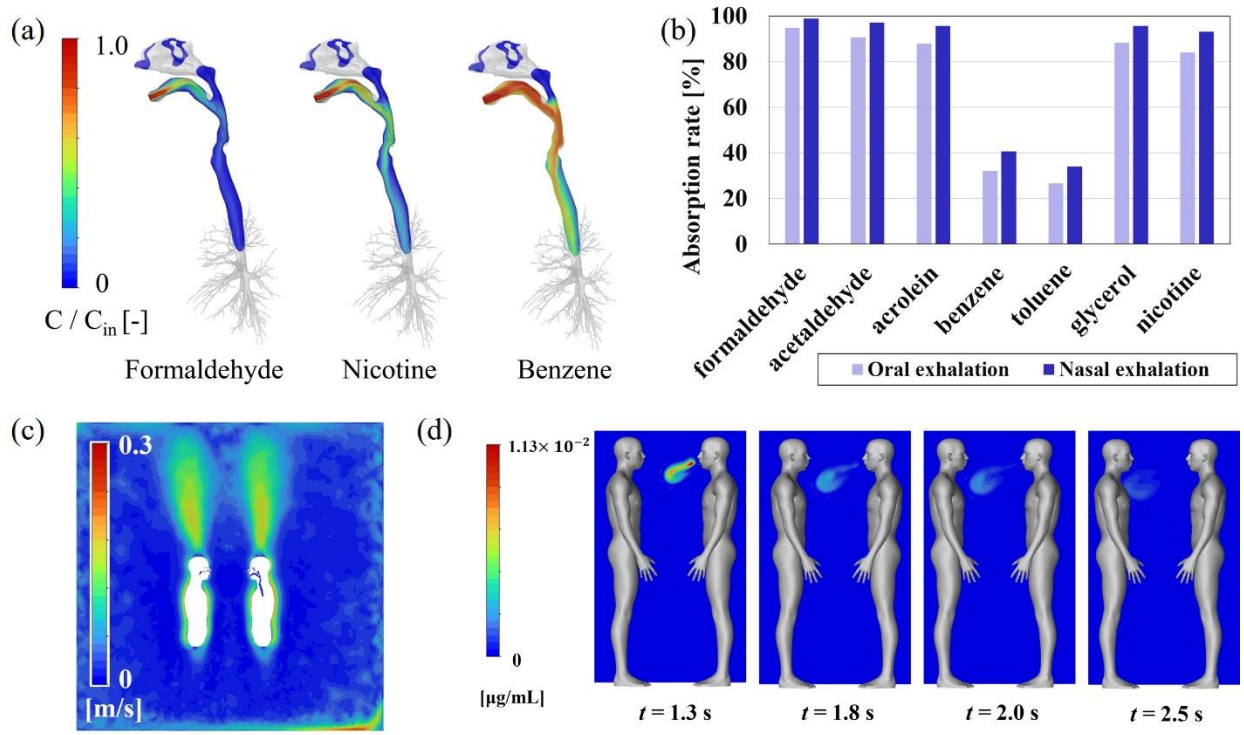

Figure 3. (a) Normalized concentration distribution of pollutants within the numerical airway model at the end of inhalation, (b) the absorption rates of all pollutants into the airway walls, (c) the initial indoor airflow field, and (d) the temporal variation of formaldehyde concentration exhaled by the smoker

4. CONCLUSIONS

This study integrated CFD and PBPK modeling to quantitatively assess e-cigarette-related exposure risks. First-hand exposure analysis demonstrated that pollutant deposition varies based on chemical properties and inhalation pathways. Second-hand exposure assessment confirmed that pollutant dispersion and absorption depend on spatial arrangement, ventilation, and exhalation methods. Comparisons with previous studies (Kuga et al., 2020) suggest that inhalation exposure among non-smokers is significantly influenced by airflow patterns and the relative positioning of smokers. These findings contribute to understanding the health risks associated with e-cigarette use and emphasize the need for further research on exposure mitigation strategies.

SUMMARY

To ease traffic congestion and improve walkability, densely populated cities have put more emphasis on developing footbridge systems. Given the shortage of thermal comfort research on footbridges, this study measured the daytime thermal environments and evaluated pedestrian thermal comfort using the physiological equivalent temperature (PET) across nine urban footbridges in Hong Kong on very hot days. Compared to open footbridges, covered footbridges showed more stable and cooler microclimates, averagely decreasing T_a, T_g, and T_{mrt} by 1.2 ℃, 7.2 ℃, and 16.7 ℃, respectively. Pedestrians walking on covered footbridges (mean PET = 34.8 ℃) generally feel "slightly warm" in contrast to "hot" at open footbridges (mean PET = 44.7 ℃). Simultaneous comparisons further revealed that the maximum PET reduction reached 11.4 ℃ under the glass cover, extending to 16.4 ℃ under the metal cover. This study highlights the significance of overhead covers in improving thermal comfort on footbridges during hot weather.

Keywords: Outdoor thermal comfort, Pedestrian bridge, Elevated walkway, Walkable city

1. INTRODUCTION

High traffic volume has been a common scene across global cities. The resulting traffic congestion and safety risks are impeding sustainable urban development. One of the effective strategies for tackling such traffic problems is to grade separate pedestrians from vehicles by constructing flyovers, footbridges, and subways. Unlike flyovers, footbridges are designed solely for pedestrians, allowing them to cross the roads without regard to vehicles. This can considerably reduce traffic accidents, improve traffic mobility, and enhance road safety (Highways Department, 2024). In addition to the traditional perpendicular form, footbridges can be parallel to the street with functions that give way for vehicular traffic and decrease ground pedestrian flow. Beyond traffic-related functions, urban planners are giving footbridges more landscaping, recreational, and commercial value (Rotmeyer, 2006). Given the aforementioned benefits, footbridges prevail increasingly in densely populated cities.

Walkability is widely perceived as a key component of sustainable urban development because a walkable neighborhood is lively, environmentally friendly, equitable, exercise-inducing, and conducive to social interaction (Forsyth, 2015; Kim et al., 2024). Consequently, walkability is gaining prominence in high-density cities (Moreno et al., 2021). The widespread of footbridges caters to the planning vision of walkable cities. Although the exact definition of walkability is still debatable, walking safety and comfort are considered essential factors. Pedestrians are more likely

to incorporate walking into their daily routines when they feel the walking environment is comfortable. Evidence shows that thermal comfort has a crucial effect on pedestrian comfort and walking preference (Lee et al., 2020). However, few studies have considered the role of thermal comfort on footbridges' walkability.

In summer, footbridges can either be thermally uncomfortable or become locally cooling hubs (Chen et al., 2024; Yang et al., 2016), which leads to a contrary walking experience. Considering the correlation between walkability and thermal conditions, it is worth investigating thermal comfort on footbridges and exploring influential factors, especially for hot and humid cities prone to strong heat stress. Therefore, the objectives of this study are to measure the thermal environment on footbridges, evaluate pedestrian thermal comfort using a well-recognized thermal comfort index, and analyze the effects of cover type.

2. METHODS

Hong Kong is a typically densely populated city, with a land population density of 6,910 people per km^2 in mid-2023 (GovHK, 2024). By June 2024, it has constructed over 1,000 footbridges on grounds of road safety and pedestrian walkability (Highways Department, 2024). Influenced by the subtropical monsoon, Hong Kong features prolonged hot and humid summers (*Cwa* in Köppen-Geiger climate classification). The average daily maximum temperature (T_{max}) exceeds 28 ℃ during May and October. Nine footbridges with different overhead covers, located in dense districts (> 40,000 people per km^2), were selected for pedestrian thermal comfort measurement. The measuring sites are named according to their covered conditions: uncovered or open (O1, O2, and O3), concrete-covered (C1 and C2), glass-covered (G1, G2, and G3), and metal-covered (M1 and M2). Note that O1 and G2 are located on two sides of a footbridge. Photos of measuring footbridges are presented in Figure 1.

Figure 1. Photos of measuring footbridges.

During the measurements, air temperature (T_a), relative humidity (RH), and wind speed (v) were measured using the mobile weather station (model: HY-WDS9, accuracy: ±0.5 ℃, ±3%, ±2%),

while globe temperature was collected by the black globe thermometer (model: WBGT-2010SD, accuracy: ±0.6 ℃). The equipment was fixed on a solid tripod, with the highest ultrasonic sensors 1.5 m above the footbridge's floor. The Observatory will issue a "very hot" weather warning to remind the public to take precautions against heat stroke when T_a is predicted to reach 33 ℃ or above. Given the health risks under such hot conditions, it is crucial to investigate pedestrian thermal comfort on footbridges. So, measurements were conducted during the daytime on eight very hot days, generally lasting seven to eight hours between 9:30 and 17:30. Table 1 shows the official weather information on measuring days (Hong Kong Observatory, n.d.-b), during which the daily average T_a and RH were around 30 ℃ and 76%, respectively.

Table 1. Weather conditions on measuring days provided by the HKO (T_{min} is the daily minimum temperature).

Date (dd/mm)	Site	T_{max}−T_{min} (℃)	T_a (℃)	RH (%)	v (m/s)	Sunlight (h)	Global solar radiation (MJ/m^2)
13/July	G1	33.8−27.7	30.7	61−92	2.22	8.9	22.58
24/Aug	C2	34.3−28.1	30.2	57−93	2.33	11.0	24.94
25/Aug	G2/O1	33.7−28.0	30.1	57−87	2.36	9.0	23.41
26/Aug	M1/O2	33.8−28.4	30.3	56−88	2.58	11.2	25.98
27/Aug	O3	34.1−28.5	30.6	57−86	2.61	11.1	25.08
3/Sep	M2	33.5−25.5	30.2	67−94	1.75	8.3	17.86
12/Sep	C1	32.2−27.7	29.8	65−90	2.06	9.8	21.77
19-Sep	G3	33.6−28.7	30.2	65−84	3.44	9.4	20.41

This study adopted physiological equivalent temperature (PET) to evaluate pedestrian thermal comfort because of its high recognition and wide application in outdoor thermal comfort research. RayMan Pro 3.1 was used to calculate PET by inputting meteorological data and individual information (Matzarakis, 2007, 2010). Mean radiation temperature (T_{mrt}) was first calculated from T_g using Eq. (1) and then adjusted to another T_{mrt} based on six-directional radiation flux densities using Eq. (2) (Li et al., 2022). The age, height, weight, clothing insulation, and metabolic rate of pedestrians were assumed to be 25 years old, 1.75 m, 70 kg, 0.4 clo, and 100 W, respectively (Huang et al., 2017; Chen et al., 2024).

$$T_{mrt} = \left[\left(T_g + 273.15\right)^4 + \frac{1.10\times10^8\times v^{0.6}\times(T_g - T_a)}{\varepsilon D^{0.4}}\right]^{0.25} - 273.15 \quad (1)$$

$$T_{mrt}(six-directional) = (T_{mrt}(T_g) + 3.6986)/1.1383 \quad (2)$$

Where the black globe diameter (D) is 0.075 m; the back globe emissivity (ε) is set as 0.95.

3. RESULTS

3.1. Overview of microclimate and thermal comfort conditions

Table 2 statistically describes 1-minute-averaged T_a, RH, v, and T_g and 15-minute-averaged T_{mrt} and PET at ten footbridge sites. During the daytime, the mean T_a and RH at open footbridge sites were 32.68 ℃−33.68 ℃ (average = 33.07 ℃) and 53.49%−59.53% (average = 56.69%), respectively; the mean T_a and RH at covered footbridge sites were 30.99 ℃−32.60 ℃ (average = 31.91 ℃) and 58.91%−67.11% (average = 64.07%), respectively. On average, covered footbridge sites exhibited lower mean T_a but higher mean RH compared to open ones. In the context of the officially reported T_{max} being 33.65±0.56 ℃, open footbridge sites had an average maximum T_a of 35.13 ℃, higher than 33.54 ℃ measured at covered footbridge sites. Regarding wind speed, the

lowest mean v of 0.26 m/s occurred at site M2 due to its footbridge sidewalls being installed with metal panels approximately 2 m high; Site G1 had the highest mean v of 1.72 m/s, which can be attributed to its proximity to the coast.

Concerning received radiation, the average maximum T_g at open footbridge sites measured 48.14 ℃, exceeding those at glass-covered, concrete-covered, and metal-covered footbridge sites by approximately 10.1 ℃, 12.2 ℃, and 11.6 ℃, respectively; the average maximum T_{mrt} at open footbridge sites reached 68.05 ℃, surpassing values at glass-covered, concrete-covered, and metal-covered footbridge sites by 18.5 ℃, 24.9 ℃, and 28.8 ℃, respectively. According to the standard deviations, T_g and T_{mrt} fluctuated within a small range at covered footbridge sites, while evident variations appeared at open footbridge sites. On average, open footbridge sites had a mean T_g of 41.48 ℃ and a mean T_{mrt} of 56.50 ℃, which were 7.2 ℃ and 16.7 ℃ higher than those at covered footbridge sites, respectively. In particular, sites G1, G2, and C1 had higher maximum T_{mrt} (> 50 ℃) above the average of covered sites. The reason was that the sunlight could slant down from the open sidewall under specific solar altitudes.

As a result of high temperature and strong radiation, open footbridge sites' maximum and mean PET exceeded 50 ℃ and 41 ℃, respectively. The overhead cover exhibited a remarkable cooling effect on PET, resulting in an average PET of 34.80 ℃ at covered footbridge sites. Specifically, site O3 had the highest PET (maximum = 52.3 ℃ and mean = 48.57 ℃); site O2 had the lowest mean PET of 41.45 ℃ among open footbridge sites due to its small sky view factor; sites G1 and G2 had higher maximum PET (> 40 ℃) compared to the remaining covered sites.

3.2. Simultaneous comparison between open and covered footbridge sites

3.2.1. Open site vs. glass-covered site

Figure 2 compares temporal variations of T_a, RH, v, T_g, T_{mrt}, and PET between open site O1 and glass-covered site G2. Statistically significant inter-site differences ($p < 0.01$) were found in T_a, RH, T_g, T_{mrt}, and PET via Mann-Whitney U tests and in v through the independent samples t-test. Figure 2(a) illustrates that the two sites exhibited nearly parallel variation trends in T_a and RH, though with distinct mean values. The T_a differences ranged from -0.11 ℃ to 0.86 ℃ (mean = 0.34 ℃), while RH differences varied between -3.76% and -0.01% (mean = -1.85%). So, site O1 demonstrated significantly higher mean T_a but lower mean RH compared to site G2 during daytime measurements. Furthermore, both sites had highly variable wind speeds, maintaining fluctuations around 1 m/s (Figure 2(b)). The inter-site v difference (range: -1.01 to 0.59 m/s) yielded a mean value of -0.15 m/s, indicating a higher wind speed at site G2 compared to site O1. Regarding T_g, the measured inter-site differentials varied from -0.13 ℃ to 8.47 ℃, averaging 3.96 ℃. The T_g curve of site O1 predominantly exceeded site G2's curve except after 15:33 when diminishing solar radiation caused the two curves to approximate convergence. The T_{mrt} comparison revealed more distinct differences between the sites, with the maximum and mean inter-site differentials reaching 21.63 ℃ and 10.11 ℃, respectively (Figure 2(c)). Consistent with T_g, T_{mrt} patterns of sites O1 and G2 nearly merged during the late afternoon (15:45−17:00) when T_{mrt} differences were below 1 ℃. Owing to the above microclimate differentials, site O1 exhibited significantly higher PET than site G2 during daytime measurements (Figure 2(d)). In particular, the PET differences varied from 2.6 ℃ to 11.4 ℃ (mean = 7.11 ℃) at pre-15: 45, narrowing to < 1 ℃ at post-15: 45.

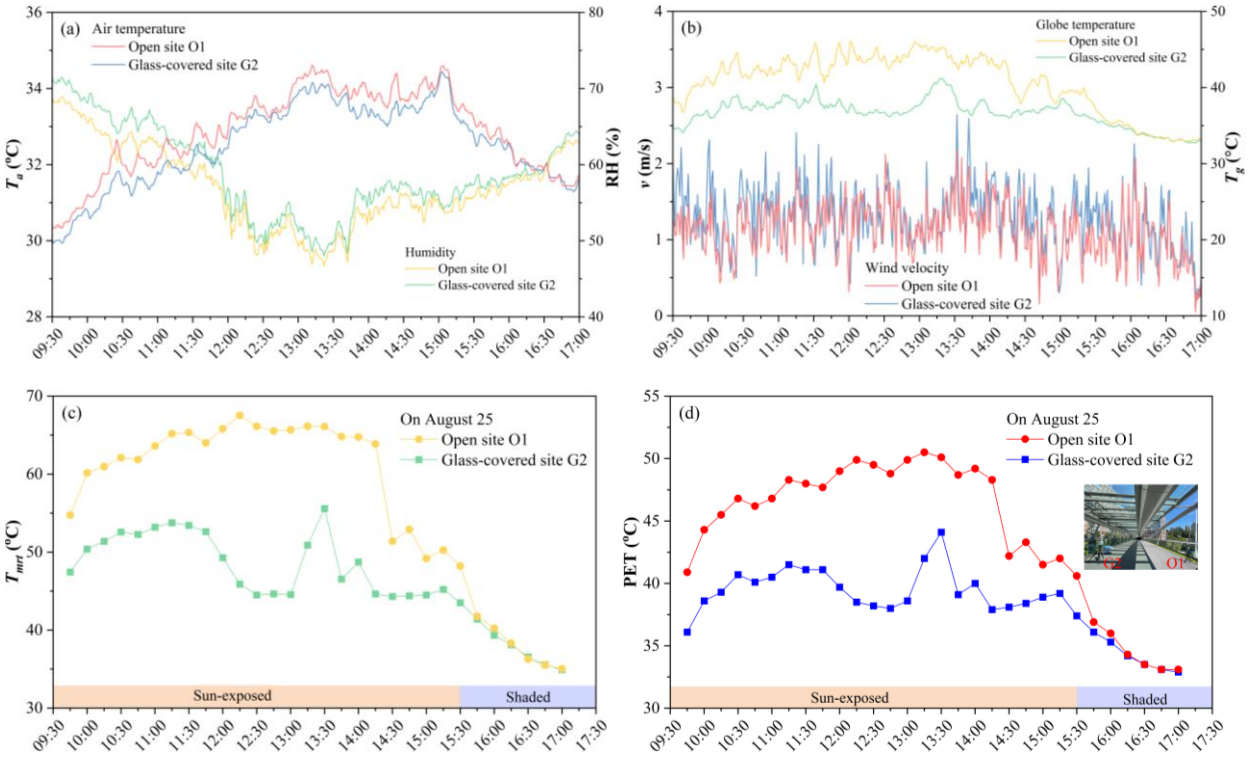

Figure 2. Variations of microclimate and thermal comfort variables at sites O1 and G2 on August 25th.

3.2.2. Open site vs. metal-covered site

Figure 3 shows temporal comparisons of T_a, RH, v, T_g, T_{mrt}, and PET between open site O2 and

metal-covered site M1. Mann-Whitney U tests revealed statistically significant differences ($p < 0.01$) for T_a, v, T_g, T_{mrt}, and PET between the two sites, while no statistically significant difference ($p > 0.05$) was found for RH. In terms of T_a (Figure 3(a)), site O2 showed apparently higher values than site M1 during direct solar radiation exposure (10:55−14:00). However, site O2's temperature superiority diminished and reversed in the mid-to-late afternoon after shaded. Inter-site T_a differences ranged from -0.97 ℃ to 2.45 ℃, with an average of 0.51 ℃ higher at site O2. RH displayed a nearly inverse trend to T_a, with inter-site differences ranging from -6.51% to 6.07%, averaging 0.86% higher at site M1. Wind speed presented high fluctuation at both sites (Figure 3(b)). Site M1 recorded 0.11 m/s higher v than site O2 on average, with inter-site differences varying between -1.97 m/s and 1.60 m/s. Regarding T_g (Figure 3(b)), site O2 exhibited rapid increases during solar exposure and sharp declines when shaded, while site M1 maintained stable values around 34 ℃. The T_g differences peaked at 14.06 ℃ and reached a minimum of -0.36 ℃, with a daytime average difference of 4.98 ℃. Figure 3(c) illustrates that site O2 remained consistently higher T_{mrt} than site M1, with a mean T_{mrt} difference of 12.28 ℃. During sun exposure, T_{mrt} differences ranged from 12.09 ℃ to 29.38 ℃, but eventually dropped to approximately 1 ℃ in the shade. Consequently, PET values at site O2 averaged 6.87 ℃ higher than at site M1, with maximum and minimum differences of 16.4 ℃ and 0.2 ℃, respectively (Figure 3(d)).

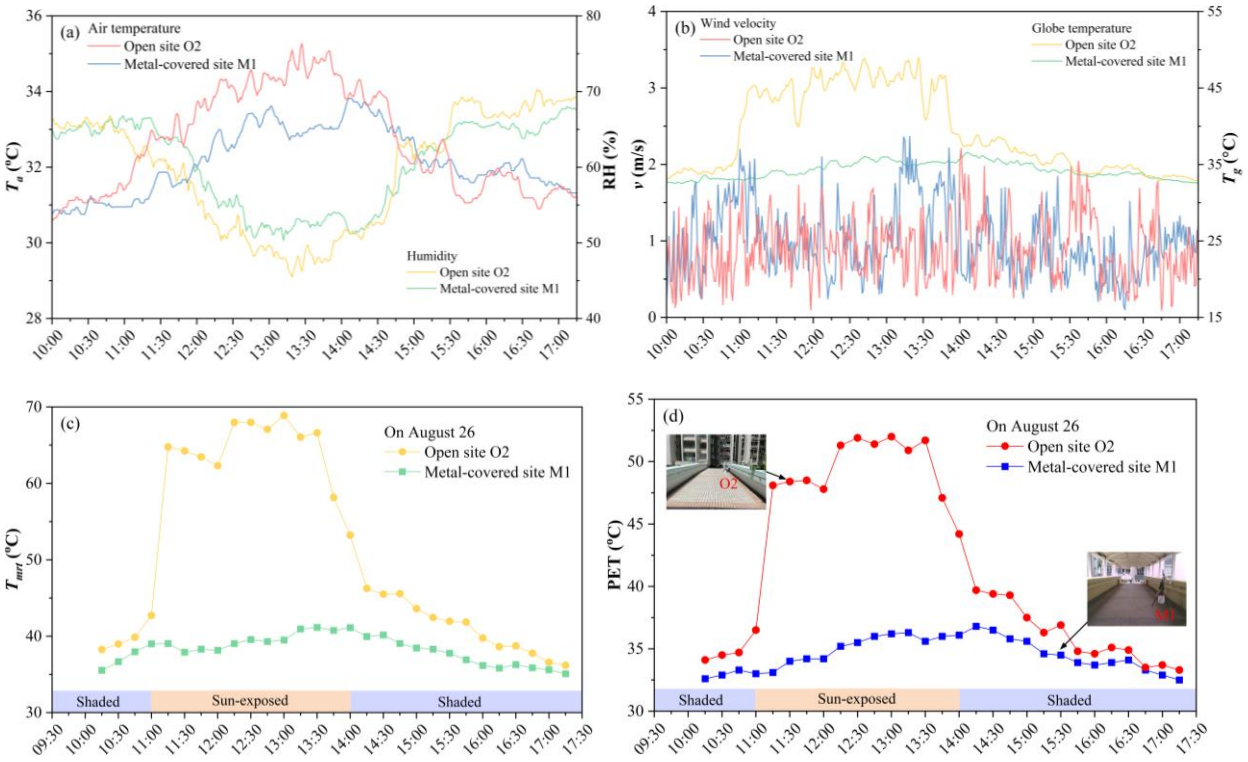

Figure 3. Variations of microclimate and thermal comfort variables at sites O2 and M1 on August 26th.

4. DISCUSSION

This study measured daytime microclimate and thermal comfort on footbridges and compared the performance of different covered conditions (open, glass-covered, metal-covered, and concrete-covered). The results reveal that covered footbridges generally provide lower daytime T_a, T_g, and

T_{mrt} but higher RH than open footbridges on very hot summer days, irrespective of the cover types. The average reductions in mean T_a, T_g, and T_{mrt} were approximately 1.2 ℃, 7.2 ℃, and 16.7 ℃, respectively, indicating the cooling effect of overhead covers on footbridges' thermal environment. The cooling magnitude is comparable to previous findings on other shading strategies in Hong Kong (Cheung & Jim, 2018; Lee et al., 2020; Ouyang et al., 2024). In contrast to thermal-related parameters, wind speed results are more prone to other factors rather than solar radiation. Distinct v differences (up to 1.5 m/s) existed among covered footbridges, highlighting the significance of open and semi-open sidewalls in footbridges' ventilation.

Concerning thermal comfort, pedestrians walking on open footbridges (mean PET = 41.5−48.6 ℃) are likely to feel "warm to hot" and suffer moderate to strong heat stress in contrast to "slightly warm" sensation and slight heat stress on the covered footbridges (mean PET = 32.9−38.4 ℃), referring to the correlation between PET level and thermal sensation class in Hong Kong (Huang et al., 2017; Lee et al., 2020). On average, covered footbridges could cool mean PET by 9.9 ℃ compared to open footbridges. Such remarkable heat stress mitigation is of great significance on hot days, especially for hot and humid cities where high humidity exaggerates thermal discomfort. Simultaneous comparisons (open vs. glass-covered and open vs. metal-covered) provide further evidence for the overhead cover's cooling effect. Compared with the open side, the glass-covered side could maximally cool T_a, T_g, T_{mrt}, and PET by 0.9 ℃, 8.5 ℃, 21.6 ℃, and 11.4 ℃, respectively (Figure 2). The metal cover shows more powerful cooling performances, decreasing T_a, T_g, T_{mrt}, and PET by up to 2.4 ℃, 14.1 ℃, 29.4 ℃, and 16.4 ℃ (Figure 3). Overall, considering summer thermal comfort, covered footbridges are recommended in Hong Kong.

This study focuses on summer daytime measurements due to pedestrians being more vulnerable to high heat exposure during this period. However, nighttime results may be opposite due to radiative cooling (Cheung & Jim, 2018) and seasonal variation can also influence the results. Moreover, the footbridge's geometric dimension, orientation, street aspect ratio, and vegetation may influence the microclimate and pedestrian thermal comfort (Chen et al., 2024), deserving in-depth research in the future. Furthermore, Lam et al. (2023) reported that concrete, aluminum, and PVC covers exhibit superior cooling effects over glass covers and the glass cover's performance depends on its transparency. More controlled studies are necessary to explore the effects of cover materials on footbridges' microclimate and thermal comfort. Last, thermal comfort assessment is limited to objective measurement, PET model, and uniform pedestrian data. Further questionnaire surveys are needed to validate PET results and investigate the effects of non-physical factors.

5. CONCLUSION

This study conducted on-site measurements on nine urban footbridges with four covered conditions in Hong Kong during very hot summer days. Daytime microclimates and pedestrian thermal comfort were statistically analyzed. The main findings are summarized as follows:

- During daytime measurements, all overhead covers demonstrate exceptional performance in blocking solar radiation, resulting in more stable and cooler thermal environments for covered footbridges compared to open ones. The average reductions in T_a, T_g, and T_{mrt} were approximately 1.2 ℃, 7.2 ℃, and 16.7 ℃, respectively.
- The daytime average PETs at open and covered footbridges were 44.7 ℃ and 34.8 ℃, respectively. Therefore, pedestrians using open footbridges are liable to feel hot and endure strong heat stress, whereas those on covered footbridges typically feel slightly warm and

experience slight heat stress.

- Simultaneous measurements between open and covered footbridges indicated that the maximum cooling effect on T_a, T_g, T_{mrt}, and PET reached 0.9 ℃, 8.5 ℃, 21.6 ℃, and 11.4 ℃ under the glass cover, and increased to 2.5 ℃, 14.1 ℃, 29.4 ℃, and 16.4 ℃ under the metal cover.

This study extends the scope of outdoor thermal comfort research to skywalk environments and demonstrates the efficacy of covered footbridges in mitigating heat stress and improving thermal comfort on hot days, offering valuable insights into the development of walkable cities in humid subtropical climates.

ACKNOWLEDGEMENTS

This study was supported by the Research Grants Council of the Hong Kong Special Administrative Region, China [Grant No. T22-504/21-R] and the Postdoc Matching Fund Scheme of The Hong Kong Polytechnic University [No. 1-W34Y]. The authors would like to thank the lab technician and students for their assistance during measurements.

SUMMARY
This study examines the impact of moderate and high lighting and indoor air quality (IAQ) conditions on students' well-being during a regular academic course in higher education. To determine the precise contribution of these two indoor environmental factors, students' perceptions of their well-being were examined with the Positive and Negative Affect, Basic Emotional Process, and Karolinska Sleepiness Scale. Data were collected from 83 students, resulting in 285 responses, distributed across four combinations of moderate and high IAQ conditions, resp. > 800 ppm ≤ 950 ppm carbon dioxide (CO_2) and < 800 ppm CO_2, and moderate and high horizontal illuminance (HI) levels, resp. 500 lx and 750 lx. The results indicated that high HI levels did not enhance students' perceived well-being compared to moderate levels. However, high IAQ conditions significantly contributes to students' well-being, compared to moderate conditions. Interaction effects between the two factors were observed at moderate conditions.

Keywords: emotional response, horizontal illuminance, higher education, indoor environmental quality.

1. INTRODUCTION

The growing emphasis on the well-being of higher education students has highlighted the significance of indoor environment research within educational buildings (Makaremi et al., 2024). Students' well-being is essential for fostering a supportive and effective learning environment in higher education and enhancing academic performance (Chaudhry et al., 2024). Evidence reveals that there is a relation between the indoor environmental quality (IEQ) and students' well-being (Brink et al., 2021). Four major factors – acoustic environment, lighting, thermal environment, and indoor air quality (IAQ) – determine the indoor environmental quality (IEQ) in schools (Frontczak & Wargocki, 2011), which may impact students' well-being.

In 2005 Mendell and Heath (2005) conducted a literature study that suggested that certain indoor air quality and thermal conditions found in schools adversely affect occupants' well-being. Furthermore, Frontczak and Wargocki (2011) stated that humans are subject to multiple environmental factors simultaneously, and that interactions among these can impact their perception and performance. Interactions between IEQ factors were observed by Kim and De Dear (2012), who developed a model to determine interaction effects and the existence of a hierarchy

among IEQ factors in an office environment. However, whether this model is applicable in an educational setting has not yet been studied to the best of our knowledge.

To determine what is known about the combined effects of environmental factors on the perceived IEQ and human performance, Torresin et al. (2018) performed a literature review. This study revealed combinations of IEQ factors that were studied and interaction effects between IEQ factors were identified. However, studies which examined multiple IEQ factors in an educational setting are limited. Furthermore, no studies have been found dealing with the interaction effects of indoor air quality and lighting conditions.

To contribute to the understanding of interaction effects and hierarchy between IEQ factors in higher education, this study focuses on the effects of two factors: horizontal illuminance (HI) level and ventilation rate representing lighting and IAQ respectively. And by doing so, this study provides more knowledge about the effect of simultaneously improving lighting and IAQ conditions on students' well-being in higher education. Additionally, when examining the impact of IEQ factors on students, it is essential to consider individual differences in students' subjective responses to identical indoor environments (Frontczak & Wargocki, 2011). These differences include individual characteristics (e.g., gender, age), building features (e.g., use, spatial qualities), or the outdoor climate, including seasonal changes and therefore daylight entrance and air quality. This study includes relevant individual differences when studying the influence of IEQ factors on students in higher education.

Specific lighting and IAQ quality conditions for this study were derived from Dutch guidelines for school buildings. These guidelines list three quality classes (A, B and C) addressing the four major IEQ parameters (RVO, 2021). When building or renovating schools in The Netherlands, school management may choose between quality classes A, B or C. To support this decision-making process, this study compares quality class A and B requirements for HI levels (HI ~750 vs ~500 lx), and IAQ (≤800 ppm vs > 800 ppm ≤ 950 ppm CO_2). The objective of this study is to answer the following research question: What is the impact, expressed as main and interaction effects, of increasing HI level from 500 to 750 lx and improving indoor air quality (IAQ) from CO_2 concentrations above 800 ppm but below 950 ppm to concentrations below 800 ppm CO_2 on students' perceived well-being during a regular academic course?

2. METHOD

2.1 Practical setting

The experiment was performed from the 20th of November till the 20th of December 2023. In this study, 32 male and 51 female freshmen, aged 19±1.7, participated in six campaigns, while following their regular academic classes. These first-year students were selected for the study, because they were lay persons and not yet versed in building physics. The study was performed in a classroom of the Hanze University of Applied Sciences (UAS) School of Future Environments, the Netherlands. The classroom's size is 10,641 x 7,041 mm, the reverberation time of the classroom is 0.4s at 250-2k Hertz, and the classroom is orientated west-south-west (53.24077N, 6.53106E). To prevent daylight entry during the experiment, the awnings on the outside of the windows were kept closed during the experiment.

The classroom was fitted with thirteen ETAP U3352 lighting armatures with a color temperature of 5000K and a color rendering index of 80. The lighting system is equipped with a dimmer and the HI at lecturer's desk was adjusted to meet the specified value before the start of every lecture. Lecturers were instructed not to adjust the illuminance level during the lecture. Furthermore, the classroom is equipped with a heating, ventilation, and air conditioning (HVAC) system. This system consisted of a combined air handling unit, including fixed plate heat exchangers and F7 filters, with a capacity of 3500 m^3/h, which results in a maximum ventilation rate of 16 l/s per person at a maximum of 30 persons. Furthermore, an air-cooled heat pump of 25

kW is installed. Using this system, both air temperature and air quality – defined by air temperature and maximum concentration of CO_2 – can be regulated in the classroom by entering the desired values into the control system. Figure 1 shows two pictures of the interior of the classroom.

Figure 1 Visual appearance of the classroom's interior. The left photo shows the classroom from the lecturer's perspective, the right photo shows the students' perspective

In approximately the middle of the classroom, a Delta Ohm HD32.3TCA Thermal Microclimate sensor, ACCREDIA calibrated, which was placed at a height of 1.1 meters. This device recorded every minute the actual air temperature (t_a), globe temperature (t_g), relative humidity (RH), CO_2, particulate matter (PM_{10}) and total volatile organic compounds (VOC). Figure 2 shows the layout of the classroom and technical details of the HVAC system.

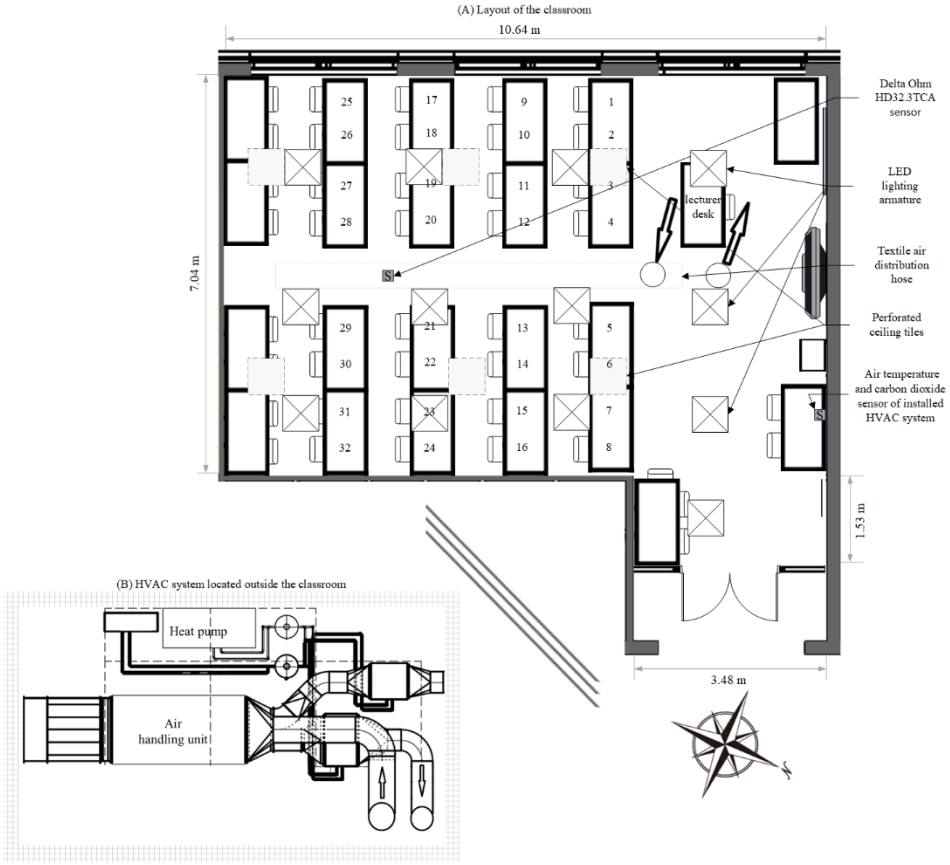

Figure 2 Layout of the classroom including the orientation (A) and technical details of the heating, ventilation, and air conditioning (HVAC) system (B)

2.2 Data collection of the actual indoor environmental quality and students' well-being

At the beginning of each lecture, the desired concentration of CO_2 (<800 ppm or > 800 ppm ≤ 950 ppm CO_2) was set in the CO_2 controlled ventilation system. Additionally, the desired HI level at the lecturer's task area was set to either 750 lx or 500 lx. The average HI level at the students' task area corresponded to that of the lecturer's task area, with a variation of approximately ±50 lx.

Students' well-being was measured with a questionnaire consisted of general items age, gender, table number, and self-reported hours of sleep before participation. Student well-being was examined with the Basic Emotional Process Scale (BEPS), which measures students' perceived levels of activation, orientation, evaluation and control (Gentile et al., 2018; Kuller, 1991). Furthermore, students reported their well-being using the Positive And Negative Affects Scale (PANAS) (Gentile et al., 2018; Watson et al., 1988). And finally, students had to rate their sleepiness in relation to their alertness using the Karolinska Sleepiness Scale (KSS) (Choi et al., 2019; Åkerstedt & Gillberg, 1990).

As a final step to enable the application of the questionnaire, all questions and statements were translated into Dutch by the authors. To validate, these questions and statements were then translated back into English by a professional translator. This translation was compared to the original English approach, differences were discussed with the translator and, if necessary, the Dutch translation of the question or statement was adjusted.

2.3 Data collection procedure

The final study design was approved by Hanze UAS' Ethical Committee (No. T2023.040). Before their participation, the students received a general outline of the study and its objective, which was to assess the quality of the classroom. All students who participated in this study signed an informed consent form. The students could end their participation in the study without any consequences and at any time. However, none of the students requested to do so or to have their data removed. The type of lecture was a tutorial, in which the lecturer gave a presentation about basic management principles. The duration of the lecture was approximately 90 minutes.

Four groups of freshmen and two lecturers (X, Y) participated in the experiment. The lecturers involved consecutively gave two lectures to two groups (A-D). For example, an involved lecturer gave a lecture on Wednesday from 8:30 a.m. to 10:00 a.m. Shortly after this first lecture, the same lecturer gave a lecture from 10:30 a.m. to 12:00 a.m. The lecturers were instructed to give the same lecture both times and were not informed which conditions were created in the classroom.

Before the experiment, students were randomly assigned to a group, initially with approximately 27 students each. All lectures were given from Tuesday to Friday and on the same day and approximately the same time for each group and in the same classroom (Figure 1). All four groups were at least one time exposed to the four tested high – moderate lighting and IAQ conditions. To complete the factorial design, all six possible combinations of high – moderate conditions were evaluated. This full-factorial design allows us to examine the main effects of, as well as the interaction effects between the two factors: HI and IAQ. Table 1 provides an overview of all conditions evaluated and six possible contrasts between the four different conditions examined during the experiment.

Table 1 Overview of study design with 4 groups of approximately 27 students and 2 lecturers over the 6 runs

	Condition			
Lecture (week)	group A lecturer X	group B lecturer X	group C lecturer Y	group D lecturer Y
1 (2)	IAQ_h - HI_m [2]	IAQ_m - HI_m [1]	IAQ_h - HI_m [2]	IAQ_m - HI_m [1]
2 (2)	IAQ_h - HI_h [4]	IAQ_m - HI_h [3]	IAQ_h - HI_h [4]	IAQ_m - HI_h [3]

3 (3)	IAQ_m - HI_m[1]	IAQ_m - HI_h[3]	IAQ_m - HI_m[1]	IAQ_m - HI_h[3]
4 (4)	IAQ_m - HI_h[3]	IAQ_h - HI_m[2]	IAQ_h - HI_m[2]	IAQ_m - HI_h[3]
5 (5)	IAQ_h - HI_m[2]	IAQ_h - HI_h[4]	IAQ_h - HI_m[2]	IAQ_h - HI_h[4]
6 (6)	IAQ_h - HI_h[4]	IAQ_m - HI_m[1]	IAQ_h - HI_h[4]	IAQ_m - HI_m[1]

[1] > 800 ppm ≤ 950 ppm CO_2, E_{hor} 500 lx; [2] ≤ 800 ppm CO_2, E_{hor} 500 lx; [3] > 800 ppm ≤ 950 ppm CO_2, E_{hor} 750 lx; [4] ≤ 800 ppm CO_2, E_{hor} 750 lx; $_m$= moderate quality condition; $_h$= high quality condition

At the end of the lecture, after approximately 90 minutes, the lecturer left the classroom, and the researcher entered asking the students to participate in the study. The degree of participation was high, reaching approximately 90% of all students present.

2.4 Data and statical analysis

To analyze the main and interaction effects of the two IEQ factors, first, mean scale values were calculated for the Positive Affect and Negative Affect Scales (PANAS), Basic Emotional Process Scales (BEPS) (Gentile et al., 2018; Kuller, 1991). Next, mixed-effects linear models (LMMs) were computed with a student specific random intercept to determine the main and interaction effects. These models include the main effects of the factors. Multiple LMMs were conducted to evaluate the students' responses under the varying conditions of the factors HI and IAQ. Student responses were statistically corrected for the moderators gender, the number of hours of sleep before participation, and distance to the lecturer (the latter being derived from their seating position) (Gentile et al., 2018; Norbäck et al., 2013). In addition, the LMMs were controlled for individual student level by random intercept. Therefore, the composed models account for both fixed effects which are consistent across individuals and random effects which capture individual variability. Furthermore, the models were computed with a general unstructured covariance matrix dealing with the dependent repeated measurements in the design. Main and interaction effects were considered statistically significant at a *p*-value <.05.

The factors HI and IAQ were considered as the independent factors in all LMMs. Those LLMs which revealed significant effects were verified by the significance of the LMM parameters' estimated by robust LMMs (Yohai et al., 1991). When these robust analyses led to a different conclusion regarding the estimated coefficient (β) beyond the first decimal, this is reported. The LMM function in the linear mixed-effects models package (lme4) in R version 3.5.0 (R Foundation for Statistical Computing, 192 Vienna, Austria) and IBM SPSS Statistics Version 28.0.0.0 (190) were used for statistical analyses.

3. RESULTS

3.1 Participation and actual indoor environmental conditions

From 83 students, 285 responses were collected and analyzed. Attendance at the lectures was not mandatory, resulting in fluctuating attendance rates and an unequal distribution of responses across the four combinations of moderate-high HI and IAQ conditions. As a result of the low number of students present in the classroom and minimum ventilation flow rate of the HVAC system, the desired moderate indoor air quality (IAQ) was not achieved in some runs. Consequently, all responses were classified based on the actual conditions observed. During the experiment, the outside temperature was 5.5°C (min 1.8– max 9.8°C). Table 2 presents an overview of the number of students who participated in the experiment and the actual classroom conditions during the four combinations of moderate-high HI and IAQ conditions. The IEQ factors temperature and relative humidity were similar in the four conditions tested, see Table 2. Moreover, the two lecturers involved gave the lectures in all four experimental conditions and in the same classroom.

Therefore, the perceived thermal and acoustic comfort of the students during the experiment was assumed to be similar and these factors were not included in the statistical models.

Table 2 Overview of preset and actual indoor environmental conditions during the experimental runs

3.2 Main effects of the factors IAQ and HI

With regard to the research question, whether increasing HI levels from 500 to 750 lx and improving IAQ from CO_2 concentrations between 800 and 950 ppm and CO_2 concentrations below 800 ppm impacts students' perceived well-being, LMMs were computed with the four basic emotional process scales (BEPS), i.e., level of activation, orientation, evaluation and control, as outcome variables and the factors HI and IAQ as predictor variables. Additionally, the variables gender, the estimated number of hours of sleep before participation, and distance to the lecturer were included as covariates in the LMMs. The factor HI did not affect students' perceived level of activation, orientation, evaluation, and control. However, the factor IAQ affected students' perceived level of activation (β=0.34; t(277)=4.16; p=.000), evaluation (β=0.10; t(277)=2.19; p=.029), orientation (β=0.15; t(277)=2.45; p=.015), and control (β=0.14; t(277)=2.32; p=.021). Furthermore, the activation, evaluation, and orientation LMMs revealed an effect of gender; males scored higher on these scales. The activation model revealed an effect of number of hours of sleep, more hours of sleep led to a higher score on these scales.

Furthermore, LMMs were computed with the PANAS. Neither the factor HI nor the factor IAQ affected students' negative affect scale (NAS) scores. And although HI also did not affect students' positive affect scale (PAS) score, the factor IAQ did affect students PAS score (β=2.60; t(278)=3.28; p=.001). Additionally, this model revealed an effect of gender (males scored higher). Furthermore, this model revealed an effect of number of hours of sleep; more hours of sleep led to a higher score on this scale.

The factor HI did not affect students' scores on the KSS. However, the factor IAQ affected students' scores on the KSS (β=0.53; t(277)=2.58; p=.010). Furthermore, this LMM revealed an effect of gender, males scored more alert; and an effect of the number of hours of sleep, more hours of sleep led to a higher perceived level of alertness. **Figure 3** shows all mean scores on BEPS, PANAS, and KSS at high and moderate IAQ and HI levels.

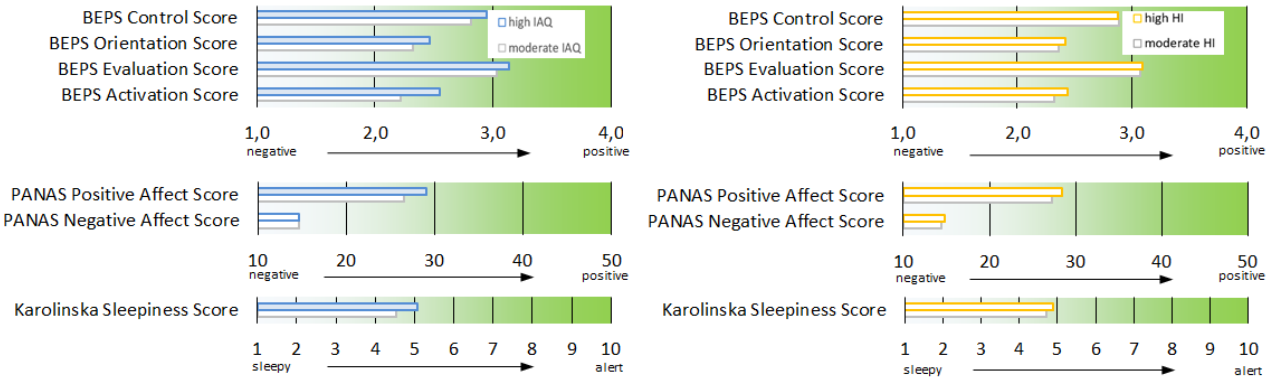

Figure 3 Mean scores on BEPS, PANAS, and KSS at high and moderate indoor air quality (IAQ) and horizontal illuminance (HI) levels. Shading of the bar is applied when the effect of the factor is significant (p<0.05).

3.3 Interaction effects of the factors IAQ and HI

To determine interaction effects between the factors IAQ and HI, LMMs were computed with the four basic emotional process scales (BEPS), i.e., level of activation, orientation, evaluation, and control, PANAS and KSS as outcome variables and the factors HI and IAQ as predictor variables. Additionally, the variables gender, the estimated number of hours of sleep before participation, and distance to the lecturer were included as covariates in the LMMs. Significant two-way interactions only occurred at moderate IAQ and moderate HI levels in LMMs activation (β=0.33; t(279)=3.10; p=.002), evaluation (β=0.12; t(279)=2.05; p=.041), and orientation (β=0.20; t(279)=2.70; p=.007).

5. DISCUSSION

The single and combined effects of lighting conditions measured by Horizontal illuminance on the lectures desk and IAQ in higher educational settings are critical factors influencing both the quality of teaching and learning, as well as students' well-being. Individually, optimal lighting conditions have been shown to enhance visual comfort, reduce eye strain, and improve students' level of concentration (Brink et al., 2021). Similarly, good IAQ, characterized by adequate ventilation and low levels of pollutants, is essential for maintaining students' health, reducing absenteeism, and enhancing cognitive performance (Brink et al., 2021).

Although a relationship between illuminance level and students' IAQ sensation votes was earlier reported by Jiang and Yang (2011) and Pittana et al. (2022), Torresin et al. (2018) concluded that the interaction between illumination and air freshness and odor perception is not very clear. Furthermore, no evidence is available that examines the interaction effect of the IEQ factors lighting and IAQ conditions on students in higher education (Brink et al., 2021; Torresin et al. 2018). This study tries to fill in this gap. And although Du et al. (2020) reported that studies that examine IAQ conditions with CO2 concentrations between 600 and 1100 ppm do not provide unequivocal evidence, our study reveals multiple significant effects of high IAQ conditions (CO_2 < 800 ppm) on students' perceived well-being, compared to moderate (800 < CO_2 < 950 ppm), this study shows a significant positive effect of high IAQ conditions on students' well-being, compared to moderate conditions. This finding highlights the importance of good IAQ conditions in higher education classrooms. Achieving this requires the installation of CO_2-controlled ventilation systems, which have been shown to have positive effects, as previously reported by Norbäck et al. (2013). Additionally, it is important to maintain CO_2 concentrations below 800 ppm during use.

In this study, lighting is only measured via HI. Other lighting factors, such as color temperature or exposure to natural daylight, that affect personal lighting conditions were not examined (Van Duijnhoven et al., 2021). Although limited evidence is available about different lighting systems (Gentile et al., 2018), future research may focus more on how other lighting factors affect student well-being. Furthermore, in previous work, authors reported an effect of HI on students' responses under moderate IAQ conditions; however, this effect was not observed under high IAQ conditions (Brink et al., 2023). However, in this study the factor HI did not affect students' well-being although an interaction effect of moderate HI and IAQ on students' well-being was observed.

6. CONCLUSION

This study examined the impact of enhanced lighting (horizontal illuminance at the lecturers desk) and indoor air quality measured via CO2 as a proxy on students in higher education. With a full-factorial experimental design, the effect of quality class A and B requirements of Dutch guidelines for school buildings for horizontal illuminance levels, respectively 750 and 500 lux at lecturer's desk, and indoor air quality, respectively $CO_2 \leq 800$ ppm and $800 < CO_2 < 950$ ppm. This effect was examined during a tutorial, as part of a regular academic course, with a duration of 1.5 hr. The findings indicate that high indoor air quality conditions have a positive effect on students' well-being, compared to moderate conditions. Furthermore, in this study at high indoor air quality conditions, moderate or high horizontal illuminance levels do not impact students' well-being, whereas at moderate indoor air quality conditions they do.

SUMMARY
Building-Integrated Wind Turbines (BIWTs) present a promising renewable alternative in urban areas, offering potential sustainable energy production directly where it is consumed. However, the performance of BIWTs is influenced by the complex turbulent wind flow patterns caused by urban environments. This study investigates the performance of both Horizontal Axis Wind Turbines (HAWTs) and Vertical Axis Wind Turbines (VAWTs). First, the performance is measured in wind-tunnel (WT) conditions, focusing on the impact of various parameters such as wind speeds, directions, and upstream roughness. These controlled tests aim to replicate diverse urban environments and compare the outputs with the manufacturer's nominal performance values. The second phase involves real-world testing on Concordia University's Future Buildings Laboratory (FBL) rooftop, assessing the wind BIWTs' long-term performance in complex urban wind environments. Consequently, this study provides valuable insights into optimizing BIWT installations and improving the efficiency of urban wind energy systems.

Keywords: Urban wind energy, Building Integrated Wind Turbine (BIWT), Wind-tunnel and field measurements.

1. INTRUDUCTION

The growing demand for localized energy generation to reduce transmission costs and power losses has increased interest in urban wind energy solutions. Wind power in urban settings offers a promising low-cost renewable alternative to conventional wind power (turbines in open wind farms) and demonstrates significant potential for development (Campbell et al., 2009). BIWTs are categorized based on the axis of rotation into two types: Horizontal Axis Wind Turbines (HAWTs) and Vertical Axis Wind Turbines (VAWTs). HAWTs have demonstrated higher effectiveness for large-scale energy production compared to VAWTs. However, VAWTs offer greater flexibility in installation, particularly on rooftops or building sides.

Unlike turbines situated in open wind farms, BIWTs' output is influenced by diverse factors. Key parameters affecting BIWT performance include wind speed, wind direction, installation height and location, building geometry, roof shape, surrounding obstacles, urban density, urban layout, and the type of BIWT (Juan et al., 2021). These variables can significantly impact BIWT's efficiency, making the effective positioning of BIWTs a challenge in urban areas. For instance, the shape of the roof is a significant factor influencing wind flow patterns and turbulence intensities. The accelerated wind velocity near the building roof can result in up to 56% more power output compared to a free-standing wind turbine (Abohela et al., 2013). Another example is a CFD-based study that examines both buildings and BIWTs on rooftops. The study shows that selecting the optimal BIWT installation location, building geometry, and BIWT type (e.g., number of blades) can lead to an increase in the power coefficient from 0.043 to 0.24 (Larin et al., 2016). However,

a poor installation choice can lead to zero energy output even in high-wind conditions (Toja-Silva et al., 2013). Therefore, despite extensive investigations into BIWTs, the complexity of urban airflow, turbulence characteristics, and the numerous influential parameters mean that much remains unknown and is still under investigation (Rezaei and Paraschivoiu, 2023; Stathopoulos et al., 2018; Vranešević et al., 2022). In this study, a comprehensive investigation of BIWTs was conducted under both fixed conditions in WT and real-world field measurements to better understand the impact of various geometrical parameters, wind flow pattern, and turbulence characteristics in urban areas.

2. WIND-TUNNEL (WT) MEASUREMENTS

The inflow profiles are measured for four wind speeds, at a location 1.2 m upstream of the BIWTs within WT. **Fig. 1** shows the dimensionless profiles of simulated Atmospheric Boundary Layer (ABL) inflow velocity, $\frac{\bar{U}(z)}{\bar{U}_{max}}[-]$, and Turbulent Kinetic Energy (TKE), $\frac{k(z)}{\bar{U}_{max}^2}[-] = \frac{1}{2}\frac{(\bar{U}^2 I_u^2+\bar{V}^2 I_v^2+\bar{W}^2 I_w^2)}{\bar{U}_{max}^2}$, in which $I_{u,v,w}$ (measured as %) is the turbulence intensity. The streamwise mean velocity increases with height from the WT floor up to 0.7 m before decreasing due to the effect of the WT ceiling. $\overline{U}_{max}$, measured at the height of 0.7, is 6.2, 10.8, 12.3 and 13.1 m/s for Low, Mid_1, Mid_2, and High wind speeds, respectively. Roughness cubes of varying sizes were placed over a 6-meter section of WT, starting 2.4 m upstream of the BIWTs. The TKE exhibits high values near the floor due to surface roughness and the carpet, decreases up to a height of 0.9 m, and then slightly increases. Moreover, the inflow profile with higher streamwise velocity corresponds to higher TKE.

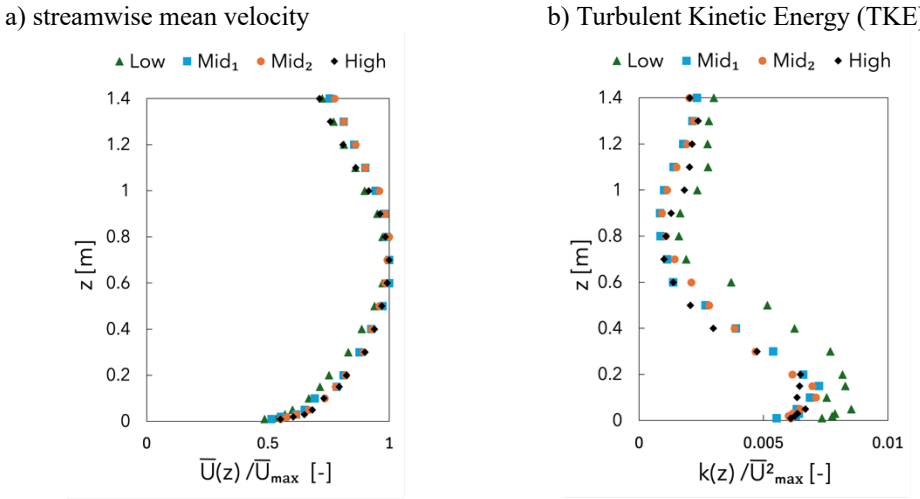

Figure 1. Dimensionless inflow ABL profiles, measured at Concordia University's wind-tunnel

Figs. 2a and 2c show the HAWT and VAWT installed in Concordia University's wind-tunnel. Both wind turbines used in this study were purchased from Leading Edge Power, and details regarding their dimensions and manufacturing specifications are available in the company manuals (Leading Edge Power, LE-300 Turbine Installation & Operation Guide; LE-v150 & LE-v150 Extreme & LE-v150 Extreme Storm Installation & Operation Guide, 2025). The blockage ratios for the HAWT and VAWT are 7% and 9%, respectively, based on the WT cross-section dimensions of $W \times H$=1.8×1.7 m^2. Higher blockage ratios (>5%) lead to the acceleration of wind flow around BIWTs, potentially leading to discrepancies in power output results. **Figs. 2b and 2d**

present the power output comparisons between the nominal and measured values at various wind speeds. For the VAWT, the effects of different wind directions, i.e., front, side, and back, were also studied. The swept areas of the HAWT and VAWT begin at heights of 0.187 m and 0.1 m above the WT floor, respectively. Thus, the average streamwise velocities impacting the turbine blades were calculated specifically within these swept areas. For the HAWT, the average velocities are $\overline{U}_{ave} = 5.60, 10.17, 11.60$ and 12.24 m/s. For the VAWT, the corresponding average velocities are $\overline{U}_{ave} = 5.54, 10.06, 11.49,$ and 12.17 m/s, shown in **Fig. 1**. The best performance of VAWT is observed for front wind directions (lower discrepancy) and the worst for side wind directions.

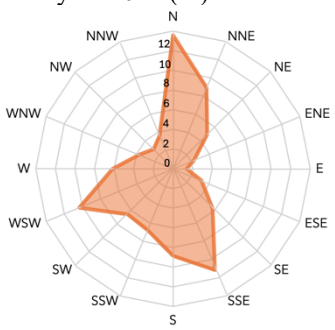
3 FIELD MEASUREMENTS

Fig. 3a shows Concordia University's Future Building Laboratory (FBL) located on the Loyola Campus. Additional information regarding the size and location of the FBL can be found on the Concordia University Website. Preliminary wind measurement data has already been collected from a station on the roof of the FBL, which will be used to optimize the installation process for the BIWTs. **Fig. 3b** presents the wind direction distribution (in %) for the year of 2024, excluding a few days of data loss, highlighting the predominant wind directions from the N, SSE and WSW. **Fig. 3c** shows nine years of wind direction distribution, measured at Dorval/Lac Saint-Louis weather station in Montreal to compare and verify the local measurements (Al-Quraan et al., 2016).

a) Future Buildings Laboratory (FBL) b) FBL in year 2024 (%) c) Montreal from 2007 to 2016 (%)



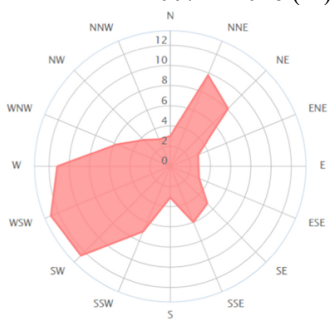


Figure 3. Wind rose comparison between measurements on the roof of Concordia University's FBL in year 2024 and Dorval/Lac Saint-Louis weather station in Montreal from 2007 to 2016 (Al-Quraan et al., 2016)

4. CONCLUSIONS

- Horizontal and vertical axis wind turbines (HAWT and VAWT) were tested in Concordia University's wind-tunnel under controlled conditions with fixed wind speeds and directions. The measurements show that HAWT power output aligns more closely with the nominal values provided by the manufacturer compared to VAWT, particularly under side wind direction. The discrepancies may be due to the higher blockage ratios (7% and 9%).
- The preliminary wind measurements from the weather station on the FBL's roof provide essential information for optimizing the installation of the BIWTs, including their location, height, and orientation.

SUMMARY
Extreme winds pose high risks for the loss of functionality of structures, which is not yet well studied and incorporated into risk analyses. This work aims to quantify the impact of intense winds on buildings, focusing on the case study of the Cattinara Public Hospital in Trieste (Italy). The hospital stands on an isolated hill exposed to strong local winds, e.g. the Bora. A powerful storm event (which occurred in winter 2012) was numerically reproduced on the city scale using the Weather Research and Forecast (WRF) model. Subsequently, a statistical downscaling procedure was used to set up high-resolution simulations with computational fluid dynamics models. The weather-informed Reynolds-Averaged Navier-Stokes simulations reproduced the local wind dynamics and a detailed estimation of atmospheric load on the hospital compound. Beyond the specific case study, the work proposes a general methodology for estimating the impact of extreme winds on structures by numerical downscaling at very high resolution.

Keywords: Extreme Weather Events, Downscaling strategies, Environmental Fluid Dynamics.

1. INTRODUCTION

Extreme weather events are expected to increase in intensity and frequency due to ongoing climate change. These include highly energetic thunderstorms, which can strongly impact assets and socio-economic activities. Specifically, the last decade has seen several extreme wind events that have resulted in significant damage to infrastructure, e.g. building roofs, power grids, warehouses, window glass and frames. Although the structural stability of infrastructures and buildings is hardly at risk, intense winds can produce extensive damage and loss of functionality, (Pastori and Mazzucchelli, 2023), which become critical when it comes to key socio-economic infrastructures such as hospitals, transport networks, energy distribution and communications. Despite this, the assessment of the risks from extreme wind events is still not properly included in the emergency and risk mitigation plans developed by infrastructure managers. This is also because realistic wind load estimation at the building scale is complex and challenging: it requires accurate numerical modelling of the local terrain topography, building area morphology, and the reproduction of atmospheric dynamics and turbulence, which play a key role in the estimation of the wind impact (Dagnew and

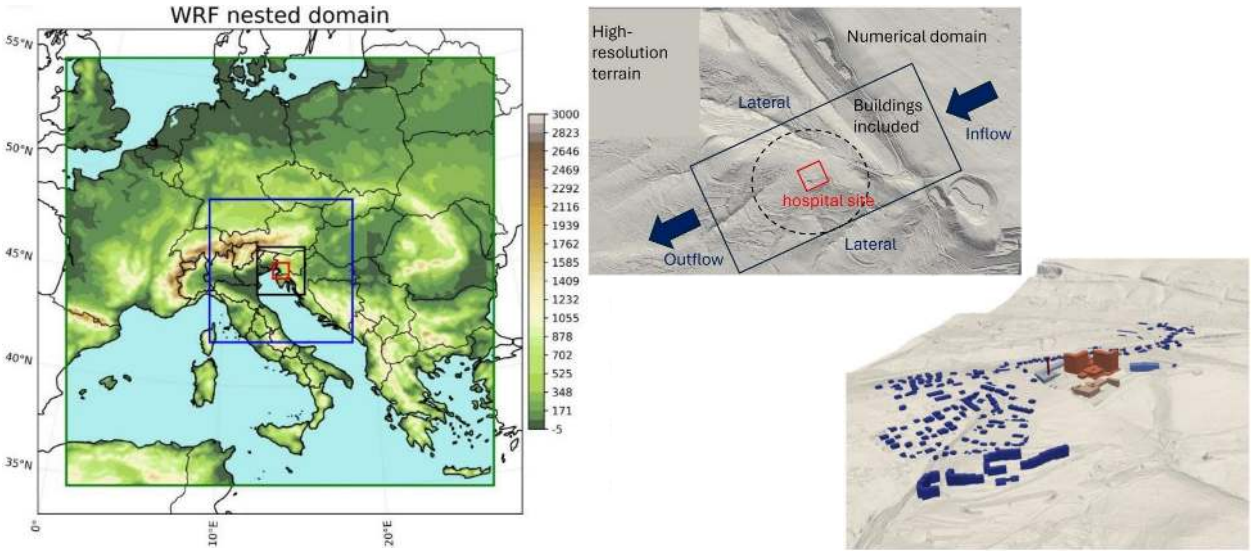

Figure 1. The case study of Cattinara public hospital in Trieste, Italy. Left panel, nested domains for WRF simulations; Right panels, an overview of the simulation domain including complex topography and major buildings of the areas.

Bitsuamlak, 2013). Such elements cannot be reproduced with a single tool, but require the coordinated and complementary use of multiple simulation models covering the variety of spatial and temporal scales that characterise the problem. This issue is here addressed by implementing and applying to a real-world case, a (general) numerical downscaling strategy that aims to reproduce the realistic atmospheric load on buildings by transporting information from the meteorological scale to the very small, local, building scale.

2. METHODOLOGY

The work focusses on the case study of the Cattinara Public Hospital in Trieste (Italy), which is taken as a representative of a relatively tall building and is regularly exposed to strong local wind (the Bora wind) characterised by high intensity and strong gusts. Specifically, a particular extreme event of strong Bora wind (registered in February 2012) has been selected to be numerically reproduced and analysed. Wind velocity is the main meteorological variable used to estimate the atmospheric load on building facades, quantified as the surface pressure load. An additional element that can increase the load is the wind-driven rain, which can be included through semi-empirical relations. The wind dynamics at the building scale is obtained through a chain of numerical simulations and different scales, strategically linked together (Figure **??**): the meteorological simulations have been carried out to reproduce the selected extreme event using the Weather Forecast and Research (WRF) model - version 4.5.1 (Zonato et al., 2022). Three nesting domains have been used to obtain a horizontal resolution in the Cattinara area of 333 m. A sensitivity study has been carried out on different submodels and schemes, and the simulation results have been evaluated against measured data available from the public Environmental Protection Regional Agency (ARPAFVG) of the Trieste region. The WRF simulations allowed us to characterise the mesoscale dynamics of the Bora wind. Raynolds-Averaged Navier-Stokes (RANS) simulations at a very high

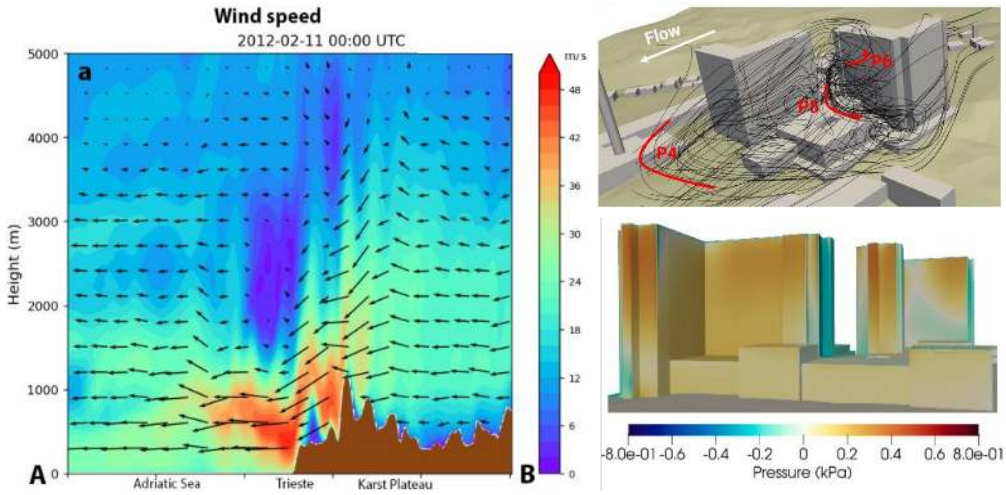

Figure 2. Statistical downscaling of wind dynamics from mesoscale to building scales. Left panel, wind speed from WRF simulation at the area of the city of Trieste (vertical section); Right panels, channelling effect between the hospital towers and recirculation region in the downwind yard (top panel), and pressure coefficient distribution on building surfaces.

resolution around the hospital compound are used to reconstruct the turbulent wind field at the building scale—for the numerical approach, see e.g. Ampatzidis et al., 2024. The simulation code is the open-source software OpenFOAM and the domain dimensions are $37H \times 33H \times 15H$ in the streamwise, spanwise and vertical directions, with respect to the prevalent wind direction and the hospital height $H = 54$ m. The complex terrain topography is reproduced together with the secondary buildings around the hospital within a distance of 300 m. The computational mesh is composed of around 50×10^6 cells and the cell height at the hospital facades is 0.6 m to ensure a direct resolution of the wall-boundary layer, while elsewhere wall functions are applied.

3. DISCUSSION AND FINAL REMARKS

Three simulations with different inflow conditions are carried out: (1) uniform inflow condition, the inflow is very simplified and consists of a constant wind value; (2) log-law inflow, where the inflow wind has a theoretical profile of an atmospheric boundary layer; (3) WRF-informed inflow, using the first- and second-order statistics of wind velocity and key atmospherical variables (wind velocity, direction, turbulent kinetic energy) derived from WRF simulations. The comparison between the three simulations provides information about the effects and features reproduced by realistic boundary conditions with respect to the simplified ones and allows to evaluate the loss of accuracy when simplified conditions are used.

WRF simulations satisfactory reproduce the extreme weather event selected and highlight the synoptic drivers of the Bora wind: it was generated by the difference of pressure between the Adriatic Sea and the Balkans (see Figure 2-left panel). Results provide velocity statistics at the inflow boundary for the high-resolved simulations. RANS simulations show that the uniform inflow condition results in an oversimplification of the system and overestimates the atmospheric load on buildings while not correctly reproducing several features of the general wind circulation. In par-

ticular, the interaction with the complex topography is not properly reproduced, which affects the overall simulation results. The log-law and WRF-informed inflow show similar results in terms of wind load on the hospital buildings, but the global circulation exhibits different features (see Figure 2-right panel). This is mainly due to the presence of a vertical velocity component in the WRF-informed inflow, which interacts with the complex terrain. The effect of the local topography on the circulation and intensity of the winds is analysed, together with the influence of the building morphology in accentuating or not the wind impact (e.g. triggering channelling effects that locally increased the speeds, or generating recirculation and stagnation zones - Figure 2-right panel).

In short, the atmospheric load on buildings is highly dependent on specific local topography and building area morphology, as well as contingent weather conditions. Hence, deriving a universal conclusion about the effects of local topography and building morphology on wind circulation and intensity is a challenging goal which has not been explored here. However, the work proposes and applies a general methodology for estimating the impact of extreme winds on structures by numerical downscaling at very high resolution. The loss of functionality risk estimation is not directly addressed in this work, but the outcome of the simulations serves as input for such an estimation.

Large eddy simulations of downburst propagation in urban environments

Mohammad Hadavi [1], Djordje Romanic [1]

[1] *Department of Atmospheric and Oceanic Sciences, Faculty of Science, McGill University, Montreal, Canada*
mohammad.hadavi@mail.mcgill.ca, djordje.romanic@mcgill.ca

SUMMARY
Downbursts are damaging downdrafts of negatively buoyant air generated within thunderstorms. Their intense winds near the ground pose significant risks to urban safety. Previous studies have mainly focused on isolated downburst-like winds or the propagation of atmospheric boundary layer (ABL) winds in cities. Consequently, the interaction between downbursts, ABL winds, and urban geometries remains relatively underexplored. This study employs large eddy simulations (LES) based on the Smagorinsky model to fill this gap. The simulations are validated against experimental studies through two scenarios: one involving ABL winds in urban environments and the other focusing on isolated downburst-like winds. The results indicate that the channelling effect causes wind speeds at pedestrian level to exceed the downburst centerline velocity. Although the spatially averaged velocity in urban areas is generally lower than in open terrain, the high-intensity winds persist over a greater vertical distance. This exacerbates the impact of downburst outflows on the built environment.

Keywords: Downburst, Urban environment, LES, Experiment.

1. INTRODUCTION

Downbursts are negatively buoyant air currents generated within thunderstorms that impinge upon the surface and spread radially (Hjelmfelt, 1988). Their high-intensity, transient, and spatially localized winds distinguish them from typical atmospheric boundary layer (ABL) winds. During these events, wind gusts can exceed 60 m s^{-1} at heights of 50 to 120 m above ground level, endangering both natural and built environments (Solari, 2020). The hazardous nature of downbursts is particularly pronounced in urban areas, where complex interactions with buildings can amplify localized wind speeds.

Collecting data on downbursts in urban areas is challenging due to their sudden onset, non-stationary nature, and the complexities of city environments. Furthermore, weather radars, a standard meteorological tool for observing near-surface flow fields in downbursts, cannot measure winds in urban areas due to ground clutter from buildings and other urban structures that interfere with radar signals. This results in limited full-scale data with sufficient spatiotemporal resolution. Wind tunnel measurements also encounter financial (Hangan et al., 2017) and physical constraints when simulating various configurations. Computational Fluid Dynamics (CFD) offers a valuable alternative for gaining insights into full-field flow characteristics, complementing experimental data. With advancements in computational resources, large eddy simulations (LES) are increasingly utilized. LES provides accurate results by resolving a significant portion of turbulent eddies within the entire spectrum of the turbulent kinetic energy fluctuations. This is essential for understanding the highly turbulent flow of downburst propagation (Aboshosha, 2015).

Several techniques exist to simulate downburst-like (DB) winds. One common method is the impinging jet (IJ), which is a turbulent, axisymmetric air jet that strikes the ground perpendicularly and spreads radially. This approach is well-regarded in wind engineering (McConville et al., 2009) for its effectiveness in replicating key dynamic features of a downburst outflow, including primary and secondary vortices.

Previous studies have extensively examined the effects of ABL winds in urban environments (Ricci and Blocken, 2020; Hadavi and Pasdarshahri, 2021). The dynamics of isolated DB winds in empty chambers are also well-documented (Romanic and Hangan, 2020; Žužul et al., 2024). However, the interaction between downburst winds, ABL winds, and urban areas remains relatively underexplored. This gap is particularly critical given the projected increase in the frequency and intensity of thunderstorms (Rädler et al., 2019) alongside rising urbanization (Uttara et al., 2012). Therefore, this research focuses on the propagation of a downburst-like wind within a representative urban setting under the influence of a background ABL wind.

2. METHODOLOGY

2.1. Case scenarios

This study considered two validation cases. First, the behavior of ABL winds in an urban environment was validated using wind tunnel measurements. A case from the Architectural Institute of Japan (AIJ) database (Tominaga et al., 2008) was selected to represent a typical idealized urban neighborhood. This case is referred to as "ABL validation" in this paper. Second, an isolated IJ without ABL and buildings was numerically simulated, and the results were compared against various experimental and numerical studies. This case is termed "IJ validation" in the present study. The validated simulations were then used to investigate the interactions of ABL and DB winds with the idealized urban environment.

2.2. LES simulations

The unsteady-state and isothermal LES simulations based on the Smagorinsky model were performed using the pimpleFoam solver from the OpenFOAM v2306 open-source CFD library (Ricci, 2024). The snappyHexMesh utility was used to generate a hexahedron-based unstructured mesh from a background grid. Details on the grid refinement are provided in the following subsections. The Courant–Friedrichs–Lewy number was kept below 0.5 throughout all simulations. A ratio of resolved turbulent kinetic energy (k_{res}) to total turbulent kinetic energy (k_{tot}) above 80% was maintained (Pope, 2001).

2.2.1. ABL validation

The idealized urban neighborhood consists of a grid of nine cubic building blocks (H_{Urban}=0.2 m). A refined uniform cell size of H_{Urban}/10=0.02 m was used for the target region (Fig. 1). The cells were kept as uniform as possible across the entire domain, with a stretching ratio below 1.05. This resulted in a grid of ~9.3 million cells. No-slip conditions were specified at the top, ground, sides, and building facades, while a zero-static gauge pressure was set at the outlet; the inlet ABL profile was imposed based on the wind tunnel data. The near-surface flow was modeled using Spalding's universal law of the wall.

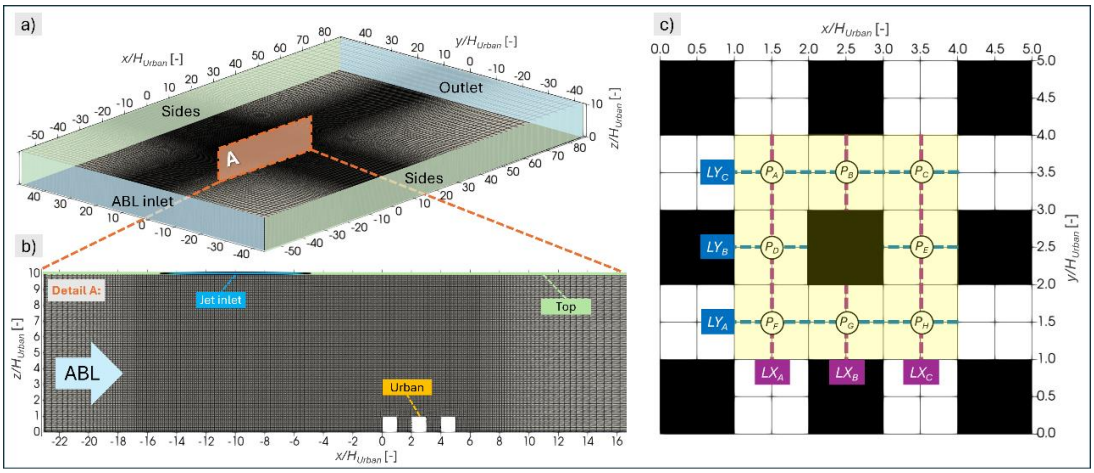

Figure 1. (a-b) Computational domain with the details of mesh refinement in the target region and boundary indications. The same computational grid was used for the ABL validation case and the ABL+DB scenario. c) Geometry of the urban neighbourhood. Results will be presented along the indicated lines. The yellow shaded region is designated for calculating the spatially averaged velocity within the urban area.

2.2.2. IJ validation

Figure 2 illustrates the dimensions, boundary conditions, and grid resolution of the IJ validation case. The jet has a diameter of D=0.0381 m, a height of 2D, and a downdraft centerline velocity of 7.9 m s^{-1} (Kim and Hangan, 2007). To optimize computational resources, half of the IJ was simulated, assuming axisymmetric behavior (Kim and Hangan, 2007). The cell size was refined to 0.0002 m near the ground surface and within the downdraft region, gradually increasing with a ratio of ~1.04 throughout the entire domain.

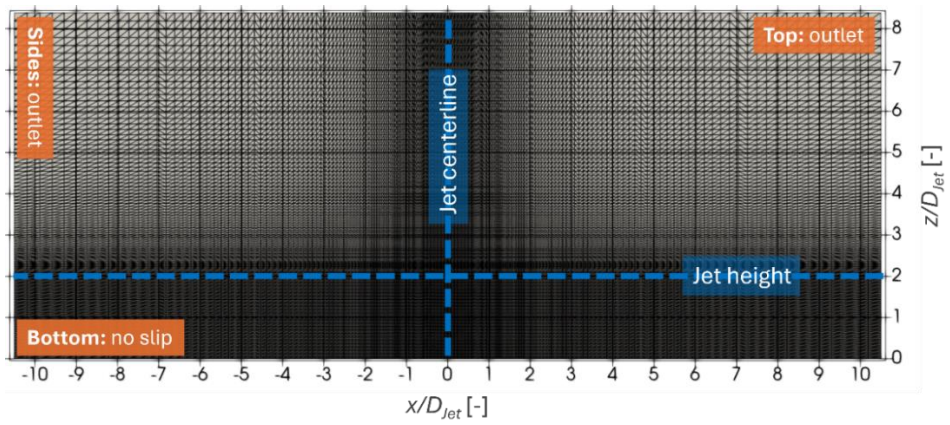

Figure 2. A cross-section of the computational domain for the IJ validation case at the jet centerline, showing the boundaries and mesh refinement details. The dimensions are based on the work of Kim and Hangan (2007).

2.2.3. Main case studies

A DB wind was modeled using a jet with a height and diameter of 2 m and a centerline velocity (w_{jet}) of 10 m s^{-1}. The urban area was located at a distance of one diameter from the jet centerline (Fig. 1b), i.e., a region of expected maximum radial velocity. With a spatial scale of 1:200, this study simulates a small microburst with a height and diameter of 400 m (Romanic et al., 2020),

impacting a mid-rise urban neighborhood with a height of 40 m in reality. For normalization, the urban height was used as the reference, with $U_{Urban} = U(H_{Urban})$, where U_{Urban} denotes the velocity of the ABL flow in the empty chamber.

The computational domain is identical to that used in the ABL validation case. This domain was developed through preliminary simulations to ensure the DB flow evolves without boundary interference. We observed that the size of the domain influences the flow, particularly upstream of the touchdown point (not shown due to space constraints). Moreover, the jet is injected directly at the top of the domain without employing a bell-mouth or nozzle geometry. This approach was selected because preliminary simulations indicated that the nozzle geometry disrupted the flow and created turbulent eddies, which affected the near-building flow. These disturbances were undesirable, as the focus is solely on the impact of the jet flow.

The non-dimensional distance from the wall (y^+) values across the ground ranged from ~2 in the stagnation region to ~218 in areas of highest radial velocity. These values fluctuated over time due to the passage of turbulent structures. For urban blocks, the minimum y^+ value was ~5, while the maximum reached ~306.

The LES simulations were conducted in three phases over a total duration of 14 s. In Phase 1 (0–4.5 s), the jet inflow is turned off, allowing the ABL flow to develop within the domain. Phase 2 (5–9 s) introduces a jet velocity of 10 m s^{-1}. In Phase 3 (9.5–14 s), the jet inflow is turned off again to replicate the dissipation stage. A uniformFixedValue boundary condition was applied, with a 0.5-second interval between each phase to allow for smooth transitions in velocity from 0 to 10 m s^{-1} and back.

3. RESULTS

3.1. Validation cases

Figure 3 presents the comparison between wind tunnel measurements and LES results of the ABL wind across three lines within the urban environment. The LES simulations effectively reproduce the flow characteristics in the open gaps between buildings and the wake regions behind them.

Figure 4a presents the IJ validation results as a vertical profile of horizontal velocity. The instantaneous maximum radial velocity profile extracted from the LES simulations aligns well with previous experimental and numerical studies. A discrepancy is noted with the field measurements from JAWS data (Hjelmfelt, 1988), which could be attributed to the influence of the ABL winds and cloud motion in the real environment. Moreover, the specific spatial location of real data collection, including radial distance and azimuth relative to the downburst centerline, is often not documented. Additionally, the peak velocity occurs at a slightly higher elevation in our LES simulations compared to some other profiles (e.g., Mason and Wood, 2004). This difference could be due to the small scale adopted for the simulations, potentially overestimating the outflow thickness. The formation of the primary vortex, as shown in Fig. 4b, is consistent with what is observed in nature. This occurrence is caused by Kelvin-Helmholtz instability, which arises from the shear between the still ambient air and the strong downward jet flow.

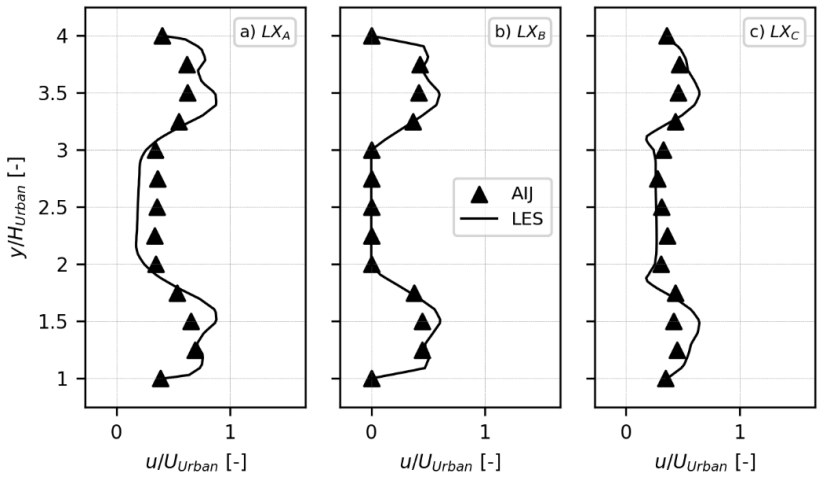

Figure 3. Results of the ABL validation case. (a-c) Comparison of experimental (AIJ) and LES results at z/H_{Urban}=0.1, across three horizontal lines of LX_A, LX_B, and LX_C. Refer to Fig. 1c for the location of these lines. The LES results are based on a cumulative average over 5 seconds following the initial transition period.

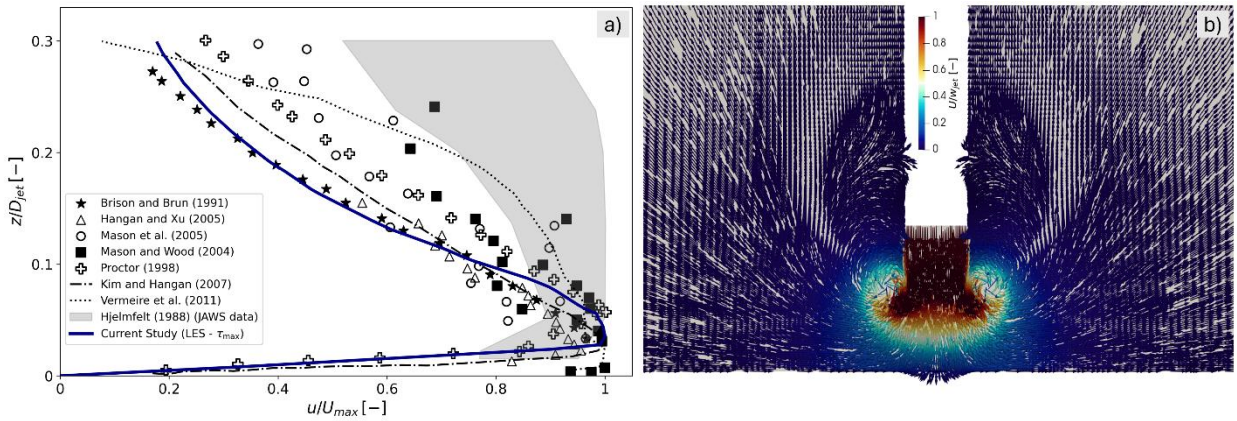

Figure 4. Results of the IJ validation case. a) Comparison of the instantaneous maximum radial velocity profile from LES with several studies. b) Generation of the primary vortex after jet release.

3.2. Main case studies

Figure 5 illustrates the wind flow variations along horizontal lines at heights z/H_{urban}=0.1, 0.5, 1, 2 for the ABL+DB scenario in both open terrain (i.e., non-buildings) and the urban environment. The profiles correspond to the time step when maximum radial velocity occurred in the open terrain scenario. As expected, recirculation zones behind buildings show the lowest wind speeds. In contrast, the channelling effect in unshielded areas between urban blocks accelerates wind speeds. These speeds exceed those in the non-urban case and even w_{jet}, worsening the impact of the downburst outflow on the built environment. This effect is most pronounced at the first and second roads. Farther downstream from the jet impingement, even unshaded locations experience a decrease in wind speeds (Fig. 5f, h), due to turbulent eddies generated by the DB propagation.

The maximum wind speed rises with height (Fig. 5c, e, g) as the impact of surface friction decreases and the ABL intensifies. In the open terrain scenario, wind speed peaks at z/H_{urban}=0.5 (Fig. 5e) before declining at higher elevations, indicating the gust front thickness. Above the urban

area (Fig. 5a), wind speeds along LX_A, LX_B, and the non-urban case are similar that shows the disappeared urban impact. However, behind the second row of buildings (LX_C), an intense peak occurs before a sharp velocity drop. This observation indicates that flow characteristics differ between the first and second roads. On the other hand, LY_A and LY_C show consistent patterns at all heights, pointing out nearly symmetrical wind flow behavior parallel to ABL and DB winds. Finally, the increase (Fig. 5b) and decrease (Fig. 5h) in wind speeds along LY_A and LY_C after y/H_{urban} ≈2.5 result from vortical structures generated downstream of the jet. This pattern is also seen in the non-urban case. An attached video at the end of this paper further visualizes the time evolution of turbulent eddies during the propagation and dissipation of downbursts in both open terrain and urban environments.

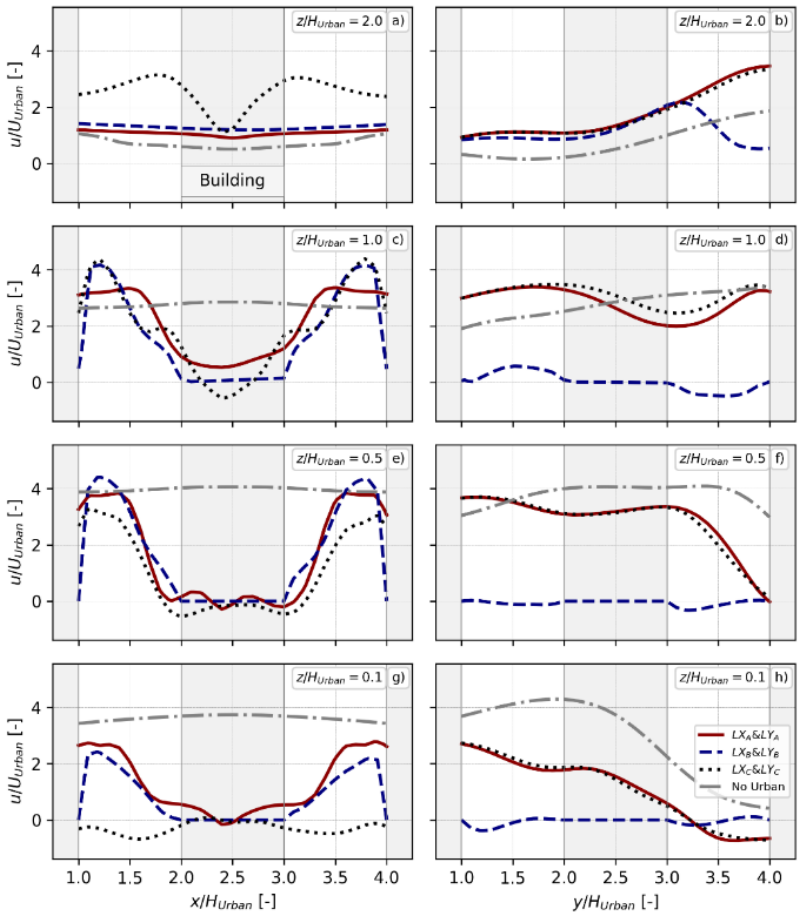

Figure 5. Horizontal wind speed variations along several lines between the urban blocks at four heights: z/H_{Urban}= (a-b) 2; (c-d) 1; (e-f) 0.5; (g-h) 0.1. The profiles correspond to the time step when the maximum radial velocity was recorded in the open terrain scenario. The left and right columns compare wind speeds along the LX and LY lines, respectively; refer to Fig. 1c for the line locations. The building locations in the urban area are shaded in grey. The profiles for the non-urban case are extracted at LX_B and LY_B.

Figure 6 depicts the vertical profile of horizontal wind, spatially averaged across the urban area. In the ABL case (Fig. 6a), a logarithmic wind profile is evident within the urban canopy layer, consistent with previous studies (Macdonald, 2000; Di Sabatino et al., 2008). The profiles for open terrain and urban cases exhibit similarities in DB propagation alone (Fig. 6b). However, mean wind speeds in the urban case are lower due to the inclusion of low-velocity wake regions in the

spatial averaging. Notably, while the non-urban case displays a typical nose-shape profile, the urban environment maintains the high-intensity winds over a greater vertical extent (Fig. 6c). This results in higher wind pressure on structures at elevated heights, exacerbating the vulnerability of the built environment to downbursts.

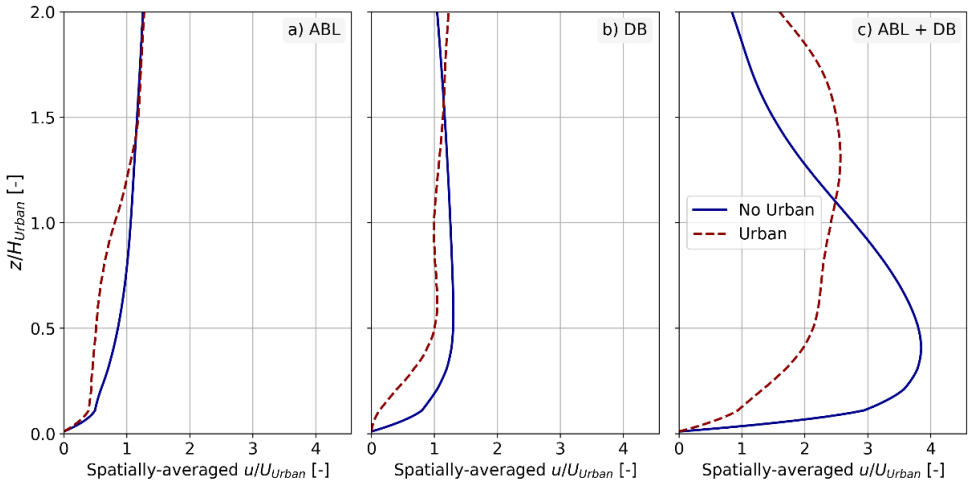

Figure 6. Vertical profiles of spatially averaged horizontal velocity for the scenarios of a) ABL, b) DB, and c) ABL+DB propagations in both open terrain and the urban area. The horizontal velocity is averaged at each vertical level within the area shown in Fig. 1c.

4. CONCLUSIONS

Downbursts are strong downdrafts of negatively buoyant air that descend from thunderstorms and impact the Earth's surface. They generate powerful outflows of intense winds close to the ground, posing risks to human safety and structures. This study explores a relatively underexplored topic in this field: the interaction between downburst winds, background atmospheric boundary layer (ABL) winds, and an idealized urban environment. We conducted large eddy simulations (LES) based on the Smagorinsky model. The simulations were validated against experimental studies through two cases: ABL propagation in an urban environment and an isolated downburst-like wind.

The results reveal that the channelling effect in unshielded areas between urban blocks accelerates wind speeds, surpassing those in the non-urban scenario and even the downburst centerline velocity. Additionally, we observed nearly symmetrical wind flow behaviour parallel to ABL and downburst winds at all heights within the urban neighbourhood. While spatially averaged wind velocities are lower in urban areas due to the inclusion of low-velocity wake regions, the urban environment maintains high-intensity winds over a greater vertical extent. Consequently, aerodynamic loads escalate at higher elevations, making urban infrastructure more susceptible to downburst wind damage.

ACKNOWLEDGEMENTS

The authors thank the Digital Research Alliance of Canada for providing access to supercomputer clusters used for running the LES simulations. We acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada (NSERC) through Discovery Grant

RGPIN-2021-02651. We appreciate the funding provided by the Fonds de recherche du Québec – Nature et technologies (FRQNT) through a Doctoral Research Scholarship. We also extend our gratitude to McGill University for their support through a Lorne Trottier Science Accelerator Fellowship.

SUMMARY
Proper management of the port areas is hugely influenced by the wind conditions. While impact of neutrally stratified atmospheric boundary layer (ABL) wind on port infrastructures and ships has been investigated, less attention was given to extreme winds like downbursts, tornados and downslope winds. Downslope winds (DW) similarly to other extreme winds are characterized by high velocity near the ground, where port infrastructures are deployed. In this paper preliminary results of Computational Fluid Dynamics (CFD) simulations and LiDAR measurements of DW are compared for the case study in the port of Genoa, showing nose shape vertical velocity profile obtained both by measurements and CFD simulations.

Keywords: CFD, LiDAR measurements, risk exposure, port areas

1. INTRODUCTION

Ports are hubs for international trade and play a crucial role for the economy of countries. However, port areas as well as coastal areas are highly exposed to extreme meteorological phenomena, especially winds (Castillo et al., 2024). Extreme winds can cause accidents in port areas as well as pose risks to human life (Zhang et al., 2015). Most commonly used international standards and codes are based on neutrally stratified ABL winds. In case of neutral stratification, ABL winds are characterized by lower mean velocities near the ground compared to other extreme winds like thunderstorm downbursts, tornados, downslope winds (DW). Despite the great efforts made by the wind engineering community in the recent years to understand downbursts and tornados (e.g. Solari et al., 2020), less attention has been given to DWs. DWs typically develop when air flows over high mountains and falls down along steep lee slopes accelerating because of the negative buoyancy (Fig. 1a). This wind is known to occur all over the world with different local names like Alpine Foehn, Rocky Mountain Chinook, Croatian Bora (e.g. Kozmar et al., 2012; Durran, 2014; Lepri et al., 2015). In Liguria, Italy, specific DWs can occur when the wind blows from the north of Apennines and Maritime Alps towards the Ligurian Sea. The DW is driven by the large-scale pressure gradient directed from the colder continental air toward warmer air above the Ligurian Sea (Burlando et al., 2017). Understanding the nature of DWs is vital for improvement of existing formulations for wind provisions on port structures, which will help to safeguard the port

operations. This manuscript describes part of the first stage of a PhD project which started in early 2024 with the aim to provide port stakeholders with practical tools to better manage the safety of port areas. CFD simulations, LiDAR scanner and profiler measurements are carried out on DW, and a preliminary comparison in terms of vertical wind profiles is provided. It is worth mentioning that even though DWs were extensively studied by atmospheric scientists and simulated with weather forecast models, to the best of the author's knowledge they have never been simulated by means of CFD techniques with focus on their effect on the urban environment.

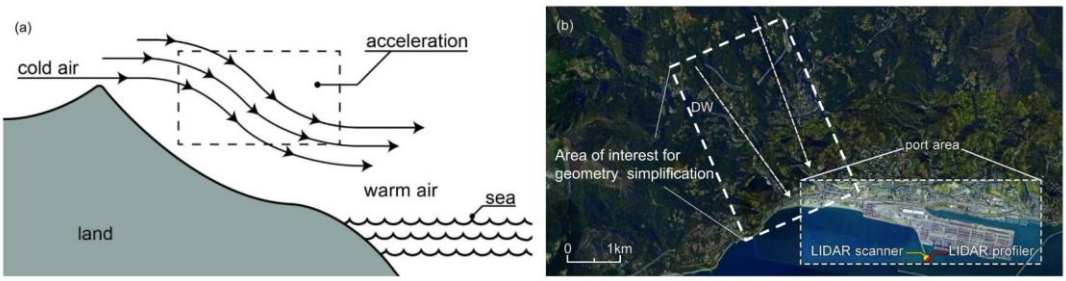

Figure 1. a) Schematic view of DW. b) Aerial view of the port of Genoa with the LiDAR scanner and LiDAR profiler positions with the indication of DW approaching direction and area of interest for construction and simplification of geometry

2. METHODOLOGY

2.1. LiDAR measurements

In the Turchino valley, situated in the western part of Genoa city, DW occurring during the winter period are much stronger than those occurring during other seasons. Therefore, measurements in the port of Genoa are carried out in the winter season using the LiDAR scanner WindCube 400S and LiDAR profiler WindCube-V2. The LIDAR scanner operates in a range of 14 km and a gate resolution set to 75 m, while the LiDAR profiler measures at 12 levels from 40 to 250 m above the sea level. LiDAR stations are situated at the end of the quay, which is a suitable position for measuring DWs approaching from the Turchino valley and nearby valleys towards the sea (Fig. 1b). The LiDAR profiler can provide wind velocity and turbulence intensity at 12 different levels above the sea level allowing for the reconstruction of a vertical profile. The LiDAR scanner can provide the wind velocity field in terms of radial velocity ensuring at this stage a qualitative understanding of the 3D flow field and a preliminary comparison with wind velocity contours obtained by CFD. In this paper only data obtained by the LiDAR profiler are shown.

2.2. CFD simulation

Steady Reynolds-averaged Navier-Stokes (RANS) simulations were performed on a simplified 2.5D computational domain (Fig. 2a). Simplification of the Genoa region was performed in two steps. Firstly, the 3D geometry of Genoa's region was used to obtain characteristic slopes of the terrain orography by “slicing” the area of interest and saving the coordinates of each characteristic slope. Secondly, coordinates of characteristic slopes were imported in opensource software Blender for simplification (Fig. 2a). The computational grid was constructed with the *blockMesh* utility of the opensource code OpenFOAM (Fig 2b). The boundary conditions are shown in Fig 2c. At the inlet face, a log-law mean velocity profile was imposed to reproduce neutral ABL wind.

The aerodynamic roughness length (z_0) was assumed equal to 0.05 m with reference velocity of 5 m/s at of 660 m above the sea level. Temperature at the inlet was set according to the thermal gradient of dry adiabatic lapse rate (i.e. 10 K/km), with surface temperature equal to 16°C. No slip conditions were imposed on the walls with z_0 = 0.05 m for mountain and z_0 = 0.0002 m for the sea. The *buoyantBoussinesqSimpleFoam* solver, with *k-ε* turbulence model was used.

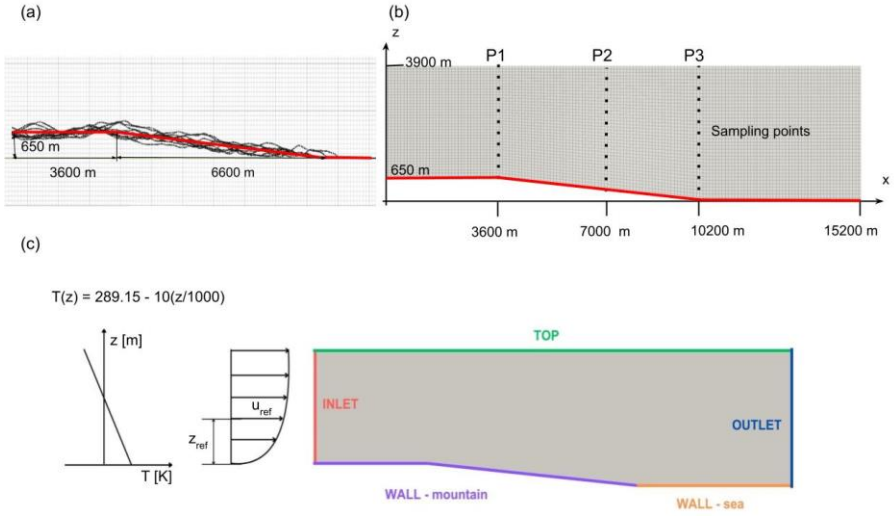

Figure 2. a) Characteristic slopes obtained from the area of interest (see Fig 1b); b) 2.5 D computational domain and grid with the indication of sampling positions for the vertical profiles of the mean wind velocity; c) Boundary conditions imposed on the domain

3. RESULTS AND CONCLUDING REMARKS

Fig 3a shows the development of the vertical profile of mean velocity at three positions (P1, P2, P3): beginning, middle, and end of the slope upstream the coastline (see also Fig. 2b). The velocity profiles are normalized with the maximum velocity (U_{max}) measured/simulated at each sampling point. In general, Fig. 3 shows a significant development of the mean velocity profile, from a standard neutral ABL profile (inlet) to a vertical nose-shape profile typical of DWs (outlet). This nose shape is certainly caused by the temperature gradient and gravity force further emphasized by the nature of the slope. Considering the high level of simplifications introduced in the computational model, the first qualitative comparison of CFD and LiDAR in terms of vertical profiles showed a good agreement between 40 and 250 m. Additional results will be shown during the presentation.

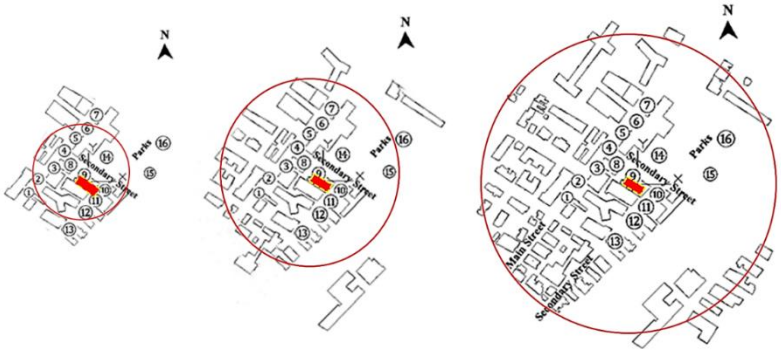
SUMMARY
With the rapid urbanization process, there is a growing concern regarding the wind environment in suburban and urban regions. The purpose of this study is to investigate the influence of the upstream fetch length on environmental wind engineering issues, such as the pedestrian level wind (PLW) and the wind comfort assessment around newly built buildings. The suburban region of Westmount in Montreal and the urban area of Kowloon in Hong Kong are selected for case studies. The investigation has been experimental and results were obtained from two atmospheric boundary layer wind tunnels. The results indicate that the upstream fetch length that influences the PLW estimation in suburban areas is as short as 200 m and in urban areas is as short as 450 m, as illustrated in Figure 1. For the wind comfort assessment of a newly building, an upstream fetch length of 100 m from the building site can be utilized depending on the criteria used.

Keywords: environmental wind engineering, upstream exposure, pedestrian level wind.

1. CASE STUDIES

1.1 Westmount, Montreal

The Westmount, Montreal case study is distinguished by sparsely distributed, low- to mid-rise buildings. To analyze the impact of upstream exposure on environmental wind flows, three upstream fetch lengths of 100 m, 200 m, and 300 m are utilized, as indicated by the red circles in Figure 1. Within this region, a proposed building is positioned at the center, marked by a red rectangle.



(a) Fetch length of 100 m (b) Fetch length of 200 m (c) Fetch length of 300 m

Figure. 1 Investigated area with varying lengths of upstream fetch.

1.2 Kowloon, Hong Kong

Kowloon, Hong Kong exemplifies a typical urban exposure characterized by heavily distributed high-rise buildings. This case study is chosen for evaluating the wind environment around existing buildings, with a specific focus on the wind velocity of pedestrian height within the inside circle with a radius of 450 m. Notably, the two most critical wind directions, W and E, have been identified. As the E wind direction faces the open sea, a wind direction of 260° is adopted to explore the impact of upstream urban exposure on the PLW, which extends up to 3,300 m in this wind direction, as depicted in Figure 2. In this study, fifty observation locations uniformly distributed in this area are selected.

Figure 2. Observation locations and upstream fetch length in investigated wind direction

2. EXPERIMENTAL METHOD

Experimentation of Westmount, Montreal was conducted at the wind tunnel of Concordia University in Montreal, Canada. The model is scaled down at a ratio of 1:400 with a blockage ratio of 3%, which is maintained below the 5% threshold recommended by (ASCE 49, 2021). The Reynolds number during the test exceeds 4.3×10^4, meeting the requirement for Reynolds number independence. Figure 3 shows a photo of this experimental model in the wind tunnel. PLW velocities were measured at 0.005 m above the floor in the reduced scale model, representing 2 m of the pedestrian height in full scale.

The experimental study of Kowloon, Hong Kong was conducted at the XNJD-3 wind tunnel of Southwest Jiaotong University. Considering the wind tunnel size and model dimensions, the scaling down of model is set at 1:800. Figure 4 shows a picture of the experimental model of Kowloon. The models were manufactured from foam, and finer details which have a minimal impact on PLW were eliminated. Only the wind direction of 260° was explored in this case study. Wind velocities were observed at a level of 0.0025 m in the tests, aligned with 2 m of full scale.

Figure 3. Experimental study of Westmount, Montreal.

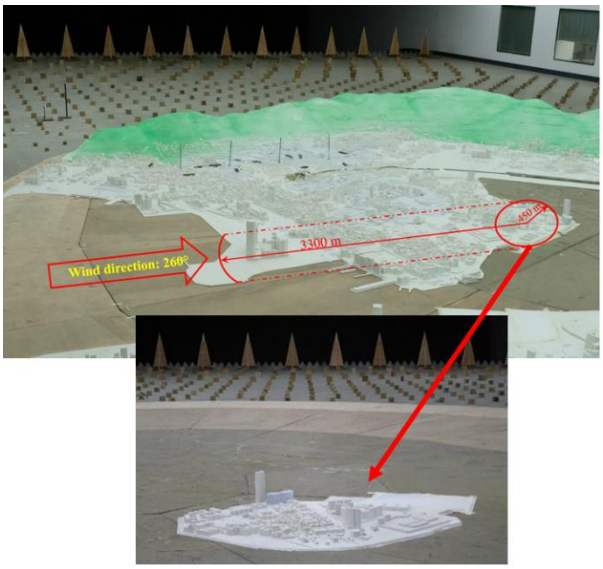


Figure 4. Experimental study of Kowloon, Hong Kong.

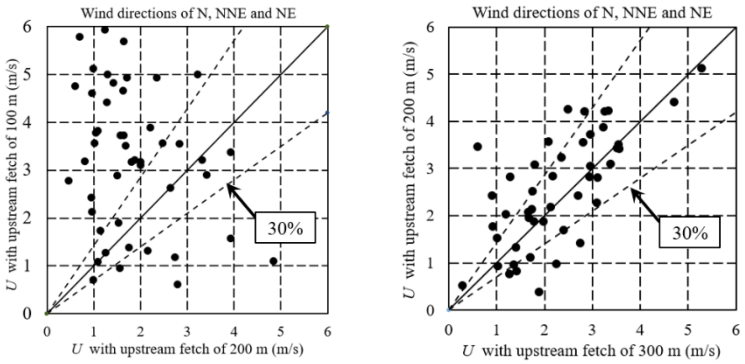
3. IMPACT OF UPSTREAM FETCH ON ENVIRONMENTAL APPLICATIONS

Figure 5 shows the differences of wind velocities of at pedestrian level with upstream fetch lengths of 100 m versus 200 m, as well as 200 m versus 300 m of suburban exposure. The figures indicate that the differences in the results between the upstream fetch length of 200 m *versus* 300 m are considerably smaller than the results between those of 100 m *versus* 200 m, although there are significant deviations in the parts with lower wind speeds, say less than 2 m/s. In the study of pedestrian wind environments, more attention is paid to the effects caused by higher wind speeds. This implies that the variation of velocity at pedestrian height stabilizes as the fetch length increases. The results demonstrate that the upstream fetch length of 200 m can be adopted for the wind comfort assessment of a proposed building in a typical suburban exposure.

The comparative analysis of PLW velocities across various upstream fetch lengths of urban exposure is presented in Figure 6. Clearly, while PLW velocity exhibits slight sensitivity to different upstream fetch lengths, the deviations at the majority of observation points between upstream fetch lengths of 450 m and 3,300 m remain within the 30% range. This indicates that assessing the wind comfort in urban exposure with consideration for an upstream fetch of 450 m

is reliable, as deviations within this range are deemed acceptable. However, It is essential to extend the analysis to figure out the minimum upstream fetch length impacting PLW velocity in urban exposure.



(a) 100 m versus 200 m. (b) 200 m versus 300 m.

Figure 5. Comparison of PLW velocities. Dashed lines denote 30% deviations.

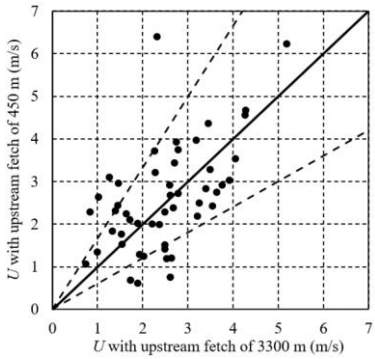


Figure 6. Comparison of wind velocities at pedestrian height. Dashed lines denote 30% deviations.

4. CONCLUSIONS

This study investigates the influence of the upstream fetch length on environmental wind engineering issues by experimental. The suburban region of Westmount in Montreal and the urban area of Kowloon in Hong Kong are selected for case studies. The results indicate that the upstream fetch length that influences the PLW estimation in suburban areas is as short as 200 m and in urban areas is as short as 450 m.

SUMMARY
For over a decade, computational fluid dynamics (CFD) has been essential in urban physics and wind engineering, tackling topics like pedestrian wind comfort, pollutant dispersion, and structural wind loads. These studies demand detailed modeling of complex landscapes as mountains, forests, and water bodies. While CFD can provide accurate results, generating geometries and grids for such environments poses significant challenges. Input geometry simplification, in particular, plays a key role in the success of the reconstruction. This study proposes an innovative high-fidelity digital twin modeling approach for the generation of complex environments. A digital twin model of Genoa municipality, Italy, was used to investigate the wind flow in the urban boundary layer by means of steady-state Reynolds-averaged Navier-Stokes (RANS) simulations. Hazard maps for extreme winds and temperatures are the ultimate goal of this work, aiming at improving the safety management and risk awareness during adverse weather.

Keywords: digital twin, RANS simulations, complex environment, wind, temperature, hazard map.

1. INTRODUCTION

Computational Fluid Dynamics (CFD) simulations have become a cornerstone for exploring urban physics and wind engineering phenomena at mesoscale levels, addressing topics such as pedestrian wind comfort, air pollutant dispersion, urban heat effects, and structural wind loads. At the mesoscale, such investigations could also involve the construction of digital twins - virtual replicas of intricate natural and built environments. Yet, developing a digital twin for expansive urban areas remains a formidable challenge, sparking growing attention from the research community in recent years (e.g. Alemayehu and Bitsuamlak, 2022; Pađen et al., 2022; Žužul et al., 2024). Despite progress, a comprehensive framework for accurate digital twin creation and mesh generation in complex settings is still lacking. These models often encompass diverse terrain features - hills, water surfaces, and vegetation - where topography introduces notable complexity. However, it is the detailed representation of the built infrastructure that proves most pivotal to the success of digital twin development. The relevance of specific geometric features depends heavily on the study's scale and objectives, with some details being vital for certain applications yet negligible for others. As a result, geometrical simplifications are frequently employed to facilitate automated reconstruction of large urban areas, a step critical for effective mesh generation. Striking the right balance in simplification is essential, as excessive reduction can alter the simulated flow field significantly (Ricci et al., 2017). Additionally, as urban scales expand, computational limitations endure, requiring geometry simplifications to control the total size of the computational mesh, while carefully balancing the retention of adequate details to fulfil the objectives of the analysis.

This study will outline key considerations, practical recommendations, and propose a systematic process for automating digital twin development in CFD wind engineering studies. An application of this approach is provided through the automated 3D geometry reconstruction of Genoa municipality, Italy, a coastal city of roughly 600,000 people, framed by sea and mountains.

2. DIGITAL TWIN CREATION FOR CFD APPLICATIONS

The framework for constructing a digital twin begins with meticulous geometry preparation, treating the built infrastructure and terrain topography as distinct entities. This approach aligns with the methodology of the City4CFD tool (Pađen et al., 2022) and forms the foundation of the procedure proposed in this study. The process starts with acquiring and pre-processing terrain topography data for the area of interest. As mentioned above, the large-scale city of Genoa (Italy) spanning 37 × 18 km², was selected. A high-resolution digital terrain model (DTM) with 1 m resolution was smoothed using a 50 × 50 m² moving window to mitigate outliers from measurement uncertainties. However, irregular topography at the domain boundaries can still hinder successful CFD simulations. To address this, the artificial buffering technique was used, extending the terrain outward to ensure a smooth transition to the far-field elevation (set at sea level, $z = 0$ m). This buffering adopts a two-zone strategy inspired by Žužul et al. (2024): (*i*) an inner buffer, where the terrain surface is smoothed by solving the Laplace equation, and (*ii*) an outer buffer, fixed at a constant elevation of 0 m. The resulting terrain data is then exported as a point cloud for subsequent processing.

The built infrastructure data, represented as polygons with assigned heights (in GeoJSON format), required additional simplification due to the complex and irregular shapes typical of Mediterranean coastal cities. Direct reconstruction proved impractical, prompting a series of simplification steps. Buildings shorter than 5 m or with roof areas below 25 m² were excluded. The Ramer-Douglas-Peucker algorithm (Douglas and Peucker, 1973) was applied to reduce the number of points defining each building's footprint. Additionally, buildings within 2 m of one another were merged to eliminate narrow gaps and passages, enhancing mesh quality. These simplified building polygons were then converted into a stereolithography (STL) file using OpenSCAD (2024). The entire terrain and building preparation workflow are automated via an in-house Python script, producing a CFD-ready geometry representation, as illustrated in Fig. 1.

The prepared terrain point cloud and building STL files were then processed through the City4CFD tool Pađen et al. (2022), an essential component of the digital twin generation workflow that corrects persistent triangulation errors and ensures seamless topological connectivity between buildings and terrain. With the computational domain boundaries established, generating a computational mesh becomes feasible. The mesh was created using `cfMesh`, an automated meshing library available in `OpenFOAM`. To manage the scale of Genoa's digital twin and excessive RAM memory requirements during the mesh generation process, the domain was divided into eight distinct subdomains, each meshed individually. The subdomains were subsequently combined to form a final computational mesh comprising of about 600 million cells in total. Although the grid-sensitivity study was not conducted due to the large scale of the case, it was created following the standards established in the community. This robust digital twin enables high-fidelity CFD simulations of atmospheric wind flows over large-scale complex environments.

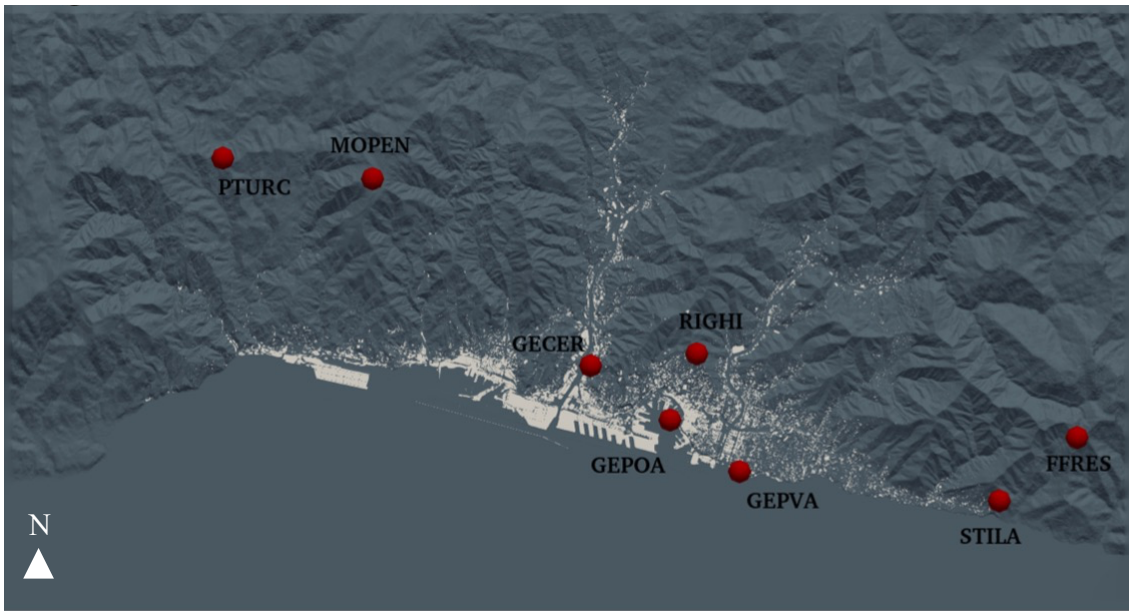

Figure 1. The target complex domain covering a 37 × 18 km^2 area around Genoa, including the reconstructed buildings and infrastructures. Red dots indicate meteorological stations collecting data for validation of CFD results and wind hazard map generation.

3. RESULTS

A 3D steady RANS approach coupled to realizable k-ε turbulence model was used to conduct simulations for 12 reference wind directions (i.e. $\alpha = 15°, 45°, \ldots, 345°$) under neutrally stratified atmospheric boundary layer (ABL) wind conditions. The ABL was based on the measurements taken at the nearby airport. The aerodynamic roughness lengths (z_0) were assigned as follows: 0.0002 m for the sea surface ($z_{0,\text{sea}}$), 0.4 m for rural regions ($z_{0,\text{rural}}$), and 0.8 m for urban zones ($z_{0,\text{urban}}$). Fig. 2 illustrates key aspects of the study: a side-by-side comparison of the computational mesh (Fig. 2a) with the expansive, the complex orography of Genoa municipality (Fig. 2b), alongside detailed wind velocity contours overlaid with velocity vectors in a horizontal plane at 30 m above sea level. These results focus on the western sector of Genoa for a wind direction of $\alpha = 225°$, as depicted in Fig. 2c and Fig. 2d, highlighting the realistic flow patterns achieved. Since the research goal is to generate wind hazard maps through statistical modelling, the RANS simulations used as an input are considered sufficiently accurate for that purpose.

5. CONCLUSIONS AND PROSPECTS

This study presents insights gained from an ongoing research on automating geometry preparation to streamline the development of digital twins and mesh generation for large-scale, high-fidelity urban areas in complex terrain. Successful handling such cases requires balancing of multiple factors, with geometry preparation and simplification emerging as a key element in accurate domain reconstruction. Employing these simplification techniques and presented workflow based on the automatic mesh generator `cfMesh` and CFD library `OpenFOAM` were found to be robust and optimal for generating meshes and obtaining wind field results in wind engineering applications. This framework enhances the efficiency and feasibility of large-scale simulations, contributing to more accurate and accessible modeling in urban physics and wind engineering.

Going forward, the CFD results will be first validated by comparison with the anemometric measurements taken through the network of about 35 meteorological stations belonging to the Municipality of Genoa installed within the urban canopy, and then combined with measured meteorological data to generate wind hazard maps. These maps will improve the capacity to predict and mitigate wind-related challenges in cities with diverse atmospheric conditions. In the near future, the simulations will also incorporate temperature fields, enabling the creation of hazard maps for extreme temperatures.

SUMMARY

This paper presents a condensation-free personalized radiant cooling (CF-PRC) technique, aiming at creating a "cooling oasis" in hot (indoor) ambient environments using two condensation-free radiant cooling boards (CF-PRCBs) placed on both sides of an occupant. Each board has a membrane with high infrared transmittance to seal a layer of dry air to separate the radiant cooling surface from the air-contact surface, enabling the use of a low radiant cooling temperature (such as 5°C) to enhance the cooling power of the boards (>100 W/m^2) without increasing condensation risk. We investigated the thermal performance of the cooling oasis when the cooling boards have different configurations, such as board size and cooling temperature, through numerical and experimental studies. We found that the PRCB pair can efficiently reduce the local operative temperature, local mean radiant temperature and local air temperature of the microthermal environment and thus form "cooling oasis" within a hot ambient environment. In a warm ambient environment (such as $T_{amb} = 28$°C), the CF-PRCB with the dimension of 1m × 0.7m could achieve a thermoneutral state using a radiant cooling tempreature around 10°C. The insights gained from this study provide valuable guidance for the design and operation of the CF-PRC technique, especially when considering energy-efficient and user-centric built environments.

Keywords: Personalized radiant cooling, condensation-free, cooling oasis, hot and humid climates.

1. Introduction

Indoor space cooling for thermal comfort is energy intensive (Garimella et al. 2022), motivating much effort from scientists and engineers to understand the mechanism to achieve thermal comfort and develop measures to improve the energy efficiency of cooling systems (Fanger 1967; Booten et al. 2021). Variant techniques have been developed for indoor cooling, and these techniques are categorized into air-cooling and radiant cooling. The former achieves thermal comfort mainly through the regulation of indoor air temperature, while the latter is mainly through the regulation of mean radiant temperature (MRT). Both can be used to create a global thermal-comfort indoor environment in the form of a "one-fits-all" system or a local thermal-comfort indoor environment in the form of a personalized comfort system (PCS) (ANSI/ASHRAE Standard 55-2023; Xie et al. 2020). Compared with a "one-fits-all" system, a PCS has been considered an efficient technique to save energy in conditioning a large-scale indoor space, especially when this space is partially occupied (Kim et al. 2018, Vesely et al. 2014). This is because a PCS for cooling enables the use of higher ambient temperature (e.g., 28°C) than "one-fits-all" systems (e.g., 24°C). Imanari et al (1999) shows that a PCS could increase the ambient temperature by 4.2°C compared with a "one-fits-all" cooling system under the same thermal conditions. This increment might lead to

significant energy saving as the increase of 1°C could save energy by ~3% (Zhang et al., 2015).

Generally, there are two types of systems that can be used to achieve personal cooling comfort: personalized ventilation (PV) systems and personalized radiant cooling (PRC) systems. A PV system creates a comfortable microthermal environment for occupants using a high airflow rate (Niu et al. 2007; Yang et al. 2010; Kalma et al. 2013). Since PV systems should be placed close to occupants, the cool air with a high velocity will produce a cold-draft and noise. This unwanted local thermal discomfort could hardly be avoided when using PV systems. Thus, PRC systems have been proposed to overcome the limitations of PV systems. PRC systems inherit the merits of a radiant cooling system that is installed on the ceiling in the form of radiant cooling panels, such as lower noises, smaller vertical temperature differences, and less draft risk (Rhee et al. 2015; 2017). Similar to PV systems, PRC systems should be installed close to users. However, unlike PV systems, PRC systems utilize radiant cooling surfaces to provide a cooling sensation rather than relying on high-speed cold air.

There are different designs of PRC systems in literature, including radiant cooling cubicle reported by Garg et al. (2017) and radiant cooling desk by He et al. (2017). However, these designs do not directly deal with the condensation problem but require that the radiant cooling surface temperature should be kept above dew-point temperature to avoid condensation. Therefore, these designs suffer from very limited cooling power. Membrane-assisted radiant cooling technology has been proposed to increase the cooling power of radiant cooling systems while avoiding condensation risk, which provides a fundamental solution to the condensation problem (Morse 1963; Teitelbaum et al. 2020; Zhang et al. 2021; Liang et al. 2021; 2022). Their studies show that when low-density polyethylene (LDPE), which has an average transmittance of 0.82 for the infrared radiation between 2-22μm, is used as the membrane, the cooling panel can provide a cooling power of 110 W/m^2 using the radiant cooling temperature of 5°C without condensation.

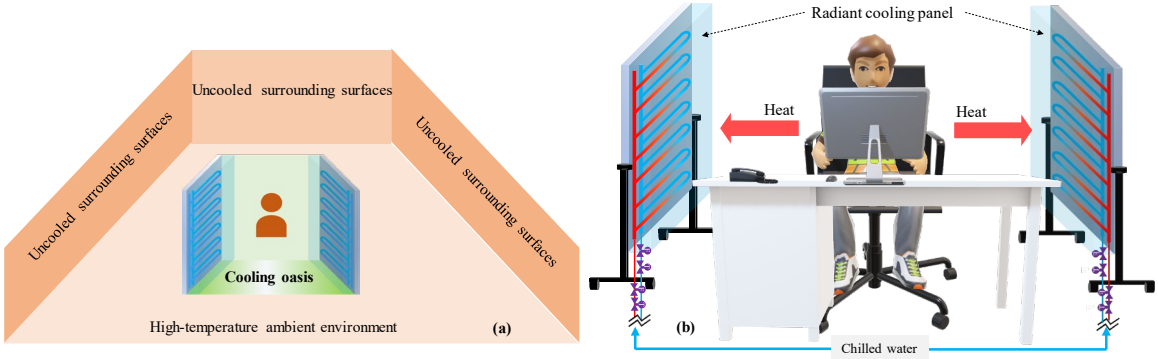

Figure 1. (a) The concept of 'cooling oasis' in a hot ambient environment; (b) the developed personalized radiant cooling technique (Liang et al. 2024)

Motivated by the above works, we propose a condensation-free PRC (CF-PRC) technique, aiming at creating a comfortable microthermal environment, or "cooling oasis", within warm/hot ambient environments through enhanced radiative rather than convective heat exchange. The concept of the cooling oasis is shown in Figure 1(a). The CF-PRC system consists of two CF-personalized radiant cooling boards (or CF-PRCB pair), installed on the right and left-hand side of the occupant, shown in Figure 1(b). The radiant cooling surface of the CF-PRCB pair is cooled to a preferable temperature using the chilled water from a chiller plant, and the occupant disposes of the body heat directly to the PRCB pair mainly through radiant heat

exchange. Our previous works explore the fundamental issues of CF-PRCBs, such as heat transfer modelling, thermal comfort survey and energy performance (Liang et al., 2024; 2025). In this paper, we will investigate the thermal environment created by a CF-PRCB pair with three different dimensions and demonstrate their capability in creating comfort thermal conditions within warm/hot ambient environments.

2. THERMAL ENVIRONMENT MODELLING

The structure of the CF-PRCB is given in Figure 2(a). The radiant cooling surface is coated with a high emissivity material (such as graphene-composite carbon nanotube with emissivity of 0.95) and a set of chilled water capillaries is fixed on a wooden board behind the radiant surface. An insulation layer is fixed on the other side of the wooden board to prevent cooling loss. A 10cm-air layer is sealed by an LDPE membrane to provide enough thermal resistance for the heat exchange between the air-contract and the radiant cooling surface to maintain a high temperature at the air-contact surface to prevent condensation. In application, a CF-PRCB pair could be installed for each workstation in a large office to create an individually preferable microthermal instead of cooling down the whole office; and individual CF-PRCB pairs should be switched on or off as simple as a desk lamp.

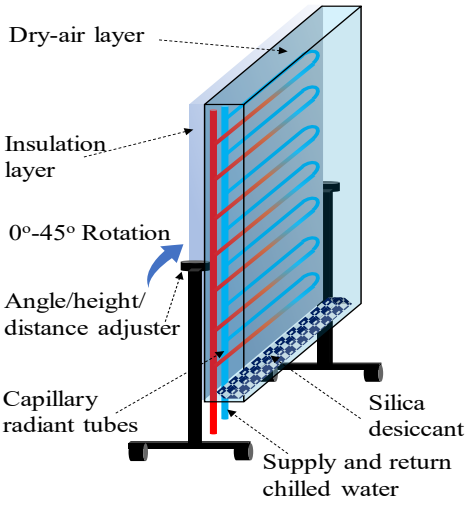

Figure 2. The structure of the CF-PRCB in the test chamber.

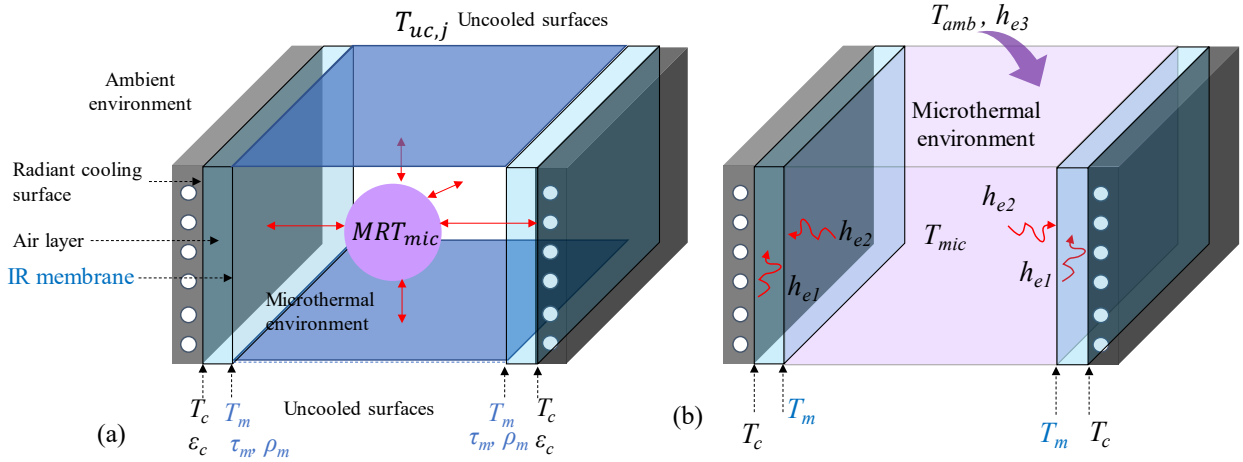

Figure 3. Microthermal environment modelling for the microthermal environment: (a) radiant heat transfer; (b) convective heat transfer.

The microthermal environment model for the CF-PRCB pair is developed based on the assumption that an imaginary cuboid, formed by the CF-PRCB pair and four imaginary boundary surfaces (as shown in Figure 3a), can isolate the microthermal environment from the surrounding ambient environment. The virtual boundary surfaces facilitate heat transfer through radiation and convection between the microthermal environment and the ambient environment, as illustrated in Figures 3a and 3b, respectively. Additionally, the two LDPE membranes, being semi-transparent, allow heat transfer between the radiant cooling surfaces and the microthermal environment.

Given the size of the CF-PRCBs and the distance between the CF-PRCB pair, the local mean radiant temperature MRT_{mic}, the local air temperature T_{mic}, and the membrane temperature (T_m) are estimated as follows. MRT_{mic} is given by Eqn. (1):

$$MRT_{mic}^4 = (2\varepsilon_c ERT_c^4 F_{P\to RCP} + \sum_{j=1}^{n_{uc}} \varepsilon_j T_{uc,j}^4 F_{P\to uc,j})/\varepsilon_o \quad (1)$$

where ε_c is the emissivity of the radiant cooling surface; ε_o is the uniform emissivity of the enclosure surface; $F_{P\to RCP}$ is the angle factor between the occupant and the radiant cooling surfaces; $T_{uc,j}$ is the temperature of the j^{th} uncooled surrounding surface; and $F_{P\to uc,j}$ is the angle factor between the occupant and the j^{th} uncooled surface. ERT_c is the equivalent temperature of the radiant cooling surfaces, defined as the temperature of a PRCB without the membrane and the dry-air layer that could provide the same cooling power by the membrane-integrated PRCB with the radiant cooling temperature of T_c. ERT_c can be calculated using the algorithm detailed in the supplement notes in (Liang et al. 2024).

Assuming the local air temperature of the microthermal environment is homogenous, we calculate the local air temperature T_{mic} and membrane temperature T_m using Eqns. (2) and (3)

$$T_{mic} = \frac{h_{e2}A_{e2}}{h_{e2}A_{e2}+h_{e3}A_{e3}} T_m + \frac{h_{e3}A_{e3}}{h_{e2}A_{e2}+h_{e3}A_{e3}} T_{amb} \quad (2)$$

$$T_m = \frac{h_{e1}}{h_{e1}+h_{e2}} T_c + \frac{h_{e2}}{h_{e1}+h_{e2}} T_{mic} \quad (3)$$

where $A_{e1} = A_{e2} = A_1 + A_6$, $A_{e3} = A_2 + A_3 + A_4 + A_5$; and A_1, A_6 are the left and the right area of the membrane surface, respectively, $A_1 = A_6$; A_2, A_3, A_4, A_5 represent the area of the virtual boundary in the microthermal environment, for the two side, bottom surface, and upper surfaces, respectively. The coefficients h_{e1}, h_{e2} and h_{e3} in Eqs. (2) and (3) should be known before the calculation and they can be identified using experimental data (Liang et al. 2024).

To validate the environmental model, a test rig was setup in a controllable environment chamber (9m × 5.4m × 2.4m), shown in Fig. 4, where the ambient air temperature and relative humidity (RH) were controlled by electric heaters and humidity regulators. Two PRCBs (0.7m × 1m each) were placed 1.2m apart, accommodating the arm length of a 175 cm tall person. The bottom edges were 0.4m above the floor, with the center height at 0.9m, targeting cooling for the upper body of a seated person. Swema test equipment and Lutron recorders measured air velocity and temperature at various heights (0.1, 0.6, 0.9, 1.1, and 1.7m), black globe temperature (0.9m) and relative humidity (0.9m).

Figure 4. Experiment setup, where a mannikin was placed between two CF-PRCBs

3. RESULTS AND ANALYSIS

3.1 Microthermal environment analysis

Table 1 summarized the main temperatures of the ambient environment, including T_{amb}, *MRT* and T_{op}, before and after the CF-PRC system was switched on. Even when the heaters were fully off, the ambient environment was "warm" or slightly "hot" and outside of the generally thermal comfortable range (T_{op} = 24 - 26ºC) defined by ANSI/ASHRAE Standard 55-2023. Table 1 also showed that the CF-PRC system had a limited capacity to affect the ambient environment. Even if the radiant cooling temperature was as low as 5ºC, the ambient environment was not significantly affected. For example, there was only 0.3ºC in the air temperature difference before and after the PRC system was on. At each scenario, the radiant cooling temperature T_c was controlled and stabilized at 5, 10, 15, and 20°C. The local air temperature T_{mic}, the local *MRT* and the local operative temperature $T_{mic,op}$ at different T_c were recorded and listed in Table 2. These data were used to validate the model briefly introduced in Section 2, where we compared the membrane temperature, local air temperature and local MRT from the experiment with those calculated using the models. All absolute errors were less than 0.5°C and we thus conclude our model in Section 2 is accurate and reliable.

Table 1. Main variables of the ambient environment.

Scenario (Electrical heater)	before PRC system on			after PRC system on (with $T_c = 5$°C)		
	T_{amb}(°C)	*MRT* (°C)	T_{op} (°C)	T_{amb}(ºC)	*MRT* (ºC)	T_{op} (ºC)
1 (Fully on)	31.3	31.3	31.3	31.0	30.9	30.9
2 (Half on)	29.2	29.5	29.4	29.2	29.3	29.3
3 (Full off)	27.7	27.7	27.7	27.4	27.4	27.4

Table 2. Main variables of the microthermal environment created by the CF-PRCB pair (1m × 0.7m).

Radiant cooling temperature	Scenario 1	Scenario 2	Scenario 3
	$MRT_{mic}, T_{mic}, T_{mic,op}$	$MRT_{mic}, T_{mic}, T_{mic,op}$	$MRT_{mic}, T_{mic}, T_{mic,op}$
$T_c = 20$°C	29.9, 30.0, 29.9	28.7, 28.7, 28.7	26.3, 26.7, 26.5
$T_c = 15$°C	29.2, 29.7, 29.4	27.9, 28.3, 28.1	25.5, 26.4, 25.9
$T_c = 10$°C	28.4, 29.4, 28.8	27.3, 28.0, 27.6	24.7, 26.1, 25.2
$T_c = 5$°C	27.8, 29.1, 28.3	26.7, 27.6, 27.1	24.2, 25.9, 24.9

Note: all the temperatures are in degree Celsius (°C)

The CF-PPRCB pair can significantly reduce the local MRT through radiative heat exchange with the radiant cooling surface, as shown in Table 2. For example, when the radiant cooling temperature of the PRCB pair was 5ºC, the local MRT was lowered from 31.3ºC, 29.5ºC and 27.7ºC to 27.8ºC, 26.7ºC and 24.2ºC, with the decrease of 3.5ºC, 2.8ºC and 3.4ºC in Scenarios 1, 2 and 3respectively. Using the data generated from the validated environment model, the local MRT for different sizes of the CF-PRCB boards can be estimated by

$$MRT_{mic} = 0.125T_c + 0.875T_{ew}, \text{ for } 1m \times 0.7m \quad (4a)$$

$$MRT_{mic} = 0.188T_c + 0.812T_{ew}, \text{ for } 1m \times 1.0m \quad (4b)$$

$$MRT_{mic} = 0.229T_c + 0.771T_{ew}, \text{ for } 1m \times 1.2m \quad (4c)$$

where T_{ew} is the equivalent uncooled surface temperature. The weighting factor associated with T_c indicates the significance of T_c contributing to the local MRT of the microthermal environment. A higher value means more contribution. Comparing the weighting factor in Eqns. (4a)-(4c), we can find that a larger CF-PRCB has a stronger capability to regulate the local MRT. For example, when the ambient temperature is 31.3ºC and $T_c = 5$ºC, the local MRT for the CF-

PRCB is 27.8ºC, which will be decreased to 26.4ºC when the board becomes 1m × 1.2m.

The CF-PRCB pair reduced the local air temperature through the heat exchange with the membrane surface. As shown in Table 2, the local air temperature was lowered from 31.3ºC, 29.2ºC and 27.7ºC to 29.1ºC, 27.6ºC and 25.9ºC, with the decrease of 2.2ºC, 1.6ºC and 1.8ºC by the PRCB pair with 5ºC, being around 2ºC. This reduction was not significant, indicating that the PRCB pair had a limited capacity in adjusting local air temperature of the microthermal environment. This could also be explained using the formular derived through fitting the data from the model:

$$T_{mic} = 0.076T_c + 0.924T_{amb} \text{ , for } 1m \times 0.7m \quad (5a)$$
$$T_{mic} = 0.112T_c + 0.888T_{amb} \text{ , for } 1m \times 1.0m \quad (5b)$$
$$T_{mic} = 0.120T_c + 0.880T_{amb} \text{ , for } 1m \times 1.2m \quad (5c)$$

Here the weighting factor for T_c was only 0.076 for the CF-PRCB pair with 1m × 0.7m, much smaller than the weighting factor for $T_{amb}(0.924)$. This shows that the local temperature was mainly affected by the ambient temperature. A large PRCB should enhance the contribution of T_c to T_{mic}. For example, when the PRCB was enlarged from 1 m × 0.7 m to 1 m × 1 m and 1 m × 1.2 m, the weighting factor for T_c was increased to 0.112 and 0.120 respectively. Compared Eqns. (4a)-(4c) with Eqn. (5a)-5(c), the PRCB pair has a stronger capability to regulate the local MRT than the local air temperature.

Table 2 also shows the local operative temperature $T_{mic,op}$ of the microthermal environment when T_c was 5ºC, 10ºC, 15ºC, and 20ºC under the ambient temperature of 31.3ºC, 29.2ºC and 27.7ºC respectively. It shows that the CF-PRCB pair can efficiently reduce the operative temperature. Using the data generated from our environment model, $T_{mic,op}$ is approximated by

$$T_{mic,op} = 0.611\, MRT_{mic} + 0.389\, T_{mic}, \text{ for } 1m \times 0.7m \quad (6a)$$
$$T_{mic,op} = 0.616\, MRT_{mic} + 0.384\, T_{mic}, \text{ for } 1m \times 1.0m \quad (6b)$$
$$T_{mic,op} = 0.618\, MRT_{mic} + 0.382\, T_{mic}, \text{ for } 1m \times 1.2m \quad (6c)$$

The coefficient α (0.611), much larger than β (0.389), indicating that the contribution of the local MRT to the local operative temperature is higher than that of the local air. When enlarging the PRCBs' size, the coefficient for MRT_{mic} and T_{mic} was not significantly changed.

3.2 Operation guideline

As CF-PRCB pair is used to create comfortable environment preferred individually, we first investigate the thermal comfort of the microthermal environment created by the PRCB pair through a comfort survey. To simplify the analysis, we focused on a common office scenario, where the metabolic rate was assumed to be 1.2 met and clothing insulation at 0.5 clo. A total of 24 participants were invited to provide feedback on their thermal sensation within the thermal environment generated by the PRCB pair. The radiant cooling temperatures were set at 5°C (cold), 10°C (moderate), and 15°C (cool), while the ambient temperatures were 28°C (warm) and 30°C (hot). The comfort survey was designed in accordance with the established procedure outlined in the ANSI/ASHRAE Standard 55-2023. Using the available 1008 data sets, the TSV in the microthermal environment created by the PRCB pair was estimated by

$$TSV = 0.063T_c + 0.414T_{amb} - 12.28 \quad (7)$$

Based on this equation, we calculated the radiant cooling temperature range for the CF-PRCB pair with the dimension of 1 × 0.7m, 1 × 1.0m, 1 × 1.2m repectively when we use $TSV = \pm 0.5$ as the criterion for the individual thermal comfort. The results are shown in Figure 5(a) for $T_{amb} = 28$°C and Figure 5(b) for $T_{amb} = 30$°C. The radiant cooling tempreatgure for the CF-PRCB pair with the dimension of 1 × 0.7m should be adjusted inside (3.0, 18.9)°C for $T_{amb} = 28$°C and (-10.2, 5.7) °C for T_{amb}= 30°C. The thermoneutral state was achieved at $T_c = 10.9$°C for $T_{amb} = 28$°C and at $T_c = -2.2$°C for $T_{amb} = 30$°C. In the current practice of chiller plants, the chilled water supply with a temperature below 3°C is not practical. Therefore, the PRCB pair with the dimension of 1 × 0.7 m could not be used to achieve general thermal comfort when the ambient temperature was higher than 28°C. The radiant cooling tempreatgure for the CF-PRCB pair with the dimension of 1 × 1.0m should be adjusted inside (11.9, 23.9)°C for $T_{amb} = 28$°C and (1.8, 13.8)°C for T_{amb}= 30°C. The thermoneutral state can be achieved at $T_c = 17.9$°C for $T_{amb} = 28$°C and at $T_c = 7.8$°C for $T_{amb} = 30$°C. When the CF-PRCB pair with the dimension of 1 × 1.2m is used, the radiant cooling tempreatgure should be adjusted inside (14.4, 24.6)°C for $T_{amb} = 28$°C and (6.1, 16.2)°C for T_{amb}= 30°C. The thermoneutral state can be achieved at $T_c = 19.5$°C for $T_{amb} = 28$°C and at $T_c = 11.1$°C for $T_{amb} = 30$°C. Both can can achieve the thermoneutral state at a feasible chilled water supply temperature above 3°C.

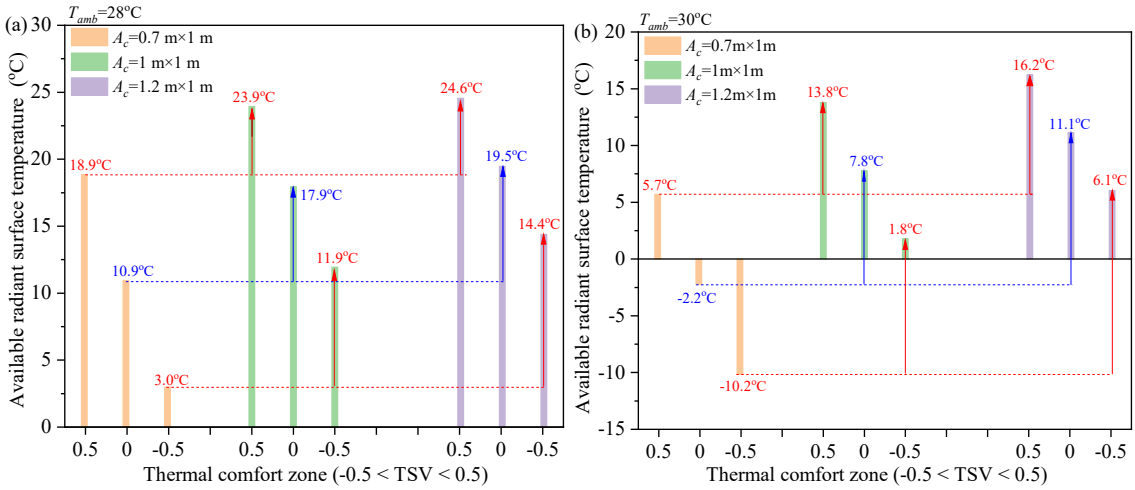

Figure 5. Radiant cooling temperature fulfilling the requirement of (-0.5 < *TSV* < 0.5) when the PRCB with different sizes was used for (a) $T_{amb} = 28$°C and (b) for $T_{amb} = 30$°C.

4. CONCLUSIONS

We have demonstrated that the proposed CF-PRC system can create a comfortable microthermal environment for occupants by adjusting board size and cooling temperature. The main conclusions are listed below:

- The PRCB pair can efficiently reduce the local operative temperature, local mean radiant temperature and local air temperature of the microthermal environment and thus form "cooling oasis" within a hot ambient environment. A larger PRCB has a stronger capability to regulate the microthermal environment.
- The thermal comfort created by microthermal environment can be estimated by $TSV = 0.063T_c + 0.414T_{amb} - 12.28$. In a warm ambient environment (such as $T_{amb} = 28$°C), the CF-PRCB with the dimension of 1m × 0.7m achieved a thermoneutral state using a radiant cooling tempreature around 10°C . However, if the ambient temperature is higher, such as

$T_{amb} = 30$°C, a large PRCB pair should be used.

SUMMARY

This paper presents a long-term monitoring study performed on an occupied timber-frame building in which straw bales are used as wall and roof filling. Temperature and relative humidity are measured in ten locations within straw bale walls with different orientations. The monitoring took place over three years to capture seasonal variations and plausible temporal evolution of hygrothermal behavior and durability. In addition, indoor air quality parameters (temperature, relative humidity, CO2 concentration) are measured in an open living room and a landing. The results showed that the average indoor temperature and relative humidity are 20°C and 60%rh, respectively. In summer, a phase shift of 3 hours and a damping of 11% are observed accross the walls. This case study confirms the potential of straw bale low-energy construction in providing thermal comfort fabric while minimizing the whole-life carbon of buildings. Regarding durability, mold growth is suspected only on the north-facing wall, an area less exposed to solar radiation.

Keywords: Relative humidity, hygrothermal comfort, mold growth, case study

1. INTRODUCTION

In recent years, low-carbon construction has emerged as an essential approach to mitigate the environmental impacts and energy demands of the construction sector. Bio-based materials such as straw, bamboo, and wood are increasingly used to decarbonize the construction sector. Straw was first used in construction around 1880 in Nebraska (D'Alessandro et al., 2017) and reemerged in the 1980s (Wall et al., 2012). In France, the first straw bale house was built in 1921 (Douzane et al., 2016). In the last decades, straw bale construction has gained attention and the advantages of this bio-based material have been recognized (Douzane et al., 2016). First, straw is cheap and easily accessible. In France, the national harvestable straw potential was estimated at 25 million tons in 2020. In addition, the use of straw in construction is a means of valorizing through recycling (Ashour et al., 2011; Wall et al., 2012). Besides, straw has also interesting thermal properties, such as low thermal conductivity. Depending on the orientation of straw stems to the heat flux and on density, the thermal conductivity ranges between 0.05 W/mK (D'Alessandro et al., 2017), 0.0723 W/mK (Douzane et al., 2016), 0.0939 W/mK (Gallegos-Ortega et al., 2017). These values are, of course, higher than those of conventional insulation materials (XPS, EPS, glass wool), but straw is prepared in the form of bale with thicknesses ensuring high thermal resistance (Chen et al.,

2024). This conditioning implies straw bales to be used mainly as infill materials in timber-framed buildings (Rota Font et al., 2024).

In the last two decades, numerous studies aimed to evaluate the hygrothermal behavior and/or the thermal performance of such buildings. (Ashour et al., 2011) monitored temperature and relative humidity within the building envelope of a straw bales timber-framed house in Bavaria, Germany, over a period of 450 hours. The results show that the straw walls attenuate extreme temperature peaks on the outside and that the migration of relative humidity from the outside to the inside of the straw is very slow (a difference of 3.4% to 2.5% after 400 hours). (Douzane et al., 2016) then studied the thermal and hygric performance of a house in Picardie, France, over 14 months. The results show that the indoor temperature stabilises between 20°C and 25°C in both summer and winter. Despite fluctuations in the outdoor RH, the indoor RH varies only between 40% and 60%. Analysis of the data recorded in the south façade in summer shows that there is a phase shift of 6h and a damping of 91%. For the north facade, the straw RH remains around 40% at 500mm depth, even for an outdoor RH of 100%. Last, comfort analysis based on the Bragger model combined with the Fauconnier model (Fauconnier, 1992) shows a level of discomfort of 26% to 32% for a level of satisfaction of 80% and 90%. Similarly, the work carried out by (Miljan et al., 2017) highlighted that straw bale walls can be used in an area with a harsh winter, such as Estonia. In Tecate, Mexico, (Gallegos-Ortega et al., 2017) monitored a building for 66 days in the summer. The result indicated a damping of 93.6% and a phase shift of 9.12h. Once again, a building envelope made of straw bales can provide comfort for the occupants, with the indoor temperature stabilizing at around 25°C whereas the outdoor temperature varies between 14 and 28°C.

Regarding the durability of straw walls, (Chen et al., 2024) mentioned that the great thickness of walls may lead to mold problems, particularly in cold, wet environments. Nevertheless, a visual inspection of the inside of the straw bale wall performed by (Thomson and Walker, 2014) after three years of service life showed no visible signs of decay in their experimental cell located in Liskeard Cornwall, United Kingdom, an area exposed to heavy rainfall. Besides, their laboratory analyses also highlighted that cyclical condition (28 days with high humidity and 14 days in a dry environment) does not compromise durability.

The number of case studies on a straw building is unfortunately limited and lasts for short periods that are not long enough to understand their long-term hygrothermal behavior and performance in view of validating their broader adoption. Note that when walls are monitored, only one orientation is considered in each study. In this view, this article describes the three-year monitoring of an occupied timber-frame building with straw-bale walls in Vannes, France, under real-life conditions. The aim is to verify the long-term hygrothermal performance and also to analyse the durability of the straw wall.

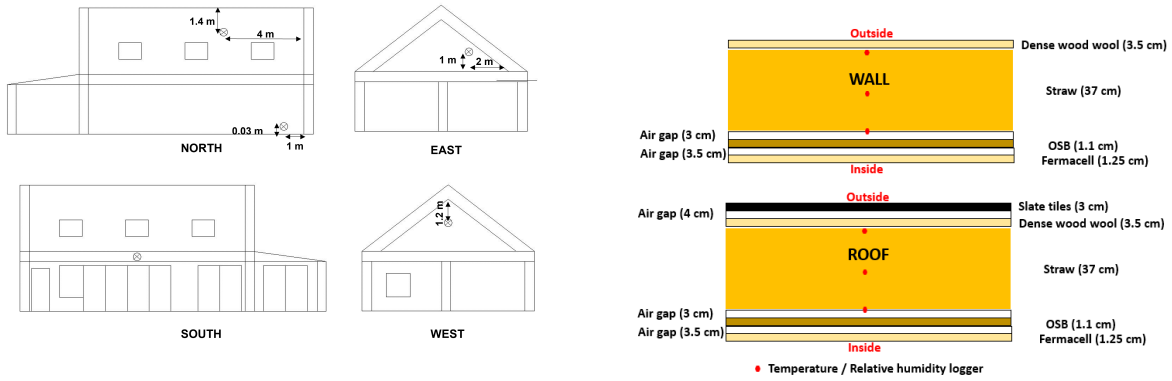
2. METHODOLOGY

2.1. Description of case study building and of its monitoring

The studied building is a two-floor family house built in 2021 near the city of Vannes (west coast of France, characterized by an oceanic climate). The building is 15.5 m long and 8.5 m wide and

has a living area of 140 m^2. The building is oriented in the E-W direction and windows are mainly oriented in the south façade. The building's walls and roof are made with 37 cm thick straw bales as an insulation layer. Their design is shown in Fig.1b. The wall and roof have U-value of 0.11 and 0.207 $W.m^{-2}.K^{-1}$ respectively. Last, heating system and controlled mechanical ventilation without heat recovery are installed.

Ten temperature and relative humidity sensors (S-THB-M008 from HOBO connected to HOBO Micro Stations H21-002) are embedded in the building envelope to assess the hygrothermal behavior and durability of the straw. Here, all wall orientations are investigated, which is the originality of the work. Sensor positions in the wall and roof are shown in Fig.1a. A weather station (made with HOBO sensors) monitors outdoor conditions just around the building (air temperature and relative humidity, wind speed and direction, global horizontal irradiance). In addition, one could access data from a weather station located 5 km from the studied building. Tow HOBO MX1102 logger provides measurements of indoor temperature and relative humidity, CO2 concentration in an open living room and in a landing. All data are recorded every 15 min. The experimental campaign started at the end of building construction (in July 2021) and was carried out for 3 years (until July 2024). During this period, the dwelling is occupied by a 4-person family. As usual for long-term experiments, some measurement problems arise during the monitoring period and some data are missing due to data acquisition failure and power outage, particularly for indoor ambient data.



(a) **(b)**

Figure 1. Sensors positions in the wall (a) and view of wall and roof design (b)

2.2. Methods of analysis

The temperature and relative humidity variations are analyzed during the monitoring period. Then, the phase shift and damping rate of the straw bale wall are calculated in order to highlight its thermal performance. Last, mold growth risk is broadly evaluated by comparing temperature and relative humidity measured locally to isopleth defining critical conditions for mold growth. Here, the Fraunhofer Institute's isopleth curve (Eq(1)) is used (Sedlbauer et al., 2011).

$$RH_{critical} = 0.0001 \times T^3 + 0.0286 \times T^2 - 1.817 \times T + 100 \quad (1)$$

The time of wetness TOW is defined as the cumulated time when critical conditions are exceeded. Nevertheless, TOW criteria do not account for the mold decline during unfavorable conditions. To

overcome this limit and refine mold growth evaluation, mold growth is predicted through M index defined in the VTT model (Viitanen et al., 2011). The M index, which varies from 0 to 6, measures the level of mold growth.

3. RESULTS

3.1. Hygrothermal performance of building

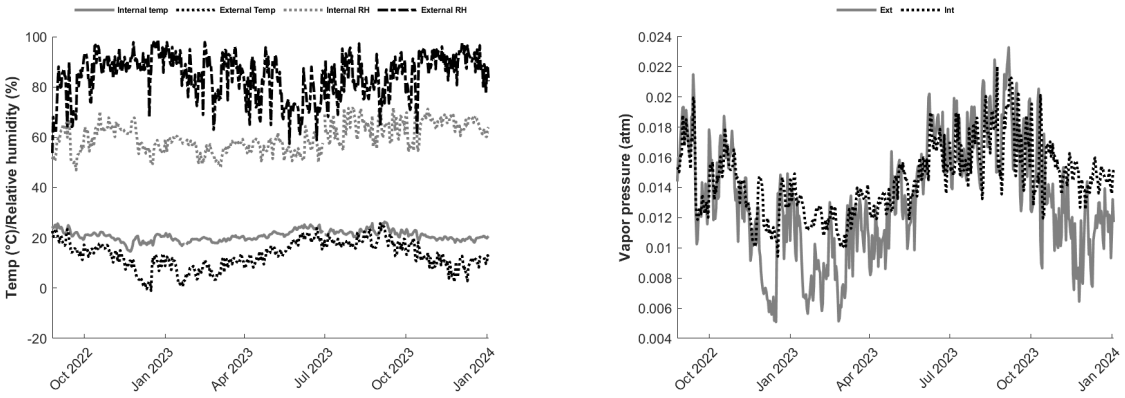
Fig.2a illustrates the mean daily outdoor and first-floor indoor temperatures and relative humidities recorded from August 2022 and December 2023. Indoor temperature is stable around 20.2°C, whereas outside it varies between -1°C in winter and 25.7°C in summer. Regarding relative humidity, the value stabilizes around 60% despite strong fluctuations outside. When focusing on the period between June 2022 and October 2022, the indoor environment remains relatively stable (with an average of 22,5 °C) despite the large variations in outdoor temperature (up to 37 °C). Fig.2b compares the evolution of outdoor vapor pressure with the one measured in landing. The later is often higher of about 0.01 atm than outdoor vapor pressure during winter (December-March). Heating increases the indoor temperature, which in turn raises the vapor pressure. In July, outdoor vapor pressure slightly exceeds the indoor one. This indicates a migration of water vapor from inside to outside during winter and punctually in the opposite direction during summer.

Since occupancy could not be assessed, evaluation of hygrothermal comfort using psychrometric chart or adaptive models in occupancy is not possible. Nevertheless, the evolution of indoor temperature and relative humidity let us think that hygrothermal comfort could be achieved. This is confirmed by the occupants during an interview. The questionnaires, prepared by students, address thermal comfort (temperature perception and degree of discomfort), visual comfort (satisfaction with natural lighting), and indoor air quality (perception of dry or humid air, and the presence of unpleasant odours).

This hygrothermal comfort is notably achieved during the summer when straw bale walls can mitigate high outdoor temperature peaks. For example, in July 2022, outdoor temperature reaches 41°C, compared to 27.5°C indoors. It is due, among other thermal phenomena, to the thermal inertia of the building envelope. Phase shift and damping are evaluated during this period as shown in Fig.3. A phase shift of approximately 3 hours and a damping rate of 11.8% are noted between outdoor and indoor temperatures. This result is lower than what is reported in the literature. For example, (Douzane et al., 2016) report a phase shift of 7 hours and damping of 9%. Similarly, (Gallegos-Ortega et al., 2017) observe a phase shift of 9.12 hours and a damping of 6.4% during the summer period in a straw bale house in Mexico. These differences can be explained by different strategies for managing solar radiation and ventilation.

3.2. Hygrothermal performance of straw bale walls

Fig.4a and Fig.4b show the evolution of temperature and vapor pressure at different depths of the west-oriented wall, respectively. One observes that, during the night until noon, T and pv decrease with a gradient directed inward. Once solar radiation reaches the west wall, T and pv start rising from noon and reach their maximum around 10 PM. The amplitude of T and pv variations depends logically on the position of the sensor: the highest amplitude is observed close to outdoors. This highlights the possibility of straw bale to dampen and shift solicitation. For this west-oriented wall,



(a) **(b)**

Figure 2. Evolution of outdoor and indoor temperatures and relative humidities (a) and of vapor pressure (b)

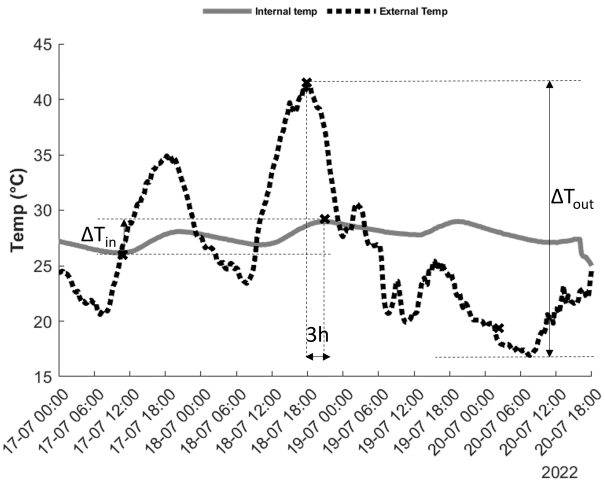


Figure 3. Evaluation of phase shift and damping during 3 days in summer 2022

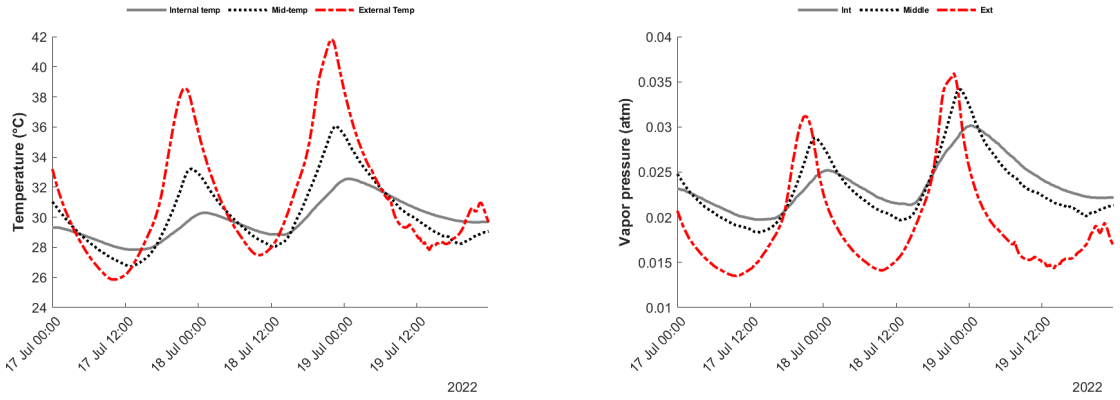
dampening and time shift are about 50.4% and 2.25h for T and 45.5% and 3.75h for pv. These results are almost in line with the ones predicted with the EN ISO 13786 standard (3.88h and 9.1% damping). Regarding vapor pressure, the behavior is mainly driven by temperature variations as the relative humidity does not vary to a large extent. Close to outdoor, relative humidity increases suddenly in line with temperature increase, highlighting local evaporation of moisture adsorbed by straw (Colinart et al., 2017). Nevertheless, this vapor does not have time to flow elsewhere in the straw bale and is re-adsorbed locally by straw once temperature decreases. When analyzing the data for the north and south-oriented walls, one comes to a time shift of 1.25h and 8.25h, respectively, and damping of 35%. These values differ significantly from the theoretical ones. Nevertheless, the sensors of these walls are located at single positions (close to the floor for the north wall and just above the windows for the south wall - see Fig.1a) where the assumption required by EN ISO 13786 does not prevail. For the south wall, the strong solar radiation and the local thermal bridges may influence the analysis. For the north wall, high humidity levels are noted, modifying the thermal properties of straw and involving enhanced coupling between heat and moisture transfer.



(a) **(b)**

Figure 4. Evolution of the temperatures (a) and vapor pressure (b) accros the west-oriented wall

3.3. Mold growth risk analysis

The durability of a straw wall depends on the type of environment it is used in. Therefore, it is essential to compare the relative humidity measured at different locations with the critical relative humidity evaluated with the measured temperature for each timestep. An example of comparison is shown in Fig.5a for one sensor located in the north wall at the straw–exterior cladding interface. The exceedance occurs for more than a third of the year. The air trapped in the wall is often saturated with humidity or close to saturation. Consequently, for years 1, 2, and 3, the time of wetness TOW is 126 days, 150 days, and 290 days, respectively. This process encourages the growth of mold on the straw and also damages the timber-framed structure. According to Fig.5b, the mold index M increases from 0 and to 3.5 after three years. (Johansson et al., 2013) indicate that even in an environment unfavorable to growth, spores and certain fungal structures do not disappear and can resume colonizing surfaces when humidity levels rise again. This is demonstrated in our situation, where the arrival of summer is not enough to decline mold, which keeps growing every year. Such M index indicates 10 to 50% coverage of mold if the material is directly in contact with air. For interfaces and surfaces which are not in direct contact with the interior air, (Viitanen et al., 2011) suggest to use M index as the threshold above which the mold growth risk is not acceptable. For instance, (Marincioni and Bradshaw, 2023) suggest that $M > 2$ represent a possible risk and requires further assessment, while $M > 3$ should be avoided. These conservative values were recommended to support safe design.

(Thomson and Walker, 2014) used the isopleth curve to see how often the critical moisture threshold was exceeded. Their results indicate that for a point in the mold growth zone, the measured MC is equal to 28.4%, although no signs of decomposition are visible. However, according to the literature, mold growth begins at a MC > 20% or RH > 70%. Hence, in our case, a visual inspection is planned in the coming months to confirm or rule out the presence of mold at this location. Note that this location is the most critical in the building: the north wall is logically not exposed to solar radiation and the bottom of the wall is very close to vegetation, which hinders air convection, maintains higher outdoor relative humidity levels and, thus, prevent the wall's drying out.

For the west facade, a lower exceedance is observed, resulting in mold index M of 0.02 at the end of the studied period (Fig.5c). For all other facades, no risk is noted, highlighting the durability of

the walls.

4. CONCLUSION

This study analyzed the hygrothermal behavior and the durability of a straw bale house using sensors embedded within the walls or located in the room. The collected data, representing three years of monitoring, have been analyzed. Results have shown that hygrothermal comfort is achieved in the building, even during heat waves. Among other reasons, this is due to the thermal inertia of the building envelope, which allows damping and shifting of the heat wave within the current section of the walls. Nevertheless, the contribution of specific parts of the wall becomes more significant and requires specific attention. This is particularly the case for the shaded bottom part of the north façade, where high relative humidity levels are noted. High levels of mold are expected according to the VTT model. The water infiltration issue at the base of the wall, combined with the excessive vegetation near the wall, could be responsible for this phenomenon. Visual inspection are planned to confirm or not this risk. Further works will focus on modelling the hygrothermal behavior of this house, first at the wall scale and then at the building scale.

Investigating and quantifying the Impact of Non-thermal Factor Influences on Thermal Sensation

Jiawei Wang [1], Jianong Li [1], Jianlei Niu [1]

Department of Building Environment and Energy Engineering, The Hong Kong Polytechnic University, Hunghom, Kowloon, Hong Kong, China

SUMMARY
In transition season, studying how non-thermal factors affect people's thermal sensation is crucial for optimizing public outdoor spaces (POS) design. Field measurements in Jordan Valley Park and Lok Wah Estate revealed a 5 mPET °C difference in thermal comfort due to age distribution and building shape. A Non-Thermal Factor Coefficient (NTFC_TSV) was developed to relate non-thermal factors to Thermal Sensation Votes (TSV), showing significant influence within comfort ranges. These results stress the need to account for both thermal and non-thermal factors in POS design for improved POS users' thermal comfort.

Keywords: Public outdoor space; Thermal sensation; Non-thermal factor

1. GENERAL INSTRUCTIONS

More than half of the world's population now lives in cities. With rapid urbanization and a soaring urban population, public outdoor spaces (POS) are becoming more valuable (Huang et al., 2020). POS offers people opportunities to relax and do some activities, which is crucial in maintaining citizens' physical and mental health. Therefore, Improving the quality and comfort of POS while attracting and encouraging citizens to participate in outdoor activities are the ultimate goals of urban design (Marcus & Francis, 1997).

Local microclimate conditions in urban areas, such as air temperature, wind speed, and mean radiant temperature significantly affect people's thermal comfort and behavior (Wang et al., 2025). In previous research, researchers have sought to encourage people to enjoy the outdoor environment by identifying thermal comfort ranges in which people's thermal sensation vote is -0.5 to 0.5 (Li & Liu, 2020). Findings vary across different regions, with studies in Tianjin indicating an mPET range of 11–24°C (Lai et al., 2014), in Changsha reporting 24–31°C (Yang et al., 2013), in Hong Kong identifying 27–29°C (Ng & Cheng, 2012), in Taiwan finding a range of 21.3–28.4°C (Lin, 2009).

On the other hand, according to recent studies, thermal factors are not the only factor that affects people's thermal sensitivity, and non-thermal factors also play a significant role (Li et al., 2023). Li et al. found that specific attributes of POS within communities, such as accessibility and visual factors, influence residents' heat acceptance (Li et al., 2024). Wang et al. discovered that the function of POS affects the thermal thresholds of elderly POS users (Wang et al., 2025). Therefore, understanding and quantifying the role of non-thermal factors in people's thermal sensitivity will provide valuable insights for future urban design.

This study aims to investigate the thermal comfort range of different types of POS and proposes a method to quantify and assess the influence of non-thermal factors on people's thermal sensitivity. The findings of this research will provide valuable insights for urban designers, helping them understand users' activities and preferred thermal environments across different types of POS.

2. METHODOLOGY

2.1. Study Site

Figure 1. Study sites: POS in Lok Wah Estate (LH_E) and POS in Jordan Valley Park (JV_P)

In this study, five POS are selected, three of which are from Lok Wah Estate (LH_E) and two of which are from Jordan Valley Park (JV_P), the pictures of POS are shown in Fig. 1.

2.2 Field Study

The field study includes microclimate measurement, passive observation, and the questionnaire survey, the experiment time was 9:00 to 17:30 from December 8th, 2023 to April 20th,2024 in LH_E and JV_P. The equipment. The collected environment parameters by the mini-weather station include air temperature (T_a), wind speed (v), black globe temperature (T_g), and relative humidity (RH), the instrument collects weather data every second, Figure. 2 shows the detailed information of the mini-weather station. During the measurement of microclimates at POS, student assistants conduct questionnaire surveys in the POS area. The surveys include ASHRAE 7-point thermal sensation vote (TSV) and 5-point thermal comfort vote (TCV).

Specifications of mini-weather station and globe thermometer

Meteorological parameter	Instrument	Measuring Range	Accuracy	Resolution
Air temperature	HY-WDS	-40°C-+80°C	±0.5°C	0.1°C
Relative humidity		0-100%	±2%	0.1
Wind speed		0-60m/s	±2%	0.01m/s
Globe temperature	Lutron WBGT-2010SD	0-80°C	±0.6°C	0.1°C

Figure 2. Portable mini weather station and its specifications

2.3 Heat Stress Index

The modified physiologically equivalent temperature(Mpet) is selected to be the thermal comfort indicator. The mPET is calculated based on the linear relationship between mPET and PET under humid conditions as proposed by Lin et al.(Lin et al., 2019), as shown in Eq. (1). PET is calculated using the Rayman software, utilizing weather data collected by a mini-weather station, including Mean Radiant Temperature (Tmrt), Air Temperature (T_a), Wind Speed (v), and Relative Humidity (RH).

$$mPET = 0.888 * PET + 3.5401 \ (R^2 = 0.99) \quad (1)$$

2.4 JOS-3 Model

In this study, the JOS-3 model is used to predict mean skin temperature, which is developed by Takahashi et al. (2020), predicts human physiological responses in diverse thermal conditions. With 83 nodes, it accounts for factors like brown adipose tissue, aging effects, and solar heat gain on the skin. Implemented in Python-3, this open-source model accurately forecasts physiological responses in dynamic thermal settings. Validation against human tests showed enhanced accuracy in heat production and skin temperature predictions across age groups, especially in colder conditions. RMSE values for rectal and mean skin temperatures ranged from 0.12 to 0.38°C and 0.58 to 0.83°C, affirming the model's reliability and utility for further research and applications.

3. RESULTS

3.1 Difference Between POS Users' Thermal Comfort Range in JV_P and LH_E

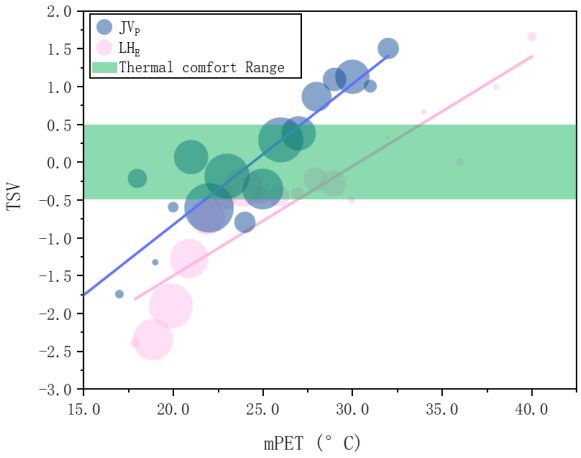

Figure 3. The relationship between the $\overline{mPET}$ which respondents experiencing and their TSV

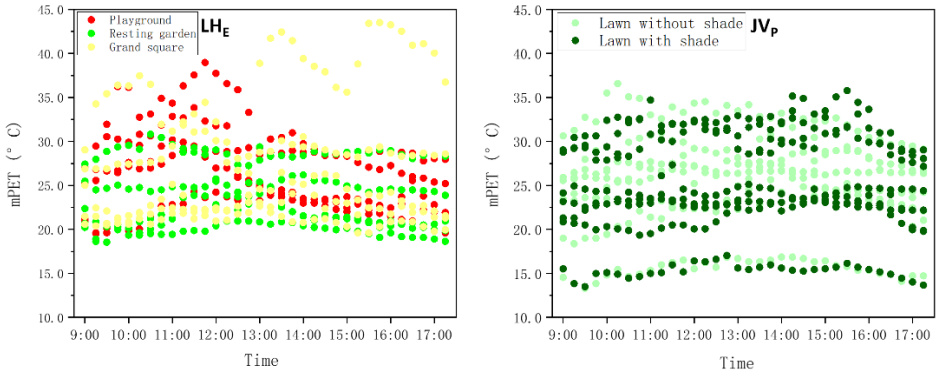
Figure 3. presents the regression relationship between the Thermal Sensation Vote (TSV) of all respondents in two regions and the corresponding 15-minute average mPET($\overline{mPET}$). The green-shaded area in the figure represents the range where TSV falls between -0.5 and 0.5, which, according to the literature, is regarded as the neutral thermal sensation zone which this interval is defined as the thermal comfort range. The points where TSV = -0.5 and TSV = 0.5 intersect with

the regression curve of TSV and the $mPET$ for both regions indicate that the thermal comfort range in LH_E extends from 26.2°C to 33.5°C, whereas in JV_P, it ranges from 22°C to 26.5°C.

3.1.1 Causes of difference by thermal factor

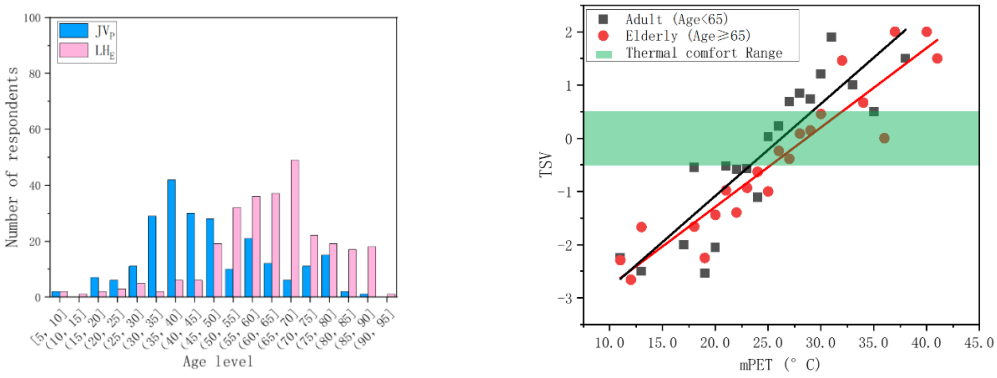


(a) (b)

Figure 4. Variation of pedestrian-level thermal environment mPET from 9:00 to 17:30: (a) LH_E; (b)JV_P

Figure 4. illustrates the distribution of $\overline{mPET}$ across five POS in two regions over a day. The data indicate that LH_E is generally warmer than JV_P, with $\overline{mPET}$ values approximately 7°C higher. This difference can be attributed to the contrasting environments: POS in JV_P is an open area, whereas large residential buildings surround POS in LH_E. As noted in Section 3.1.1, LH_E experiences higher temperatures and lower wind speeds compared to JV_P. Consequently, POS users in LH_E are exposed to a slightly warmer environment, leading to a higher thermal comfort range in this region.

3.1.2 Causes of difference: Non-thermal factor: Age



(a) (b)

Figure 5. (a) Histogram of age level in LH_E and JV_P; (b) The relationship between the $\overline{mPET}$ which respondents experiencing and their TSV in the different age group

Figure 5. (a) illustrates the age distribution of randomly selected respondents in the two regions during the questionnaire survey. In LH_E, respondents are primarily concentrated between 65 and 85 years old, with an average age of 73.5 years, whereas in JV_P, respondents are mainly between 35 and 60 years old, with an average age of 45.4 years. Figure 5. (b) presents the relationship and linear regression curve between TSV and $\overline{mPET}$ for elderly individuals (65 years old and older) and adults (under 65 years old), based on the questionnaire survey conducted in the two experimental regions. The thermal comfort range is determined using the same method as previously described. The results indicate that the thermal comfort range for the elderly spans 26.1℃ to 32.5℃, while for non-elderly individuals, it ranges from 22.5℃ to 28.2℃. These findings suggest that during the transition season, for the same $\overline{mPET}$, elderly POS users tend to have a lower TSV, indicating that their thermal comfort range is slightly warmer than that of younger POS users. This implies that the elderly generally prefer a slightly warmer thermal environment. Since the majority of LH_E users are elderly individuals who use POS, and they tend to favor warmer conditions, the overall thermal comfort range in LH_E is higher compared to JV_P.

3.2 Quantify the Impact of Non-thermal Factors on POS Users' Thermal Sensation

Due to the numerous non-thermal factors affecting thermal sensation, it is challenging to quantify the impact of each factor. Therefore, we first focus on the thermal environment experienced by POS users and, based on existing literature, use only thermal factors to predict their TSV. We then compare these predicted values (PTSV) with the real TSV(RTSV) reported by respondents to quantify the influence of non-thermal factors on thermal sensation. To achieve this, we first apply the JOS-3 model to estimate the mean skin temperature of respondents based on their experiencing thermal environment, using a phyton code derived from Takahashi et al. (2021). According to Wang & Hu (2016), mean skin temperature (MST) can be used to predict an individual's current TSV, with distinct prediction formulas for light-level, normal-level, and heavy-level activities, which are detailed in Eq. (2), (3), and (4). The prediction process of PTSV relies solely on microclimate data, making it a theoretical TSV influenced only by thermal factors. Consequently, the difference between PTSV and RTSV reflects the impact of non-thermal factors on thermal sensation. Eq. (5) quantifies this influence, with the abbreviation for the non-thermal factor coefficient impact denoted as NTFC_TSV.

$$Light-level\ activity: TSV = \frac{MST-32.3}{0.69} \quad (2)$$

$$Normal-level\ activity: TSV = \frac{MST-30.7}{0.86} \quad (3)$$

$$Heavy-level\ activity: TSV = \frac{MST-32.8}{1.59} \quad (4)$$

$$RTSV = PTSV * (1 + NTFC_TSV) \quad (5)$$

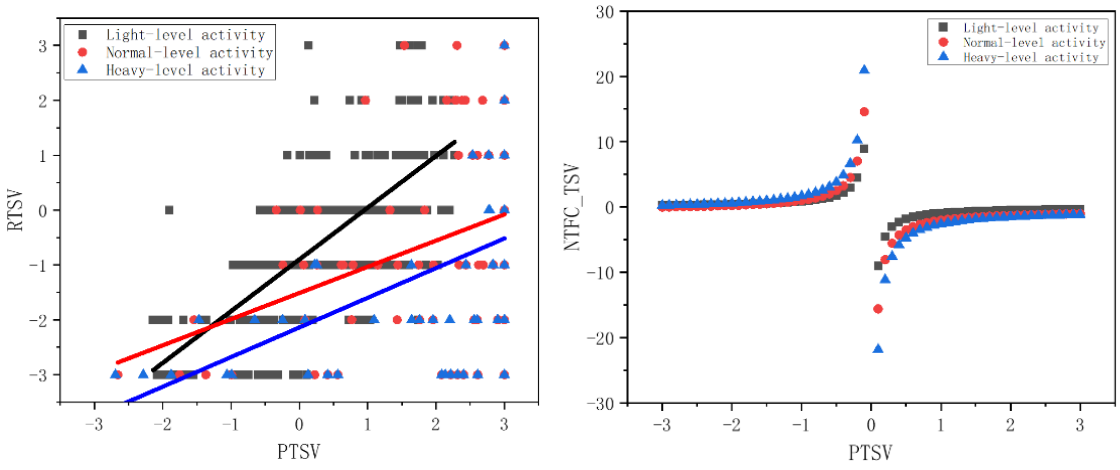
Figure 5. (a) illustrates the relationship between PTSV and RTSV across three different activity levels, along with their respective regression curves. The regression equations for light-level, normal-level, and heavy-level activities are provided in Eq. (6), (7), and (8), respectively. From

Figure 5. (a), it is evident that during the transition season, RTSV is generally lower than PTSV, indicating that non-thermal factors contribute to a cooler thermal sensation. Additionally, as the metabolic rate of the activity increases, the RTSV of heavy-level activities is consistently lower than that of normal-level activities under the same PTSV, with a difference of approximately 0.8. Compared to light-level activities, as PTSV increases, the gap between the two widens significantly. When PTSV is -2, the difference between light-level and heavy-level RTSV is only 0.1, whereas when PTSV reaches 2, the difference expands to 1.8, highlighting the increasing influence of non-thermal factors at higher heat stress levels.

$$RTSV(Light-level\ activity) = 0.943PTSV - 0.8984 \quad (6)$$

$$RTSV(Normal-level\ activity) = 0.477PTSV - 1.51 \quad (7)$$

$$RTSV(Heavy-level\ activity) = 0.5404PTSV - 2.1374 \quad (8)$$



(a) (b)

Figure 6. Sensitivity of PTSV to varying RTSV and NTFC_TSV: (a) PTSV in association with RTSV in three different activity levels; (b) Scatter plot of the relationship between PTSV and NTFC_TSV

Figure 6. (b) shows a hyperbolic relationship between NTFC_TSV and PTSV. As PTSV rises from -3 to 0, NTFC_TSV gradually increases but escalates rapidly near PTSV = -0.5. Conversely, from 0 to 3, it surges from negative infinity, stabilizing around PTSV = 0.5 and approaching 0 at PTSV = 3. This indicates that NTFC_TSV amplifies thermal sensation, making cold environments feel colder and hot environments cooler, leading to actual TSV being lower than predicted. Within the thermal comfort range (-0.5 to 0.5 PTSV), NTFC_TSV has the greatest impact, approaching infinity at PTSV = 0, making true neutrality difficult to achieve. Here, non-thermal factors (e.g., POS function and quality) outweigh thermal influences, as minimal physiological discomfort heightens sensitivity to external conditions. In extreme thermal conditions (PTSV < -0.5 or > 0.5), thermal factors dominate, with NTFC_TSV staying between -5 and 5. Users are more likely to

leave or seek a better environment, and if they stay, TSV fluctuations mainly result from microclimate changes, with non-thermal factors having a reduced effect.

Moreover, different activity levels also influence the magnitude of NTFC_TSV. As PTSV increases, activities with a higher met value experience a more rapid rise in NTFC_TSV. This suggests that during transition seasons, POS users engaged in higher-met activities have a lower TSV than those participating in lower-met activities under the same microclimate. This phenomenon occurs because, in transition seasons, Air temperatures are relatively low. Engaging in high-met activities, such as playing football which is a heavy-level activity induces sweating, which facilitates heat dissipation and makes the environment feel cooler. Additionally, compared to summer, people tend to wear slightly heavier clothing (higher clo values) during transitional seasons. Excessively heavy clothing increases the physical burden of exercise, leading to greater energy expenditure, which in turn results in heightened fatigue and a stronger sensation of cold.

4. CONCLUSIONS

This study explores the differences in thermal comfort range between a park and public housing estates in Hong Kong during the transition season, analyzing the underlying causes from the perspectives of thermal factors, as well as non-thermal factors (age). Furthermore, a method is proposed to quantify the impact of non-thermal factors on TSV. The main conclusions of this study are follows:

(1) The thermal comfort range in JV_P lies between mPET 22°C and 26.5°C, whereas in LH_E, it extends from 26.2°C to 33.5°C. This difference can be attributed to several factors. First, LHE is generally 7°C mPET hotter than JV_P, which influences its thermal comfort range. Second, most POS users in LH_E are elderly, while JV_P is primarily frequented by younger individuals. Given that the thermal comfort range for elderly people is about 4°C higher in mPET than that of younger individuals, this contributes to the observed disparity.

(2) During the transition season, POS users' actual RTSV consistently falls below their predicted PTSV, and this gap widens as activity levels increase. NTFC_TSV plays a significant role in the thermal comfort zone, whereas its influence is less pronounced in extreme cold or hot conditions, where thermal factors become more dominant. Additionally, as activity levels rise, the impact of NTFC_TSV also increases.

Abstract: Against the backdrop of climate warming and urban heat islands, ensuring pedestrian thermal comfort in outdoor walking environments has become a critical aspect of urban design. Although previous research on outdoor thermal environments has frequently emphasized large-scale shadow coverage, it has often overlooked the dynamic thermal perception of pedestrians along specific walking routes. Building on existing experimental results, this study employs theoretical derivations and a dynamic two-node thermoregulation model to analyze shading design strategies for pedestrians' entire walking trip. Key indicators—such as shading coverage ratio along the path, maximum exposure duration of continuous sunlight segments, and average (Sun–Shade) transition frequency—are proposed to optimize spatial shadow distribution. The findings not only enhance thermal comfort for urban pedestrians and encourage walking as a sustainable transportation mode, but also contribute to mitigating carbon emissions and advancing broader urban sustainability goals.

Keywords: *Outdoor walking environment; Whole-trip thermal comfort; Shade design strategy; Urban walkability; Sustainable development.*

1 INTRODUCTION

Frequent walking benefits human health, and accounting for pedestrians' thermal comfort in the design of urban outdoor walking spaces can promote walking and advance urban sustainability (Hanson & Jones, 2015; IPCC, 2023). However, escalating temperatures and the urban heat island effect intensify heat risks (Kim & Brown, 2021), where excessive heat exposure not only diminishes pedestrian comfort but also poses potential safety concerns (Liang et al., 2022). Consequently, improving outdoor thermal conditions to encourage walking has become a critical issue.

Mean Radiant Temperature (MRT) is a key indicator of outdoor thermal comfort, with solar radiation playing a pivotal role: for each 200 W/m² increase in direct solar radiation, pedestrians' thermal sensation and dissatisfaction rise by approximately 0.6 and 30%, respectively (Zhao et al., 2023). Research further shows that under high insolation, pedestrians actively seek shade (Watanabe & Ishii, 2016), and when outdoor UTCI exceeds 40°C, over half of them prefer staying in shaded areas (Watanabe & Ishii, 2016). Thus, shading design for sidewalks is crucial in ensuring outdoor comfort (Turner et al., 2023; Watanabe & Ishii, 2016). Indeed, studies have found that trees, pavilions, and building shadows can reduce PET or UTCI by 9°C to 17°C (Gai et al., 2024). Still, focusing solely on localized shading fails to address the frequent shifts between sunlight and shade during

walking (Zhao et al., 2022). Certain cities recommend a shading coverage of 20% to 80% (David & Babczyk, n.d.; Greater Phoenix Heat Action Planning Guide, 2019), but specifying coverage ratios alone cannot control sun exposure duration (Zhao, Xu, et al., 2024), highlighting the need to optimize shading at the "route" scale. While some scholars have employed multi-layer MRT or treated solar radiation as a "physical workload" (Tomasi et al., 2023), they have not fully considered pedestrians' heat memory biases and dynamic comfort needs. Frequent microclimatic variation can alleviate heat stress, and cumulative heat exposure affects whole-trip thermal perception (Li et al., 2022; Zhao, Zhao, et al., 2024). Earlier foundational studies (Zhao et al., 2023; Zhao, Xu, et al., 2024; Zhao, Zhao, et al., 2024) approached pedestrian thermal comfort from a full-journey perspective. On one hand, their models can directly inform shading designs for specific pedestrian routes by adjusting shade distribution to fulfill dynamic thermal comfort requirements; on the other, they can be applied to entire urban pedestrian networks, integrating meteorological or microclimate data to evaluate walking suitability across varying climates, times, and districts. Nonetheless, no unified set of comprehensive shading indices exists at the pedestrian-path level.

In light of this, promoting urban residents' willingness to walk requires explicit shade control indicators based on pedestrian thermal comfort models. From a "linear" perspective, this study proposes broader shade layout metrics, along with shading control strategies tailored to specific climatic conditions. The primary goal is to establish key path shading criteria that satisfy pedestrians' needs while expanding dynamic thermal comfort research and offering practical guidance for enhancing urban pedestrian environments. This endeavor ultimately aims to provide theoretical underpinnings and practical tools for professionals seeking to improve outdoor walking conditions.

2 METHOD AND RESULT

2.1 Shading Coverage Ratio (R_{shadow}) for Pedestrian Routes

Considering the pedestrian's entire walking trip, the summer shade coverage along paths must exceed a certain proportion to fulfill whole-trip thermal comfort requirements. According to the relationship between pedestrians' whole-trip thermal sensation (TSV_w) and whole-trip percentage dissatisfied (PD_w) in (Zhao, Xu, et al., 2024), when PD_w is capped at 50%, the critical value of TSV_w is approximately 1.91. This value can be viewed as the critical threshold for TSV_w, hereafter referred to as $TSV_{w,critical}$. During a trip, the instantaneous thermal sensation in sunlight ($TSV_{o,sunlight}$) typically surpasses that in shade ($TSV_{o,shadow}$). Consequently, once $TSV_{o,shadow}$ exceeds $TSV_{w,critical}$, the TSV_w under any sunlight conditions is likely to exceed this threshold, becoming a negative thermal experience for pedestrians. Therefore, ensuring pedestrians' whole-trip thermal comfort requires meeting the primary prerequisite expressed in Eq. (1).

$$TSV_{o,shadow} < TSV_{w,critcal} \tag{1}$$

When $TSV_{o,shadow}$ exceeds the critical value, the pedestrian route must maintain 100% shade coverage. Conversely, when $TSV_{o,sunlight}$ does not surpass the critical value, no minimum shade coverage is required. Therefore, this study primarily considers scenarios in which

$TSV_{o,sunlight}$ is greater than $TSV_{w,critical}$, representing most hot and sunny summer conditions. Next, TSV_w reflects pedestrians' whole-trip thermal sensation upon completing a route, yet they may encounter varying levels of heat exposure during walking. Consequently, TSV_o may fluctuate, causing TSV_w to shift between higher values in sunlight areas and lower ones in shaded areas. From a mathematical limit perspective, if the path is divided into as many alternating segments of sunlight and shaded areas as possible, the microclimatic impact in each unit of the route approximates a weighted sum based on shading coverage. Under these conditions, TSV_w comes closest to the weighted sum of $TSV_{o,shadow}$ and $TSV_{o,sunlight}$ according to their respective proportions. In other situations, the longer the continuous sunlight segment, the higher the likelihood that TSV_w, driven by $TSV_{o,sunlight}$, will exceed $TSV_{w,critical}$. Thus, the second condition to ensure TSV_w does not surpass $TSV_{w,critical}$ is that the time- (or distance-) weighted sum of TSV_o across all locations along the route remains below $TSV_{w,critical}$, as stated in Eq. (2).

$$TSV_{o,shadow}R_{shadow} + TSV_{o,sunlight}(1 - R_{shadow}) < TSV_{w,critical} \tag{2}$$

If the difference in pedestrians' thermal sensation when moving from shade to sunlight (ΔTSV_o) is known, then the required shade coverage ratio R_{shadow} under a given climate can be determined by Eq. (3).

$$R_{shadow} > R_{shadow,critial} = \frac{TSV_{o,sunlight} - TSV_{w,critical}}{TSV_{o,sunlight} - TSV_{o,shadow}} = \frac{TSV_{o,sunlight} - TSV_{w,critical}}{\Delta TSV_o} \tag{3}$$

From Eq. (3), once $TSV_{w,critical}$ is specified, substituting the instantaneous thermal sensation values in sunlight and shaded conditions is sufficient for calculation. In general, a person's instantaneous thermal sensation responds rapidly to ambient conditions and stabilizes quickly. Many previous studies have already established correlations between instantaneous thermal sensation and PET or UTCI. Thus, by applying Eq. (3), one can derive the minimum necessary shade coverage for a specific area, where the PET or UTCI values used in the calculation should match typical local parameters, such as the microclimate conditions most frequently encountered during summer daytime.

2.2 Maximum Exposure Duration ($\tau_{sun,lim}$) of Continuous Sunlight Segments

In sunny conditions, pedestrians typically walk along routes where sunlight and shade alternate frequently. Very short periods of sun exposure rarely elicit complaints from most people, but prolonged exposure can worsen their whole-trip thermal sensation and diminish their total walking experience. Therefore, for routes with frequent sun–shade transitions, identifying the upper limit of acceptable sunlight exposure time (or distance) holds significant relevance for outdoor thermal environment design and shading strategies. Figure 1 illustrates a typical example: in summer, a standard human subject (starting from a neutral environment with a neutral initial skin temperature) walks along a street, first passing through a shaded segment, then entering a sunlight segment.

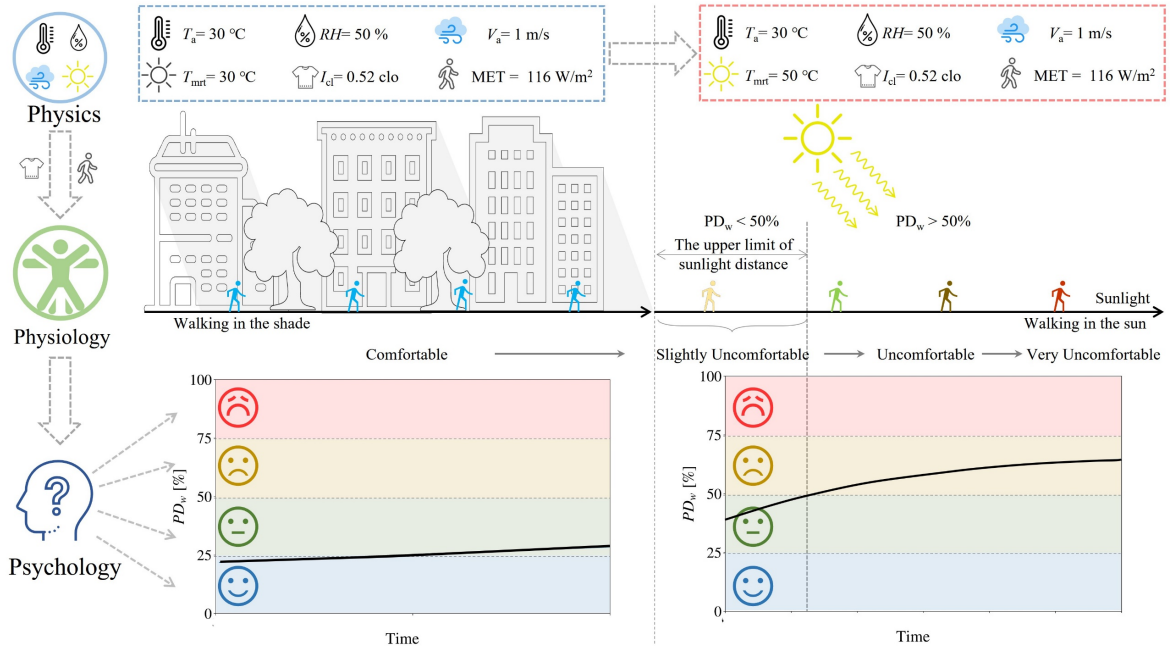

Figure 1. Schematic Illustration of Maximum Exposure Duration of Continuous Sunlight Segments

As shown in Figure 1, even when a route's shading coverage ratio is defined, an extreme adverse case may arise if there is only one continuous sunlight section, causing the pedestrian's TSV_w to reach its maximum in that portion. Hence, constraining the maximum length of uninterrupted sunlight exposure becomes crucial. Because whole-trip thermal comfort can be derived from mean skin temperature ($T_{sk,m}$), skin temperature change rate ($dT_{sk,m}/d\tau$), and stored heat deviating from thermal neutrality (ΔQ_s) (Zhao, Zhao, et al., 2024), and each can be represented as time-dependent functions in a dynamic thermoregulation model, setting an upper threshold for thermal dissatisfaction allows us to determine the continuous sunlight exposure limit necessary to maintain whole-trip pedestrian thermal comfort. By employing the two-node thermoregulation model, one can simulate the dynamic physiological responses and whole-trip thermal comfort of pedestrians in specific environments (Zhao, Zhao, et al., 2024). These simulations yield the temporal change in PD_w during sunlight exposure. If PD_w is set to 50% as the critical value, the model provides the maximum acceptable duration of sun exposure; in combination with walking speed, it then produces the corresponding limit on continuous sunlight distance. Should any urban street segment exceed this limit, pedestrians are likely to experience pronounced thermal discomfort, making additional shading measures essential to reduce prolonged sun exposure.

Previous research indicates that TSV_w represents the sum of contributions from TSV_o, T_{sk}, and ΔQ_s, encompassing both instantaneous and memory-based thermal sensations. Drawing on reference signal theory and time constants, TSV_o, T_{sk}, and ΔQ_s are treated as three distinct subsystems responding to TSV_w. Before entering the sunlight area, each subsystem's thermal sensation approaches $TSV_{o,shadow}$; once stepping into sunlight, each gradually shifts toward $TSV_{o,sunlight}$ at differing rates. At any moment τ, the pedestrian's whole-trip thermal sensation, $TSV_{w,\tau}$, is the weighted sum of these subsystem signals. Consequently, after moving from

shade into sunlight, the evolution of $TSV_{w,\tau}$ over time is described by Eq. (4).

$$TSV_{w,\tau}=TSV_{o,sunlight}-\Delta TSV_o\cdot[w_o\cdot\exp(-\tau/\tau_{c,o})+w_{sk}\cdot\exp(-\tau/\tau_{c,sk})+w_q\cdot\exp(-\tau/\tau_{c,q})] \quad (4)$$

In Eq. (4), w_o, w_{sk}, and w_q are the weighting coefficients corresponding to the TSV_o, $T_{sk,m}$, and ΔQ_s subsystems of TSV_w, respectively. The symbols $\tau_{c,o}$, $\tau_{c,sk}$, and $\tau_{c,q}$ denote the response time constants (in seconds) for each subsystem, while τ represents the walking duration (in seconds) after moving from a shaded area to a sunlight area. $TSV_{w,\tau}$ is the whole-trip thermal sensation at time τ under changing environmental conditions, and ΔTSV_o is the instantaneous difference in thermal sensation when transitioning from shade to sun.

When the human body encounters a sudden environmental change, TSV_o also undergoes a sudden shift and rapidly stabilizes near a certain level, effectively responding immediately to the new environment. Consequently, its corresponding time constant $\tau_{c,o}$ is the smallest (assumed to be 1 s in this study). However, due to the heat storage properties of various bodily tissues and the internal heat transfer process, $T_{sk,m}$ and ΔQ_s do not respond instantaneously. Instead, they gradually approach a stable state as the pedestrian remains in the new environment; their time constants are relatively larger and differ from each other. From the perspective of physiological thermoregulation, $\tau_{c,sk}$, and $\tau_{c,q}$ correlate with the degree of activation in the body's heat-regulating systems under different thermal conditions. By employing a dynamic two-node thermoregulation model, one can simulate the variation of $T_{sk,m}$ and ΔQ_s under abrupt environmental changes and, through regression analysis, estimate each subsystem's time constant. The smaller these time constants are, the quicker TSV_w reaches $TSV_{w,critical}$, making pedestrians more prone to experiencing whole-trip thermal discomfort. Consequently, based on calculations that account for all scenarios, integer minima of 200 s and 400 s are assigned to the $T_{sk,m}$ and ΔQ_s subsystems, respectively.

Let $\tau_{sun,lim}$ be the upper limit of sun exposure time, at which point the pedestrian's whole-trip thermal sensation reaches $TSV_{w,critical}$ Setting $TSV_{w,\tau} = TSV_{w,critical}$ in Eq. (4) and substituting Eq. (3) into Eq. (4) yields the relationship between $\tau_{sun,lim}$ and critical shading coverage ratio ($R_{shadow,critical}$), as shown in Eq. (5).

$$w_o\cdot\exp(-\tau_{sun,lim}/\tau_{c,o})+w_{sk}\cdot\exp(-\tau_{sun,lim}/\tau_{c,sk})+w_q\cdot\exp(-\tau_{sun,lim}/\tau_{c,q})=R_{shadow,critial} \quad (5)$$

Using this approach, one can compute the value of $\tau_{sun,lim}$ under various conditions, as illustrated in Figure 2. It should be noted that Figure 2 only displays the computed results for $\tau_{sun,lim}$ within the range of 0 s to 500 s. Outcomes exceeding 500 s are interpreted as indicating no substantial thermal discomfort during sunlight walking, and such cases are all assumed to have $\tau_{sun,lim}$ = 500 s. The figure shows that when the TSV_o in shaded conditions is higher or when the difference between sunlight and shaded thermal sensations is larger, the acceptable duration of sun exposure diminishes. Therefore, under a specific climatic setting, one may first employ microclimate data and the pedestrian thermal comfort model proposed in this study to estimate $TSV_{o,shadow}$ and $TSV_{o,sunlight}$ in near-steady states. Substituting these into Eqs. (3) and (5) then determines the value of $\tau_{sun,lim}$ for that climatic context.

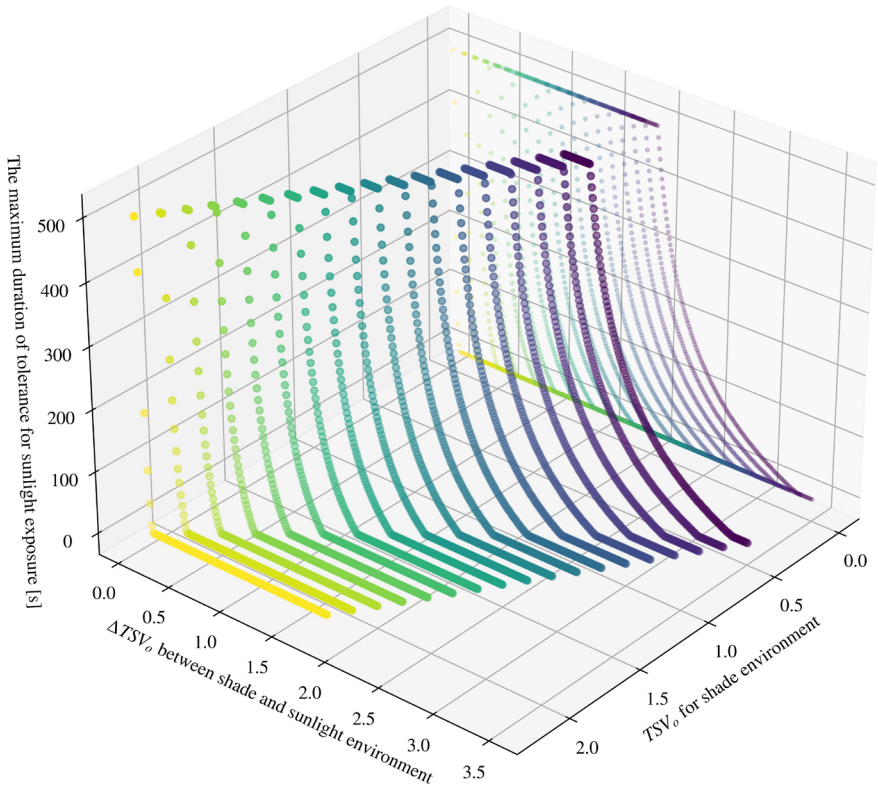

Figure 2. Relationship between the maximum exposure duration and the TSV_o for shade and sunlight environments

2.3 Average frequency of Sun–Shade Transitions (f_{300}) Along Pedestrian Routes

Even if each individual continuous sunlight section along a pedestrian route satisfies the $\tau_{sun,lim}$ constraint, problematic scenarios may still arise if two such sunlight segments are close together and separated by only a short shaded section. In that case, immediately after one sunlight segment—when TSV_w is already elevated—a brief shaded section might not be long enough to lower TSV_w to its original lower level. Thus, an additional constraint must be imposed on the minimum distance of shaded sections separating multiple sunlight segments. Given $\tau_{sun,lim}$ and $R_{shadow,critical}$, one can calculate the minimum required shaded-section duration ($\tau_{shade,lim}$). By treating the sum of $\tau_{sun,lim}$ and $\tau_{shade,lim}$ as the continuous standard observation distance (L_{std}), and then specifying that the shading coverage ratio $R_{shadow,critical}$ must be met within any L_{std}-length interval along the route, it becomes possible to prevent multiple continuous sunlight segments from clustering. Assuming a pedestrian walking speed of v_p, L_{std} is given by Eq. (6).

$$L_{std} = (\tau_{sun,lim} + \tau_{shadow,lim}) \cdot v_p = \frac{\tau_{sun,lim} \cdot v_p}{(1 - R_{shadow,critial})} \tag{6}$$

Once L_{std} is established, the extent of route division by the standard observation distance is defined, so the average frequency of sun–shade transitions per 300 m-long pedestrian route (f_{300}) (Zhao et al., 2022) has a theoretical lower bound specified by Eq. (7).

$$f_{300} > 2 \cdot \frac{300}{\tau_{\text{sun,lim}} \cdot v_{\text{p}} + \frac{\tau_{\text{sun,lim}} \cdot v_{\text{p}}}{(1 - R_{\text{shadow,critial}})} R_{\text{shadow,critial}}} = \frac{600}{L_{\text{std}}} = \frac{600(1 - R_{\text{shadow,critial}})}{\tau_{\text{sun,lim}} \cdot v_{\text{p}}} \quad (7)$$

Eqs. (6) and (7) correspond to environments where high-heat exposure is a concern, and frequent dynamic thermal experiences can effectively prevent the mean skin temperature from reaching higher levels. This helps pedestrians avoid prolonged periods of discomfort, thereby improving their whole-trip walking experience.

In summary, the above approach yields various indicators required to fulfill pedestrian thermal comfort across the entire journey. For noncompliant segments, adding shading devices to increase effective shade coverage or reducing continuous sunlight exposure can enhance thermal comfort. At the neighborhood scale, a GIS-based path shading analysis can characterize sun–shade distribution across pedestrian routes. By assessing the proportion of route segments exceeding threshold values, planners can estimate the level of "heat resistance" for pedestrians during specific time periods, then strategically adjust shade coverage where needed. Reducing the proportion of routes that lead to prolonged thermal discomfort should encourage residents to keep choosing walking as a travel option.

2.4 Limitations and future work

This study focuses on the demand for outdoor shade in hot and humid climates during warmer periods, aiming to guide shade design. It has not yet explored the potential positive effects of sunlight in colder regions or during winter, a limitation that may affect the comprehensiveness of the findings. Future research could investigate adaptive urban shade designs, ideally achieving a dynamic balance of more shade in summer and more sunlight in winter to address diverse climatic needs. Additionally, based on subjective surveys and $TSV_{w,critical}$ calculations in a specific city, this study proposes an analytical framework for local shade layout. However, variations in thermal tolerance and sunlight exposure acceptance across different cities, climates, and urban layouts suggest that the generalizability of the findings requires further validation. Future studies will incorporate multi-regional data to enhance the applicability of conclusions. For urban planning and design, this study offers an analytical approach, enabling planners to assess the shading performance of outdoor pedestrian spaces based on local shade demand indicators and optimize shade facility layouts, such as adding canopies or adjusting green coverage, to improve thermal comfort in pedestrian environments.

3 CONCLUSION

This study, guided by the practical need to ensure thermal comfort throughout pedestrians' whole-trip, proposes a method for analyzing control indicators in path shading design. Under specific climatic conditions, the shading layout must simultaneously satisfy the minimum shading ratio within a standard observation distance, the maximum allowable exposure duration in continuous sunlight segments, and the minimum threshold for shade exposure frequency. These indicators are primarily determined by typical daytime summer climate conditions, as characterized by PET or UTCI in pedestrian spaces. Nevertheless, the present findings represent preliminary inferences, and further research is needed to validate their broader applicability.

Effect of sensations in dominant body part on overall sensation prediction in the CBE comfort model

Junwei Lin, Yongxin Xie, Jianlei Niu

Department of Building Environment and Energy Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong

SUMMARY
Thermal comfort research increasingly targets human responses in non-uniform and transient environments. The CBE comfort model, an advanced multi-nodal prediction tool, was developed to predict local and overall thermal sensations and comforts. In this model, cooling effects on the dominant body parts (back, chest and pelvis) have a dominant influence on overall sensation. However, this prediction logic can lead to prediction errors in real-world scenarios. To quantitatively assess this issue and propose a feasible correction strategy, we conducted field experiments in both indoor and semi-outdoor spaces. The results indicated that the cool sensation in the back affects overall sensation but does not always dominate it. To improve alignment with actual thermal sensation votes, a modified method is proposed for the original dominated cold model. This revised overall sensation calculation method can be incorporated into the original CBE comfort model to increase accuracy in predicting thermal sensation.

Keywords: local sensation, overall sensation, CBE comfort model.

1. INTRODUCTION

To predict human subjective responses more accurately in realistic environments, thermal comfort and sensation research has shifted its focus from the ideal uniform and steady environment to non-uniform and transient conditions (Zhang, 2003; Yang et al., 2024a). Spatially asymmetrical environmental conditions, observed in both indoor and outdoor environments, can result from factors such as temperature stratification, local cooling or heating devices and solar radiation(Zhang, 2003). Temporal non-uniformity also plays a critical role in thermal comfort prediction. During a certain period, dynamic environments and human behaviours contribute to transient thermal comfort and sensation votes (Brager & de Dear, 1998; Jiang et al., 2024; De Dear et al., 2013). Targeting the prediction of human responses to simultaneous non-uniform and transient thermal conditions, a three-part series on thermal sensation and comfort prediction was developed by UC Berkeley (Zhang et al., 2010a, 2010b, 2010c), namely the CBE comfort model.

In this series, Part I developed the local sensation models based on physiological parameters (Zhang et al., 2010a). These models utilize logistic regression functions to link local skin temperatures with thermal sensations. The dynamic term for local sensation is calculated using the derivative of core temperatures and local skin temperatures. After obtaining local thermal sensations, Part II proposed the local comfort calculation models that employ asymmetrical saddle-shaped curves to represent the relationship between local thermal sensations and comfort (Zhang et al., 2010b). Based on the local comfort and sensation results, Part III introduced methods for calculating whole-body comfort and sensations (Zhang et al., 2010c). The authors also published an additional part, Part IV, introducing the smoothing functions (Zhao et al., 2014).

Although these pieced models can better predict the whole-body sensation, the thermal sensation surveys conducted in previous studies observed inaccuracies in prediction (K et al., 2024; Yang et al., 2024b). One of the most significant discrepancies between experimental and calculated overall sensation occurs in cases where the "dominated cold" effect arises. In the original calculation method, cool or cold sensations in dominant body parts, including chest, back and pelvis, are expected to dominate the whole-body sensation. This concept is embedded in one of the pieced models, the opposite-dominated cold model (Zhang et al., 2010c). In this model, if the lowest local sensation in dominant parts is less than or equal to -1, the overall sensation is set to this value. However, this dominant effect appears to be less effective in certain scenarios. Survey results from previous studies showed that under relatively high heat stress, human subjects reported feeling warm or hot even when their dominant body parts were cooled by cooling devices (K et al., 2024; Yang et al., 2024b). Consequently, special attention should be given to the logic of the opposite-dominated cold model.

To address the identified deficiencies, this study aims to refine the original opposite-dominated cold model for overall sensation prediction, targeting more accurate overall sensation predictions. In this study, the experiments under varying thermal conditions were conducted to clarify the influence of the sensations in the dominant body parts on overall sensations and thus provide a basis for subsequent model modifications. Based on the analysis, modified calculation methods were developed to improve the accuracy of the overall sensation predictions when affected by the "dominated cold" effect.

2. METHODOLOGY

In this study, the thermal sensation surveys were conducted at a university campus in Hong Kong, China, from May to September. A total number of 30 human subjects (18 males and 12 females) were recruited to participate in the surveys, with their information details in Table 1. Since the experiments took place during summer in Hong Kong, most subjects wore typical summer clothing with a clothing insulation value of approximately 0.3 clo. The clothing insulation values were derived from tabulated clothing insulation data in the standards (ASHRAE, 2023; ISO, 2009) and the clothing information collected during the experiments.

Table 1. Characteristics of subjects.

	Male	Female	Total
Count	18	12	30
Age (years)	26.3 ± 2.9	27.1 ± 6.6	26.6 ± 4.8
Height (cm)	175.8 ± 5.0	167.1 ± 4.4	172.2 ± 6.4
Weight (kg)	72.1 ± 4.6	59.9 ± 10.0	67.0 ± 9.5
Clothing Insulation (clo)	0.31 ± 0.08	0.34 ± 0.07	0.32 ± 0.08

Each experiment lasted around 35 minutes, including a 10-minute adaptation period and two stages with different exposed conditions lasting 10 and 15 minutes, respectively. These two stages are labelled as Stage 1 and Stage 2. Stage 1 featured relatively constant thermal conditions while in Stage 2, the local cooling was introduced to create the dominated cold. Starting from Stage 1, subjects were asked to continuously report their thermal sensations by completing the questionnaires. The survey included 11 questionnaires, using an extended 9-point thermal sensation scale (Zhang, 2003). The time intervals between each questionnaire ranged from one to four minutes. The entire experimental process and the timing of sensation votes are illustrated in Figure 1. For the first and second questionnaires, subjects only recorded

their overall thermal sensations. Starting from the third questionnaire, recorded just before the local cooling, subjects were required to vote on their thermal sensations for both the whole body and each body part. The analysis of thermal sensation changes focused on questionnaires 3 to 11. Each subject completed the whole procedure one or two times with different experimental settings. The experiment produced 48 sets of data with 528 thermal sensation vote entries (432 entries included values for local body parts).

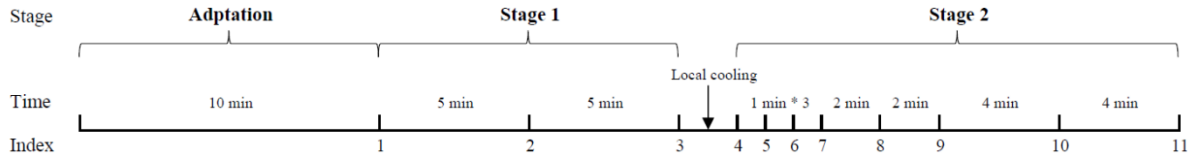

Figure 1. Procedures of the experiment.

To cover both indoor and outdoor conditions, the experiments were conducted in a climate-controlled chamber and a semi-open area. Table 2 presents the settings for four different cases designed for the experiment, consisting of two indoor cases and two outdoor cases. Four types of thermal environments were considered, including slightly cool indoors (set-point temperature: 22.0 °C), slightly warm indoors (set-point temperature: 26.0 °C), and fully and partly shaded outdoor open space with high temperatures (air temperature: 33.7 ± 1.4 °C). The globe temperatures for the fully and partly shaded outdoor cases were 34.4 ± 2.2 °C and 40.1 ± 3.3 °C, respectively. Subjects stayed in these thermal environments for approximately 10 minutes before the local cooling was introduced. The cooling devices were installed on a framework. Subjects were asked to stand with their back to the devices. For the used radiant cooling panels, the setting supply chilled water temperature was 8 °C, and the average panel surface temperature was 14.3 °C (Liang et al., 2024).

Table 2. Configurations of cases set in the experiments.

Case	Condition	Sample Size
1	Indoor (cool)	8
2	Indoor (warm)	8
3	Outdoor (fully shaded)	20
4	Outdoor (partly shaded)	12

3. RESULTS

In the experiment, four cases were designed to examine the possible “dominated cold” effect under different thermal conditions. Figure 2 shows the subjects’ overall thermal sensations during the questionnaires 3 – 11 for different cases (blue lines). When staying indoors and experiencing radiant cooling, the subjects’ average overall sensation decreased by around 1.5 for slightly warm conditions and 0.5 for slightly cool conditions. In the outdoor conditions with mediate and high heat stress (Case 3 and 4), even though the radiant cooling devices can still contribute to a slight decrease in overall sensation, the fluctuations were within 0.5.

Using the local sensations collected in the experiment, the overall sensation can be then predicted based on the CBE models. The predicted results are coloured in orange, distinct from the blue lines which represent the surveyed real overall sensations. The overall sensation predictions in Case 1 showed great agreement with the surveyed data. A larger difference was observed in Case 2 where subjects stayed in slightly warm indoor conditions with local cooling.

For the outdoor cases, the predictions for Case 4 performed well, while those for Case 3 were much less accurate. The predictions in Cases 2 and 3 underestimated the overall sensations and then caused large discrepancies.

The underestimation of overall thermal sensation when using local cooling may be attributed to the consideration of the "dominated-cold" effect. When the back side of the human body, primarily the back in this experiment, was cooled down, its sensations easily reached the threshold for the opposite-dominated cold calculation model. This process, however, may not be suitable for all cases. All four cases in this study which involved local cooling could cause the "dominated-cold" effect. In Case 1, since the differences between room air temperatures and panel surface temperatures were smaller, the radiant cooling was less efficient and thus the discrepancies caused by the "dominated-cold" effect were smaller. Similarly, the predicted sensation results in Case 4 were not affected by this effect, as with high heat stress, the back sensation could not reach the threshold for opposite-dominated cold. However, with mediate heat stress, Case 2 and Case 3 showed the largest differences between predicted and surveyed overall sensations. The underestimation of average overall sensations for Case 2 ranged from 0.1 to 0.7. In Case 3, the discrepancies were even larger, with a maximum bias of 1.1. The real average overall sensations in Case 3 kept at the hot level of around 2 while the predicted results decreased from 2 to 0.5.

Figure 2 illustrates additional lines for local sensations in the dominant part (back) and maximum local sensations. The predicted results in Case 2 and Case 3 were very close to the back sensations, supporting the supposition of the potential misuse of the "dominated-cold" effect. In both Case 2 and Case 3, the maximum local sensations were high, which might explain why the "dominated-cold" effect did not occur.

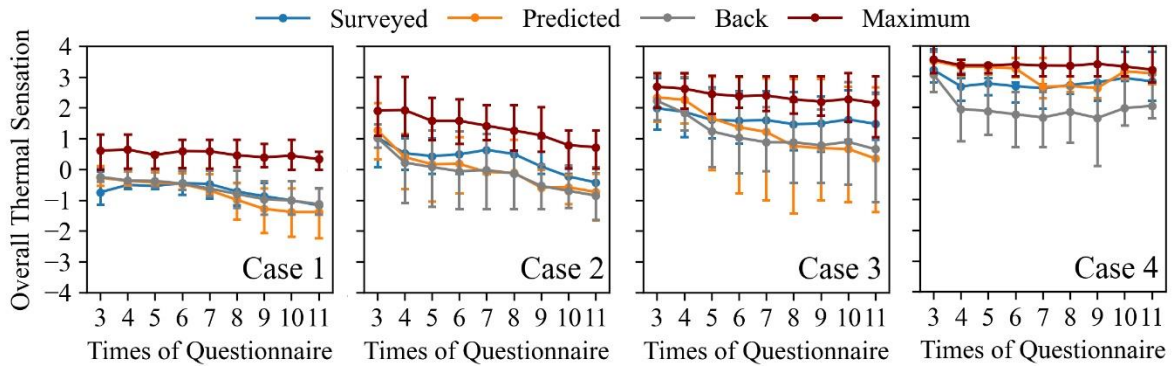

Figure 2. Comparison between surveyed and predicted thermal sensations for different cases.

4. MODIFICATION

The experiment highlighted the need for modifications to the CBE models to improve accuracy. In this section, the causes of inaccurate overall sensation were analysed and the possible solutions to these issues were then proposed. In the original models, the "dominated cold" effect occurs when the sensation group contains at least one positive local sensation. For a sensation group that contains certain local sensations $x_{(i)}$, the calculation of the predicted overall sensation for the opposite-dominated cold model can be expressed as:

$$Y = \min x_{(i),dominant} \quad (1)$$

where Y is the overall sensation and $x_{(i),dominant}$ is the local sensation in the dominant body parts including the pelvis, chest and back. If the lowest sensation in the dominant body part meets the threshold ($\min x_{(i),dominant} \leq -1$), the sensation group falls into the opposite-dominated cold model.

As analysed in Section 3, the predicted overall sensations obtained from the above calculation method were underestimated. Since the inaccuracy was observed when there existed hot or warm local sensations, the possible reason may because the influence of these sensations is overlooked. Among all the pieced models, the opposite cold model, which is similar to the opposite-dominated cold model, can serve as a reference. This model involves the opposite warm modifiers to describe the contribution of the hot or warm local sensations, following the equations:

$$Y = Y_{ex-bigger-group} + F_{warm} \quad (2)$$

$$F_{warm} = \max_1 F_{(i)} + 10\% \times \max_2 F_{(i)} \quad (3)$$

$$F_{(i)} = a_{(i)}\left[\left(Y_{bigger-group} - x_{(i)}\right) - c_{(i)}\right] + b_{(i)} \quad (4)$$

where $Y_{ex-bigger-group}$ and $Y_{bigger-group}$ refer to the overall sensation of the extended bigger group where local sensations $x_{(n)} \leq 1$ and the bigger group where local sensations $x_{(n)} \leq 0$. The calculation of $Y_{ex-bigger-group}$ and $Y_{bigger-group}$ follows the no-opposite calculation methods (the no-opposite high-level warm, high-level cold, low-level warm and low-level cold models). The modifiers $F_{(i)}$ created by opposite warm local sensations in different body parts are combined to generate the combined force F_{warm}. Each warm modifier $F_{(i)}$ is calculated based on the bias between the opposite local sensation and the precalculated overall sensation $Y_{bigger-group}$. The coefficients a, b, and c were defined in Part III (Zhang et al., 2010c).

As a special type of the opposite model, the opposite-dominated model can follow the same logic as other dominated models. To address the underestimation issues, the opposite warm modifier is also incorporated into the calculation of the dominated cold model, as follows:

$$Y = \min x_{(i),dominant} + F_{warm} \quad (5)$$

The modifier F_{warm} is also calculated using Eq. (4) with $\min x_{(i),dominant}$ replacing $Y_{bigger-group}$. The performance of the modified algorithm on the prediction accuracy improvement was evaluated in the next section.

Since the modification of the opposite-dominated cold follows the same logic as the opposite cold model, the sudden jump, when the model transitions across these two models, has been smoothed, as shown in Figure 3. A slight jump remained, which may be attributed to the inconsistency between the value of the lowest local sensation in the dominant part ($\min x_{(i),dominant}$) and the precalculated overall sensation ($Y_{bigger-group}$). A new method is needed to address this issue if the results are required to be fully smoothed.

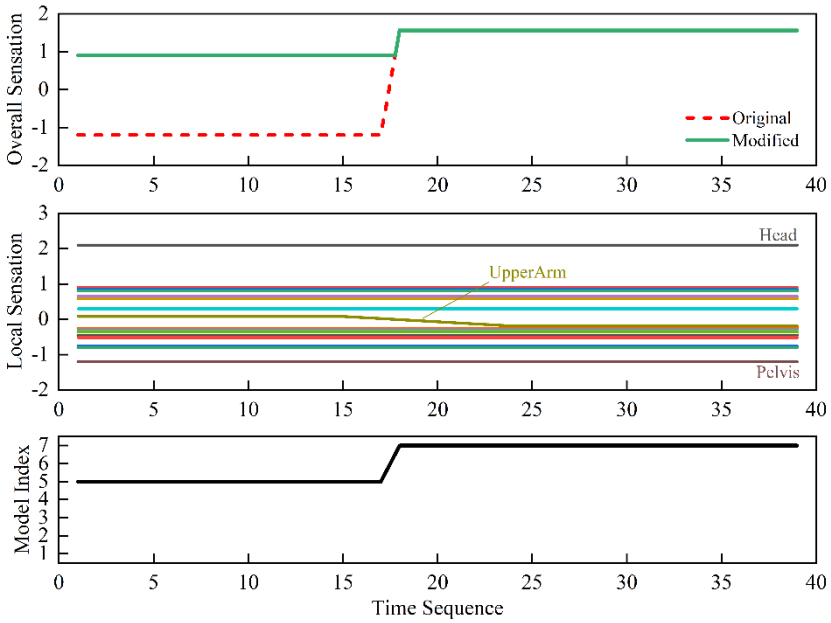

Figure 3 Overall sensation calculation results during the transition from the opposite-dominated cold model and opposite cold model. The upper figure compares the calculated results before and after modification. The middle figure shows local sensations, from top to bottom: head, face, breath, neck, chest, thigh, back, upper arm, lower arm, hands (left and right), legs (left and right), feet (left and right), and pelvis. The lower subfigure shows the model index.

5. VALIDATION

The modified model improved the accuracy of the predictions, as shown in Figure 4. Following the modifications, the predicted overall sensation in Case 2 and Case 3, which previously exhibited the largest discrepancies, aligned more closely with the surveyed overall sensations. This improvement is primarily attributed to the changes in the calculation methods for the dominated cold model. By incorporating additional modifiers generated from hot or warm local sensations, the calculated overall sensations increased, resulting in predictions that more accurately reflected real conditions.

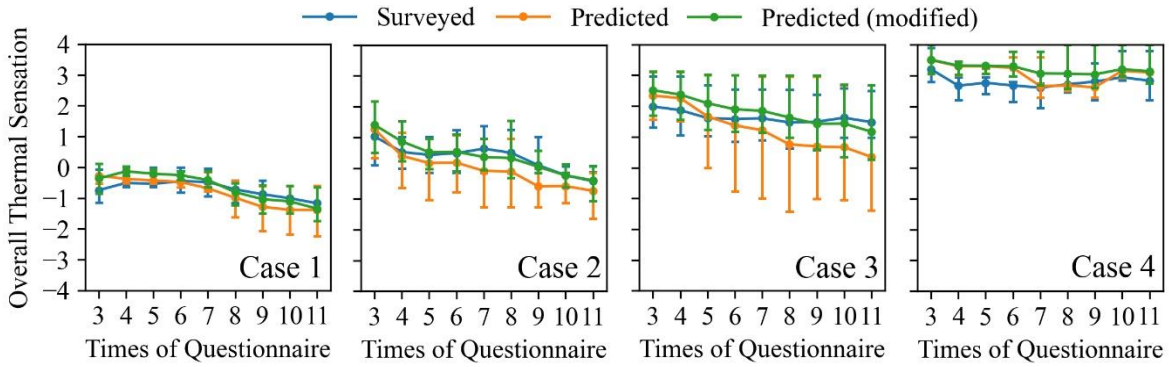

Figure 4. Comparison between surveyed and predicted overall thermal sensations for different cases.

In other cases, the modifications did not significantly impact the calculated values. No notable differences were observed between the overall sensations obtained from the original models and those from the modified models. The slight overestimation of overall sensations in Case 4

when subjects felt hot still remained unsolved even with the modified model. This issue may stem from the coefficients used for calculating warm modifiers. In this study, the coefficients developed for opposite modifiers were also used for the opposite-dominated model, which may not be suitable for all cases. Future investigations could consider developing a new set of coefficients for the modifiers to address this issue.

6. CONCLUSION

In this study, the overall sensation model in the previous papers has been modified and thus improved. Based on experimental data and logical inference, the inaccuracy issues in overall sensation prediction were detected. Modifications to the overall sensation calculation were introduced to resolve the large discrepancies between experimental results and predictions in certain test cases. For the test cases, the inaccuracy was primarily attributed to the consideration of the "dominated cold" effect, which may not always be suitable. By introducing additional modifiers generated from warm or hot sensations, the predicted overall sensations showed much better agreement with those recorded in the experiments. This modification also naturally smoothed the jump when the opposite-dominated cold model transitions to the opposite cold model.

Although the modifications narrowed large discrepancies, slight differences remain when modifiers generated from relatively extreme local sensations influence the whole body. Considerably more work is accordingly needed to optimize the coefficients of these modifiers across various thermal conditions. The modification of the opposite-dominated cold model referred to the logic developed for the opposite cold model, which showed great potential in smoothing the overall sensation results. This unified calculation method may replace the mathematic smoothing methods while maintaining interpretability. Accordingly, in the next step, more underlying patterns of the overall sensations for different local sensation groups should be identified, and further revisions of the models are expected to ensure the overall sensation results are more accurate, smooth and interpretable.

The influence of clothing moisture content on heat and moisture transfer between the human body and environment

Cheng Zhao [1], Yichen Yu [1], Jianlei Niu [1]

[1]*Department of Building Environment and Energy Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong*

SUMMARY
Evaporative heat loss is crucial to the human body's energy balance. Various thermal comfort models have been established to analyze the heat and mass transfer between the body and the environment during human sweating, yet the effects of sweat-soaked clothing on heat and moisture transfer remain insufficiently evaluated. This study investigates the thermal and moisture properties of different summer clothing and compares the heat loss of the human body in different sweating states using a sweating thermal manikin. It was found that the evaporative cooling efficiency of the body was suppressed by the soaked clothing as the sweating rate increased, which implies that sweat-soaked garments contribute additional resistance to moisture transfer. Consequently, we observed the dynamic variations in thermal and evaporative resistance of clothing ensembles at different moisture contents. A dynamic heat and moisture transfer model was established by incorporating clothing nodes in the thermal comfort model in detail.

Keywords: Heat and moisture transfer, Clothing model, Thermal comfort.

1. INTRODUCTION

Under warm to hot conditions, evaporative sweating is essential for regulating body temperature (Huizenga et al., 2001; Gagge et al., 2010). Various thermal comfort and clothing models have been developed to assess this process. Gagge's two-node thermo-physiological model was the first to quantify heat and evaporation transfer between the skin and environment, incorporating thermal efficiency and moisture permeation coefficients to calculate heat and moisture transfer through clothing. The more advanced Fiala-UTCI model refined this by detailing heat and mass transfer from the skin to the environment at each body surface and incorporating more precise local thermal and evaporative resistances (McCullough et al., 1985, 1989). The UC Berkeley Thermo-physiological Comfort Model (BTCM), derived from Stolwijk's model (Stolwijk, 1971; Fu et al., 2014), introduced a clothing node that simulates the absorption and desorption processes of clothing. However, both thermal and evaporative resistances of the clothing system remain independent of moisture content, unlike in real conditions where wet clothing alters the air gap between skin and fabric, replacing dry air with water vapor (Mangat et al., 2014). As a result, the overall thermal and hygroscopic properties of wet clothing change significantly, a dynamic process not fully captured by previous models.

This study evaluated the thermal and hygroscopic properties of typical summer clothing and compared the sensible and latent heat losses of the human body in various states of clothing wetness using a sweating thermal manikin. Modification coefficients were proposed to quantify the dynamic variation of thermal and evaporative resistances in varying wetting states. A dynamic heat and moisture transfer model for wetted clothing was developed, enabling the prediction of

temperature and vapor pressure at the clothing nodes during sweating. This model quantifies energy exchange between the skin, soaked clothing, and the environment under heavy sweating conditions, emphasizing the importance of incorporating realistic clothing parameters when assessing thermal comfort in hot and humid environments.

2. METHODS

2.1. Theoretical analysis

The heat exchanges between the skin layers, the environment, and the body's core layers affect the heat stored in the skin, which can be expressed as (Salloum et al., 2007):

$$C_{sk}\frac{dT_{sk}}{dt} = M_{sk} + Q_{co} - Q_l - Q_s + Q_b \quad (1)$$

where C_{sk} is the thermal capacity of the skin, J·K^{-1}; T_{sk} is the skin temperature, K; M_{sk} is the heat production by skin metabolic, W; Q_{co} is the heat transfer from the core layer of the body, W; Q_l represents the latent heat loss on the skin, mainly caused by the sweat evaporation, W; Q_s is the sensible heat loss on the skin, which contains the conduction or convection $Q_{s,c}$, and radiation exchange $Q_{s,r}$ with the environment, W; and Q_b is the heat generated by the skin blood flow, W.

For a clothed body surface, the total thermal resistance and total evaporative resistance were used to represent heat and vapor losses between the skin, clothing, and the environment (Eqs. (2) and (3)), and to use the clothing area coefficient f_{clo} to assess the heat transfer area of the clothing (Eq. (4)).

$$R_{t.t} = R_{t.clo} + \frac{R_{t.a}}{f_{clo}}, \quad (2)$$

$$R_{e.t} = R_{e.clo} + \frac{R_{e.a}}{f_{clo}}, \quad (3)$$

$$f_{clo} = 1 + 1.81R_{t.clo} \quad (4)$$

where $R_{t.t}$ is the total thermal resistance of the clothing, m^2·K·W^{-1}; $R_{e.t}$ is the total evaporative resistance of the clothing, m^2·kPa·W^{-1}; $R_{t.clo}$ is the intrinsic thermal resistance of the clothing, m^2·K·W^{-1}; $R_{e.clo}$ is the intrinsic evaporative resistance of the clothing, m^2·kPa·W^{-1}. The calculated nodes of the heat and moisture transfer are shown in Fig. 1.

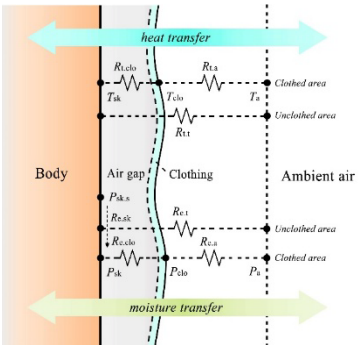

Figure 1. The calculated nodes of the skin-clothing-environment system.

For the calculation of latent heat transfer on the skin, a common method is via the mass balance on the skin surface (Jones et al., 1992). The transfer of moisture from the skin to the environment has two main components: evaporation of sweat and diffusion of moisture through the skin. These two moisture transfer processes can be expressed as Eqs. (5) and (6) (Fiala et al., 2012):

$$\frac{P_{sk}-P_a}{R_{e.a}} = \frac{\lambda_w dM_{sw}}{A_{nude}dt} + \frac{P_{sk.s}-P_{sk}}{R_{e.sk}}, \tag{5}$$

$$\frac{P_{sk}-P_a}{R_{e.t}} = \frac{\lambda_w dM_{sw}}{A_{clothed}dt} + \frac{P_{sk.s}-P_{sk}}{R_{e.sk}} \tag{6}$$

Where λ_w is the enthalpy of vaporization of the water, Wh·g^{-1}; M_{sw} is the mass of the sweat production, g; $R_{e.sk}$ is the evaporative resistance of the skin, which is equal to 0.33 m^2·kPa·W^{-1} for a well-hydrated person (Fu, 1995).

The mass balance methods provide a good assessment of the moisture transfer on the skin both from the unwetted to exactly fully wetted state and for the oversaturation state. According to the mass balance of perspiration between the skin-clothing system, the moisture content absorbed by the clothing M_{clo}, the rate of skin sweat accumulation $\frac{dM_{acc}}{dt}$, and the sweat rate $\frac{dM_{sw}}{dt}$ have the following relationship:

$$\frac{dM_{sw}}{dt} = \frac{dM_{clo}}{dt} + \frac{dM_{acc}}{dt} + \frac{A_{nude}(P_{sk.s}-P_a)}{\lambda_w R_{e.a}} + \frac{A_{clothed}(P_{clo}-P_a)}{\lambda_w R_{e.t}} \tag{7}$$

Sweat on the skin surface will transfer moisture to the clothing in the vapor or liquid state, and the warmer sweat vapor will condense on the surface of the clothing in contact with the clothing and gradually be absorbed by the fabric, which can be described by Eq. (8).

$$\frac{\lambda_w dM_{clo}}{A_{clothed}dt} = \frac{P_{sk.s}-P_{clo}}{R_{e.clo}} - \frac{f_{clo}(P_{clo}-P_a)}{R_{e.a}} \tag{8}$$

Considering the heat stored in the clothing, the heat gain from vapor condensation and sweat absorption, and the evaporative heat loss to the air, the heat transfer of the clothing node can be expressed as:

$$C_{clo}\frac{dT_{clo}}{dt} = A_{clothed}\left(\frac{T_{sk}-T_{clo}}{R_{t.clo}} - \frac{f_{clo}(T_{clo}-T_a)}{R_{t.a}}\right) + \frac{dM_{clo}}{dt}(C_w(T_{sk}-T_{clo}) + H_d) - \frac{A_{clothed}f_{clo}(P_{clo}-P_a)}{R_{e.a}} \tag{9}$$

where H_d is the differential heat of sorption, J·g^{-1} (Hearle, 2008); C_{clo} and C_w are the thermal capacity of the clothing and the water, respectively, J·K^{-1}. Based on Eqs. (8) and (9), the vapor pressure and temperature of the clothing can be derived as follows:

$$P_{clo} = \frac{R_{e.a}P_{sk.s} + f_{clo}R_{e.clo}P_a - R_{e.clo}R_{e.a}\frac{\lambda_w dM_{clo}}{A_{clothed}dt}}{R_{e.a} + f_{clo}R_{e.clo}}, \tag{10}$$

$$T_{clo} = \frac{\left(\frac{dM_{clo}}{dt}(C_w T_{sk} + H_d) - A_{clothed}\frac{f_{clo}(P_{clo}-P_a)}{R_{e.a}}\right)R_{t.clo}R_{t.a} + A_{clothed}(f_{clo}R_{t.clo}T_a + R_{t.a}T_{sk})}{\left(C_w\frac{dM_{clo}}{dt}R_{t.clo} + A_{clothed}\right)R_{t.a} + A_{clothed}f_{clo}R_{t.clo}} \tag{11}$$

The detailed quantification of heat and moisture transfer of clothing during the process of absorbing and releasing sweat can be achieved based on the above formulas.

2.2. Measurements

The experiments were conducted from 2 May to 15 June 2024 at the Wind Tunnel Atmosphere Laboratory, School of Fashion and Textiles, PolyU. The sweating thermal manikin "Walter" was used in this study to investigate the dynamic variation in thermal and moisture properties of clothing ensembles at different moisture content states (Fan et al., 2002). Throughout the measurements, the "Walter" was operated at a constant skin temperature mode, and the skin temperature was set at 34°C to simulate the real human body's temperature in warm to hot conditions. For all measurements, the manikin was placed in an artificial climate chamber to achieve stable boundary conditions (Fig. 2).

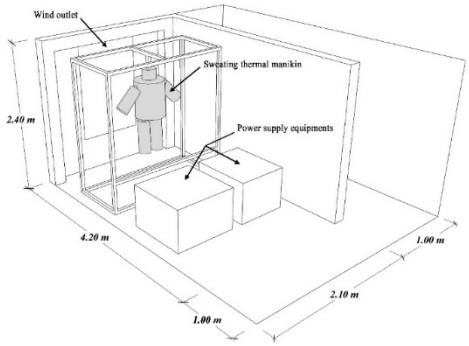

Figure 2. Experimental site and layout.

The ambient temperature and relative humidity of the chamber were set to 21°C and 40%, respectively, to comply with the requirements of the relevant standards (ASTM, 2010, 2016; ISO, 2008) for the measurement of thermal and evaporative resistance of clothing ensembles. Meanwhile, the indoor air velocity was set to 0.2 m/s to provide a natural convection environment. Measurements of the unclothed sweating manikin in this stable environment yielded two basic parameters, the thermal and evaporative resistance of the air boundary layer.

Five different typical summer clothing, namely long-sleeved T-shirts, short-sleeved T-shirts, sleeveless T-shirts, trousers, and shorts, were selected for the measurements. All selected clothing were commercially available (100% cotton) and the dry weight of each clothing was measured after drying using an electronic balance with an accuracy of ±0.02g. More information on different clothing is shown in Table 1.

Table 1. The detailed parameters of the clothing.

Clothing (abbr.)	Content	Length (cm)				Mass (g)	Maximum moisture content (g)
		Length	Chest / Waist	Shoulder / Hip	Sleeve		
Long-sleeved T-shirts (LS)	100% Cotton	75	120	47	60	214.95	253.45
Short-sleeved T-shirts (SS)		76	120	47	25	171.37	210.17
Sleeveless T-shirts (SL)		76	119	-	-	139.28	171.91
Trousers (T)		104	70	114	-	218.98	295.07
Shorts (S)		55	80	122	-	158.92	229.96

Each clothing ensemble was tested with the moisture content level varied from fully dry to saturated wet. For the dry test, clothing ensembles were placed in the drying oven for 2 hours before being worn on the manikin to commence data recording. The non-dried method was to rest the clothing in the artificial climate chamber with 40%RH for more than 8 hours (Koelblen et al., 2017). Another pre-wetting method is to spray deionized water onto the clothing surface directly based on four different water addition gradients of 25%, 50%, 75%, and 100% maximum moisture content. The clothing ensembles were weighed after finishing the tests to obtain the clothing's moisture content.

3. RESULTS

3.1. Sensible and latent heat loss of the human body at different clothing moisture content

Under steady-state conditions, the heating power supplied to the manikin is equal to the total heat loss from the human body (Foda et al., 2016). Thus, the required heating power to maintain a specific skin temperature reflects the corresponding heat loss for different clothing ensembles and moisture contents. Overall heat loss occurs mainly at the sensible heat and latent heat levels, thus the proportion of different heat loss pathways needs to be assessed (Fig. 4).

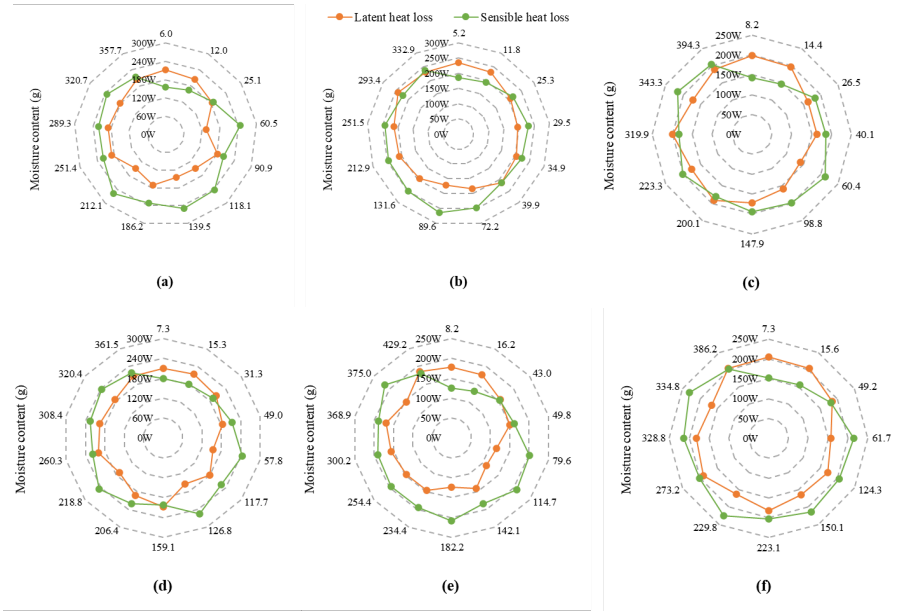

Figure 4. Comparison of the sensible and latent heat loss: (a) SL&T, (b) SL&S, (c) SS&T, (d) SS&S, (e) LS&T, and (f) LS&S.

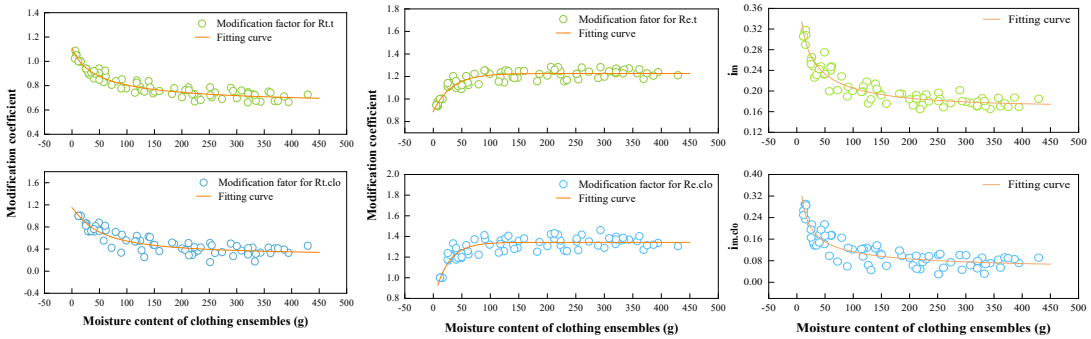
It can be observed that, except for the two lowest moisture content cases, dry heat loss generally exceeds evaporative heat loss for all clothing ensembles. This suggests that, at lower moisture levels, clothing primarily reduces dry heat loss to minimize overall heat loss. As the moisture content increases, the clothing's ability to prevent dry heat loss significantly diminishes, leading to dry heat loss becoming the dominant heat loss pathway.

3.2. Dynamics of clothing's thermal and evaporative resistance

The thermal and evaporative resistance of clothing represents its ability to limit sensible and latent heat loss, respectively—two key parameters in calculating heat and moisture transfer. To assess these properties under varying clothing moisture content conditions, modifying coefficients were introduced for evaluating thermal resistance, evaporative resistance, and permeation coefficient (Fig. 5).



(a) (b) (c)

Figure 5. The proposed modification coefficients for: (a) clothing thermal resistance, (b) clothing evaporative resistance, and (c) clothing permeation coefficients.

The results indicate that both total and intrinsic clothing thermal resistance decreases with increasing moisture content in the clothing ensembles. In the nearly fully wet condition, the total thermal resistance of the six clothing ensembles was reduced by an average of 29.7% compared to the dry ensembles, consistent with the findings of Wang et al. (Wang et al., 2016). Conversely, the evaporative resistance curves exhibit an opposite trend to the thermal resistance curves. Furthermore, the permeation coefficients decreased progressively with increasing moisture content in the clothing ensembles, with a more pronounced reduction observed in the intrinsic permeation coefficients.

The relationship between clothing's moisture content, thermal resistance, evaporative resistance, and permeation coefficient were fitted and summarized in Table 2.

Table 2. Summary of modification coefficients for wetted clothing.

Parameters	Formulas	Fitted equations	R^2
Thermal resistance	$R_{t.wet} = MC_t(M_{clo})R_t$	$MC_{t.t} = 0.637 + \frac{0.472}{1+\left(\frac{M_{clo}}{51.386}\right)^{0.900}}$	0.919
		$MC_{t.clo} = 0.277 + \frac{0.873}{1+\left(\frac{M_{clo}}{49.001}\right)^{1.149}}$	0.813
Evaporative resistance	$R_{e.wet} = MC_e(M_{clo})R_e$	$MC_{e.t} = 1.226 - 0.335 \cdot 0.969^{M_{clo}}$	0.850
		$MC_{e.clo} = 1.343 - 0.571 \cdot 0.960^{M_{clo}}$	0.748
Permeation coefficient	-	$i_m = 0.172\left(1 - exp(-0.006M_{clo})\right)^{-0.224}$	0.895
		$i_{m.clo} = 0.056\left(1 - exp(-0.002M_{clo})\right)^{-0.448}$	0.790

3.3. Heat and moisture transfer modelling for sweat-soaked clothing system

Quantifying heat and moisture transfer at clothing nodes relies on determining the temperature and

vapor pressure parameters of clothing at various moisture contents. The vapor pressure and temperature for six clothing ensembles are presented in Fig. 6.

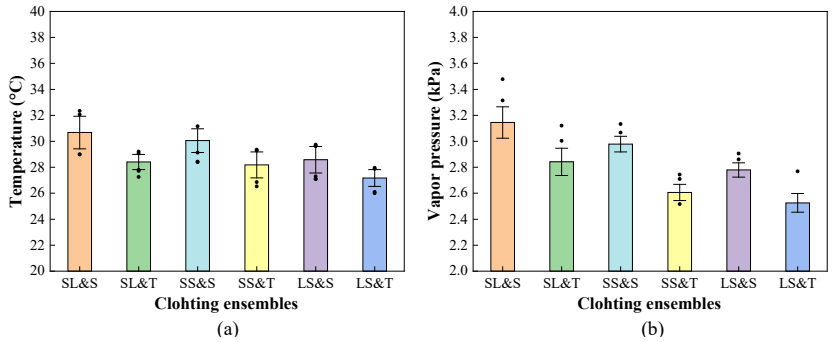


Figure 6. The calculation parameters of different clothing ensembles: (a) temperature, and (b) vapor pressure.

The covering area significantly influences the clothing's temperature and vapor pressure, with larger coverage areas corresponding to lower clothing temperature and vapor pressure. Data indicate that the surface temperature of clothing in an almost fully wet state increased by approximately 1.35°C to 3.34°C compared to dry ensembles, with an average increase of 2.26°C. This finding suggests a sustained temperature rise following moisture adsorption, a trend also observed in studies by Lu et al. (Lu et al., 2016).

4. CONCLUSION

This study explored the thermal and moisture characteristics of sweat-soaked clothing and their influence on heat and moisture transfer between the human body and the environment. As the moisture content of the clothing increased, overall body heat loss was enhanced; however, the evaporative cooling capacity of the body was diminished due to the saturated clothing, resulting in a shift toward sensible heat transfer as the primary mode of heat dissipation. Finally, a dynamic model was developed to quantify the heat and moisture transfer between the skin, soaked clothing, and the surrounding environment under conditions of intense sweating. In regions such as Hong Kong, where high humidity prevails year-round, the rate of sweat evaporation is often slower than sweat production, leading to the saturation of clothing. This condition can increase the evaporative thermal resistance of clothing by up to 20%, significantly inhibiting the body's evaporative cooling efficiency. Therefore, it is critical to incorporate the moisture content of clothing and its associated thermal and evaporative resistances when evaluating outdoor thermal comfort in hot and humid environments.

ABSTRACT

The deployment of rooftop solar photovoltaic (PV) systems is a key strategy for achieving nearly zero-energy buildings (nZEB) and promoting urban sustainability. However, accurately estimating rooftop solar irradiance potential remains challenging due to complex shading effects from surrounding structures and rooftop obstructions, which can lead to significant overestimations in PV capacity. These obstructions, including HVAC units, chimneys, skylights, parapet walls, ventilation shafts, and other mechanical equipment, reduce the usable roof area for PV installations by limiting available space and casting shadows that diminish effective solar exposure. To address these challenges, this research introduces a hybrid approach that integrates Geographic Information Systems (GIS) and deep learning to enhance rooftop solar potential assessments. Currently, a GIS-based shading analysis has been conducted using high-resolution LiDAR data to evaluate inter-building shading effects across 48 buildings in Montreal, Canada, for the year 2023. The findings reveal that neglecting shading can result in an overestimation of rooftop PV capacity by approximately 12.87%, with an estimated annual solar radiation potential of 1.48×10^8 kWh. While GIS-based methods provide a detailed spatial assessment of shading influences, they have challenges in accurately identifying rooftop obstructions. To further refine these assessments, the next phase of this study involves developing a deep learning model for precise rooftop segmentation and obstruction detection. By integrating deep learning with GIS-based methodologies, this approach aims to enhance the accuracy of solar potential estimates, offering a scalable and data-driven solution for urban energy planning. Ultimately, this research supports the development of optimized PV deployment strategies, contributing to the broader goal of sustainable urban energy transitions.

1. INTRODUCTION

Urban areas predominantly rely on conventional energy sources such as fossil fuels and coal-fired power plants, contributing significantly to greenhouse gas emissions and accelerating climate change (Emmanuel Augustine Etukudoh et al., 2024; Esfandi et al., 2024; Lang, 2018). In response to these environmental challenges, governments and international organizations have prioritized the transition toward cleaner and more sustainable energy solutions (Agrawal et al., 2024; Ebbin & Ghamarian, 1992; Sharma et al., 2025). The European Union (EU) and other regulatory bodies have introduced stringent energy efficiency targets, emphasizing the development of nearly zero-energy buildings (nZEB) (Lou & Hsieh, 2024; Pisoni et al., 2025). These targets aim to achieve energy-efficient urban infrastructures by minimizing building energy consumption (Sudhakar et al., 2019) and integrating renewable energy technologies such as solar photovoltaics (PVs) (C. Liu et al., 2019). Among various renewable energy sources, solar PV systems are up-and-coming due to their scalability, cost-effectiveness, and minimal environmental footprint (R. Liu et al., 2023). However, the accurate assessment and efficient deployment of rooftop PV systems in urban settings present several challenges, requiring a comprehensive understanding of multiple influencing factors, including solar irradiation levels (Pfeifroth et al., 2018), rooftop characteristics (Sarralde et al., 2015), shading effects from surrounding structures (Zhong & Tong, 2020), and PV panel energy conversion efficiency (Green et al., 2020). The effective deployment of rooftop PV systems depends largely on accurate estimations of solar potential, which are influenced by both environmental and urban morphological factors (Alsuhaibany & Li, 2017; Fakhraian et al., 2021). Solar irradiation levels, which generally decrease with increasing latitude, are further affected by atmospheric conditions, seasonal variations, and the urban heat island effect (Masson et al., 2014; Prasad et al., 2016). The efficiency of rooftop PV panels is not solely dependent on the availability of sunlight; it is also constrained by rooftop obstructions such as water tanks, HVAC systems, lift machine rooms, and parapet walls, as well as the shadowing effects of adjacent buildings (Albatayneh et al., 2022; Zhao et al., 2018). These shading effects can significantly reduce the amount of solar energy received by PV panels, leading to suboptimal energy generation (Vakilinezhad & Ziaee, 2024). While existing solar potential assessment methods have made significant progress in estimating energy output, many fail to account for localized shading effects and rooftop obstructions, leading to overestimations that affect system design and investment decisions (Villa-Ávila et al., 2024).

Several studies have attempted to overcome these challenges through various approaches (Amigó, 2016; Choi et al., 2019). One common method for estimating solar potential involves the use of meteorological station data and satellite-derived solar radiation models (Aliakbarzadeh et al., 2024; Kim et al., 2025; Ordoñez Palacios et al., 2023). Although these methods offer valuable large-scale insights, they lack the spatial resolution necessary for precise urban-level assessments (Baquiran et al., 2020). To address this gap, Geographic Information Systems (GIS) have been widely employed for solar potential mapping, utilizing spatial data to identify optimal photovoltaic (PV) installation sites (Choi et al., 2019). Nevertheless, traditional GIS-based models often rely on simplified assumptions about building heights and rooftop availability, overlooking complex shading interactions that can significantly impact solar energy generation. In response to these shortcomings, recent advancements in remote sensing technologies, particularly Light Detection and Ranging (LiDAR), have substantially improved the accuracy of solar potential assessments (Desthieux et al., 2018). By enabling high-resolution 3D modeling of urban environments, LiDAR data facilitates precise calculations of building heights, rooftop orientations, and inter-building shading effects, thereby enhancing the reliability of solar energy estimations (Prieto et al., 2019). Consequently, the integration of LiDAR with advanced spatial analysis techniques has become indispensable for enhancing the precision and reliability of data-driven urban energy planning.

In addition to GIS and LiDAR-based assessments, artificial intelligence (AI) and deep learning techniques have shown great potential in automating solar potential evaluations (Nadeem et al., 2024). Deep learning models, particularly convolutional neural networks (CNNs), have been employed to identify rooftop features, segment available areas, and predict solar energy output with greater precision (Ding, 2025). These models are trained on diverse datasets that include aerial imagery, LiDAR point clouds, and meteorological data, allowing for robust and adaptive predictions (Rajasundrapandiyanleebanon et al., 2023; Suresh et al., 2020). The integration of deep learning with GIS and LiDAR-based methodologies represents a significant advancement in urban solar energy modeling, offering an efficient and scalable solution for high-accuracy solar potential assessments (Kumar et al., 2024). Despite these technological advancements, high-latitude regions present unique challenges for rooftop solar energy assessments (Jiang, Hou et al., 2024). The lower solar elevation angle in these regions results in longer shadows, making shading effects more pronounced compared to lower-latitude areas. Additionally, seasonal variations lead to significant fluctuations in solar energy availability, requiring more dynamic simulation models to accurately capture these changes. Most existing studies on rooftop solar energy potential have focused on mid-to-low latitude cities, where solar irradiation levels are relatively stable (Zhang et al., 2020). However, a detailed and high-resolution analysis tailored to high-latitude urban environments remains limited. Addressing these challenges is crucial for optimizing solar energy deployment in northern cities, where maximizing energy self-sufficiency is essential for achieving sustainable urban development goals.

This study introduces a novel methodology that integrates deep learning and 3D GIS modeling to accurately assess rooftop solar energy potential in high-latitude urban areas, overcoming the limitations of traditional approaches. The research is structured around several key objectives. The first is to develop a high-resolution framework for rooftop solar energy assessment, which considers localized shading effects and rooftop obstructions using LiDAR-derived 3D urban models. Another objective is to employ deep learning techniques for the automated identification and segmentation of rooftop features, thereby improving the accuracy of available area estimation for photovoltaic (PV) installations. Additionally, the study aims to analyze the temporal variations of solar irradiance on hourly, monthly, and annual scales, ensuring a comprehensive understanding of seasonal energy generation patterns. Although the deep learning model is still in development, its integration is expected to enhance the accuracy of the shading analysis, by enabling the model to more precisely identify complex shading patterns and optimize solar irradiance predictions. Lastly, the methodology will be validated through real-world case studies in Montreal, Canada, a high-latitude city where shading effects significantly influence solar PV performance. This study sets itself apart by introducing a dynamic shading analysis that accounts for the annual trajectory of sun, integrating AI-based image processing with LiDAR data to refine rooftop assessments, and examining high-latitude climatic impacts on solar PV performance. While the deep learning results will be included in future work, the current methodology highlights the significant potential of combining deep learning with traditional shading analysis to improve solar potential estimation. These innovations not only improve the accuracy of solar potential measures but also support urban energy planning and policymaking by enabling informed decisions on PV investments, grid integration, and incentive structures. Ultimately, the research promotes sustainable urban development by facilitating decentralized energy generation and reducing reliance on fossil fuels, while offering a scalable framework for rooftop solar deployment in other high-latitude cities. The findings could significantly advance urban renewable energy solutions and support climate goals. In summary, this study addresses the critical challenges associated with rooftop solar energy assessments in high-latitude regions by introducing an integrated approach that combines deep learning, LiDAR data, and 3D GIS modeling. Although the deep learning

analysis is still being finalized, its anticipated integration will further refine solar potential estimations, contributing to the optimization of PV system placement. The proposed methodology represents a significant step forward in bridging the gap between technological advancements and practical implementation, ultimately driving the adoption of renewable energy solutions in urban environments.

2. METHODOLOGY

The integration of 3D building models in solar energy simulations has become essential for assessing power potential and evaluating receiving areas such as rooftops and facades, significantly contributing to urban development initiatives (Willenborg et al., 2018). Over recent years, research has predominantly focused on maximizing power generation efficiency through angle optimization, often employing solar tracking systems (Romero Rodríguez et al., 2017). Several studies highlight the importance of 3D building models in estimating solar energy potential in urban environments (Bill et al., 2016; Saadaoui et al., 2019; Shirinyan & Petrova-Antonova, 2024; Waqas et al., 2023). However, only a limited number of studies have explored the intersection of solar energy assessment with nearly zero-energy buildings (nZEB) or self-sufficiency, aside from those addressing urban redevelopment or revitalization (Natanian & Auer, 2020). To analyze the impact of shadowing from surrounding buildings on rooftop solar potential, the methodology follows the structured approach illustrated in Figure 1. The process begins with modeling the rooftop structure and determining its tilt and azimuth angle. The solar position, including location and angle, is then considered to evaluate shadow coverage. Based on whether a rooftop section is shaded or not, direct normal irradiation and diffuse horizontal irradiation are calculated accordingly. The final step involves estimating the total radiation received under both shaded and unshaded conditions.

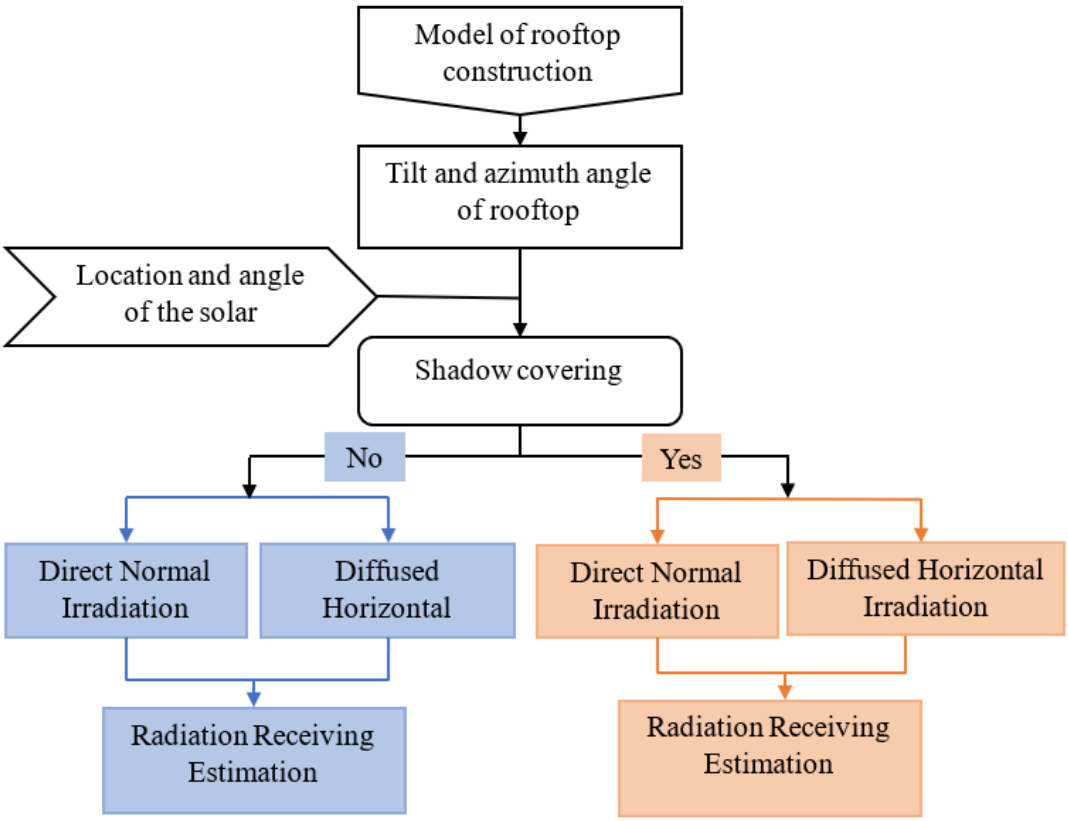

Fig. 01: Methodology Flow Chart

2.1. Study area:

The selected study area is a small urban zone in Montreal, near Place-des-Arts (45.52°N, 73.42°W), characterized by a diverse urban morphology comprising both high-rise and low-rise buildings. This location was strategically chosen due to its architectural heterogeneity, which provides a suitable setting for assessing the impact of overshadowing from taller structures on the rooftop solar irradiance of adjacent low-rise buildings. Situated within a commercial district, the study area consists of 48 buildings with varying architectural configurations, offering a robust dataset for evaluating solar potential in a complex urban environment. This area was specifically selected due to its dense urban fabric and significant solar exposure variations, making it an ideal case for analyzing the challenges and opportunities of rooftop photovoltaic deployment. Understanding how shadowing influences solar energy generation in such settings is essential for developing strategies to enhance urban energy resilience and optimize photovoltaic system placement.

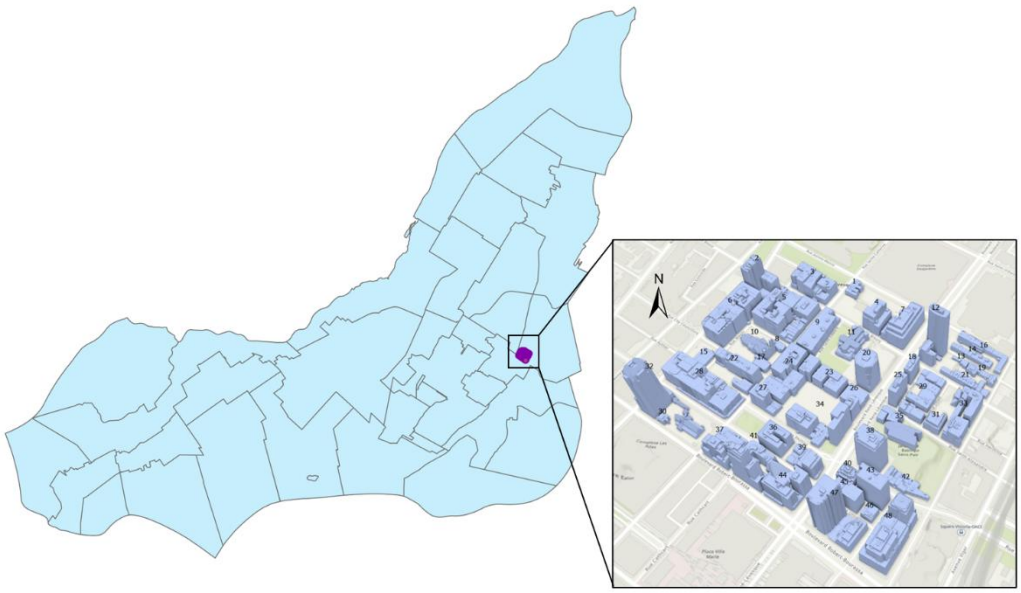

Fig. 02: Geographical scope

2.2. Data Used:

This study utilized three primary data sources: High-resolution Light Detection and Ranging (LiDAR) data, Geographic Information System (GIS) data, and Typical Meteorological Year (TMY) data.

2.2.1. High-resolution LiDAR Data:

LiDAR data was employed to generate detailed 3D models of buildings within the study area. The high-resolution nature of this data allows for precise measurements of building heights and the surrounding structures, which are crucial for performing accurate shading analysis. These measurements enable the study to assess the interaction between buildings and their environment, which is essential for evaluating solar potential.

2.2.2. Geographic Information System (GIS) Data:

GIS data was used to analyze the geographical context and layout of the buildings and their surroundings. This data includes land use information, building footprints, and other relevant geographical features. By leveraging GIS, the study can conduct a comprehensive spatial analysis of the study area, accounting for factors like urban density, terrain, and environmental conditions that influence solar exposure.

2.2.3. Typical Meteorological Year (TMY) Data:

Meteorological data was sourced from the Canadian Weather Year for Energy Calculation (CWEC) using the TMY3 dataset. This dataset provides over 30 years of hourly weather data, including crucial parameters such as direct normal irradiance (DNI), diffuse horizontal irradiance (DHI), global horizontal irradiance (GHI), and solar azimuth angles. These parameters are vital for understanding solar exposure and energy potential, enabling a more accurate assessment of solar power generation. While TMY3 data provides a standardized climatological baseline, its reliance on historical averages may not fully capture extreme weather events or recent climate trends (Wu et al., 2023). For instance, interannual variability in cloud cover or snowfall (critical in high-latitude regions) could introduce ±5–10% uncertainty in irradiance estimates. Future work could integrate multi-year datasets or stochastic weather models to improve robustness.

By integrating these three data sources, the study aims to conduct a comprehensive analysis of the solar potential and shading dynamics in the study area. The methodology consists of two steps: first, extracting detailed building geometries from the LiDAR data, and second, assessing the self-sufficiency potential through the computation of solar irradiance on the rooftops of these buildings. Notably, external TMY3 data was utilized for solar irradiance calculations, rather than relying on built-in ArcMap software data, to improve the accuracy of the solar power potential analysis for the targeted geographic area.

2.3. Building model extraction:

The building model extraction and subsequent analysis were conducted using ArcGIS tools within the ESRI ArcMap environment. In this study, all building data were converted into mesh format with a grid scale of 1 square meter, representing each building's surface as a network of 1m x 1m polygons. This detailed representation allowed for precise modeling of shading effects on solar photovoltaic (PV) performance and ensured compatibility with advanced analytical tools. To assess the slope and orientation of the rooftops for each grid cell, the 3D Analyst Tool in ArcMap was employed, utilizing calculations derived from LiDAR data, building footprint data, and elevation data of adjacent grids from aerial imagery. These calculations were crucial for accurately determining the geometric properties of building surfaces, which were essential for reliable shading analysis (Bayrakci Boz et al., 2015).

$$dy/dx = [(c + 2f + i) - (a + 2d + g)]/(8 \times cellsize) \quad \text{Eq. (1)}$$

$$dz/dy = [(c + 2h + i) - (a + 2b + c)]/(8 \times cellsize) \quad \text{Eq. (2)}$$

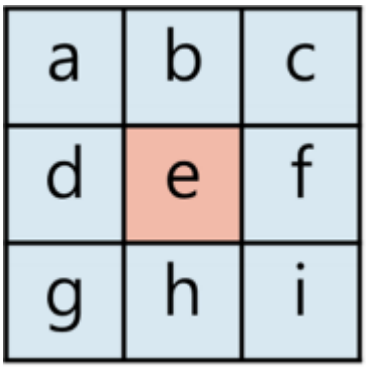

Fig. 3: Illustrating the computation of slope and aspect (Li & Han, 2022)

Eq. (1) and (2) depict the relationship among the x, y, and z axes. Variables 'a' through 'i' denote the altitude of individual grid points. Consequently, the slope and aspect angles can be computed using Eq. (3) and (4).

$$Slope = tan^{-1}\left(\sqrt{(dz/dx)^2 + (dz/dy)^2}\right) \times (180/\pi) \quad \text{Eq. (3)}$$

$$Aspect = tan^{-1}[(dz/dy)/-(dz/dx)] \times (180/\pi) \quad \text{Eq. (4)}$$

By combining slope and orientation data with solar radiation models, we can estimate the amount of sunlight received by each rooftop area throughout the day and year. This solar exposure data enables the calculation of the potential solar energy that photovoltaic (PV) panels can generate when installed on various segments of the rooftop. This research aimed to examine the impact of shadow coverage by developing two simulation scenarios for the buildings: one focusing on the individual building (Scenario A) and the other considering the surrounding structures (Scenario B). Scenario A represents a single building in optimal conditions, free from the influence of neighboring structures, while Scenario B offers a more realistic scenario that accounts for the surrounding environment. The results of Scenario A reflect the isolated conditions of the building, while those of Scenario B represent a broader, more varied context.

After performing the hillshade analysis, the hillshade values, ranging from 0 to 254, were used to calculate solar irradiance. The following formula (Equation 6) was then applied to determine the solar irradiance received at each point:

$$Solar\ irradiance = \left(\frac{Hillshade\ value}{255}\right) * DNI + DHI \quad \text{Eq. (5)}$$

$$GHI = DHI + DNI \times cos\theta \quad \text{Eq. (6)}$$

The comparison of results from both scenarios highlights the impact of shadow coverage on solar irradiance simulations. The percentage difference emphasizes the critical role of accounting for shading in rooftop solar potential assessments. These findings are valuable for optimizing solar panel placement, improving energy yield predictions, and informing urban planning decisions to maximize rooftop solar energy potential in densely built environments. Additionally, this approach can be used to assess the financial viability of solar installations by estimating energy losses due to shading. It also provides a useful tool for architects and urban planners to design buildings and neighborhoods with enhanced solar access, ultimately supporting the development of more sustainable urban energy solutions.

3. RESULTS AND DISCUSSION:

3.1. 3D Visualization Using Digital Elevation Model (DEM) Data:

The LiDAR dataset, sourced from the Government of Quebec's official website, was utilized to generate a 3D model of the selected geographic area, enabling detailed visualization. The process of model generation is illustrated in the diagram below (Figure 04). This 3D model

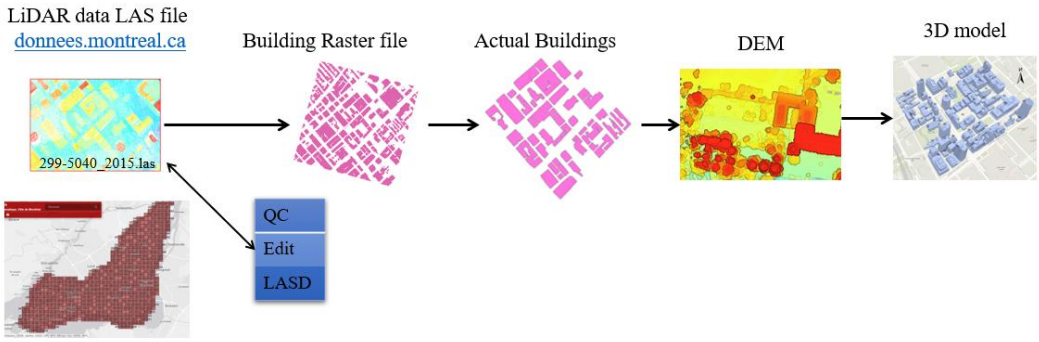

Fig. 4: Flow chart of the 3D building model

offers a clear and detailed representation of the surrounding structures and patterns within the area. The dataset encompasses key attributes for each building, including height, area, and unique identification number, facilitating a comprehensive analysis of individual structures.

3.2. Hillshade analysis:

Hourly data for Direct Normal Irradiance (DNI) and Diffuse Horizontal Irradiance (DHI) from the Canadian Weather Year for Energy Calculation (CWEC) were used for the hillshade analysis, which combined twelve Typical Meteorological Months from up to 30 years of hourly data in the Canadian Weather Energy and Engineering Datasets (CWEEDS). The solar azimuth and altitude for each hour of 2023 were calculated using Python, based on the location's longitude and latitude. Initially, calculations were made for all 8,760 hours in 2023, but after filtering out instances with negative solar altitude, the number of valid hours was reduced to 4,406. The hillshade analysis was performed 4,406 times, adjusting for the changing azimuth and altitude values each hour. Two scenarios were considered: Scenario A, which excluded the effects of surrounding buildings (hillshade analysis without shadow modeling), and Scenario B, which incorporated the influence of nearby buildings (hillshade analysis with shadow modeling). The results from Scenario A established the baseline irradiance without shading effects, while Scenario B highlighted a significant reduction in solar irradiance due to the shadowing effects of nearby structures, emphasizing the importance of considering building shadows in solar energy assessments.

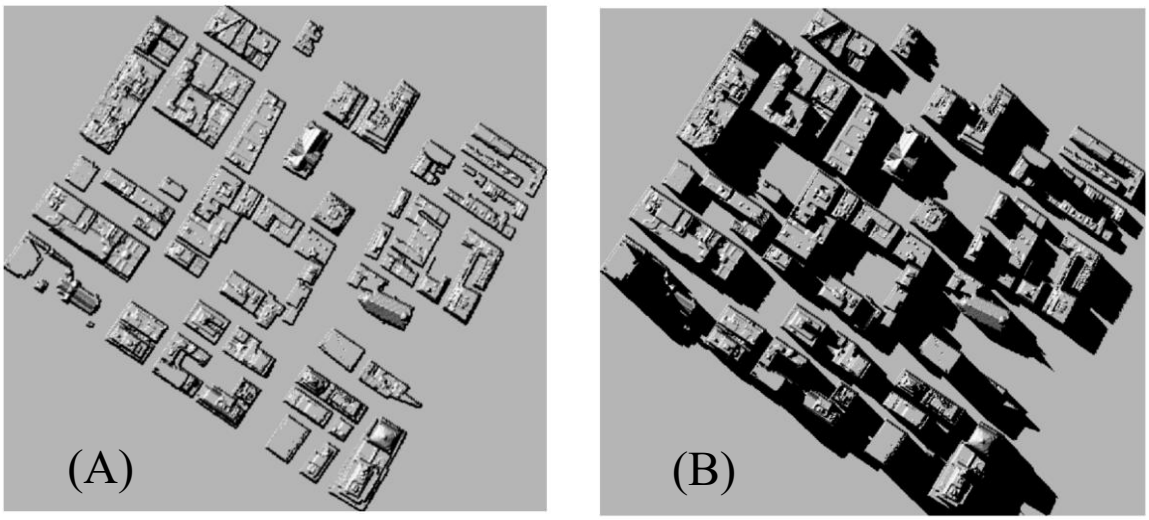

Fig. 5. Solar irradiance scenarios: (A) without shading effects, (B) with shading effects

3.3. Canny Algorithm:

Upon completion of the hillshade analysis for both scenarios, the resulting hillshade raster files were converted into point data. To refine the accuracy of the analysis and remove unnecessary building edges within a one-meter distance, the Canny algorithm was applied. This algorithm was implemented with consideration of the impracticality of parapet areas, ensuring that only significant building features were preserved for subsequent analysis.

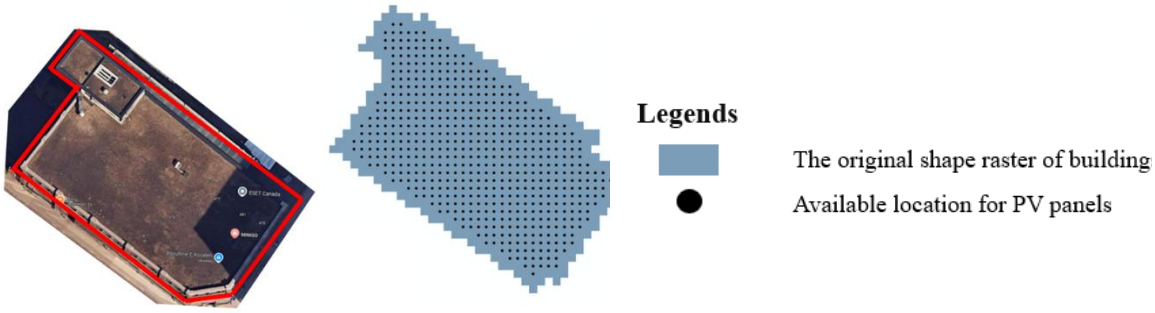

Fig. 6: The example of a feasible area for solar panels by applying the Canny algorithm

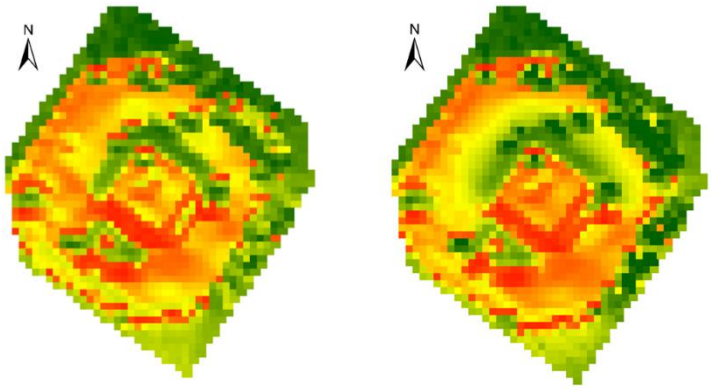
3.4. Rooftop solar irradiance simulation:

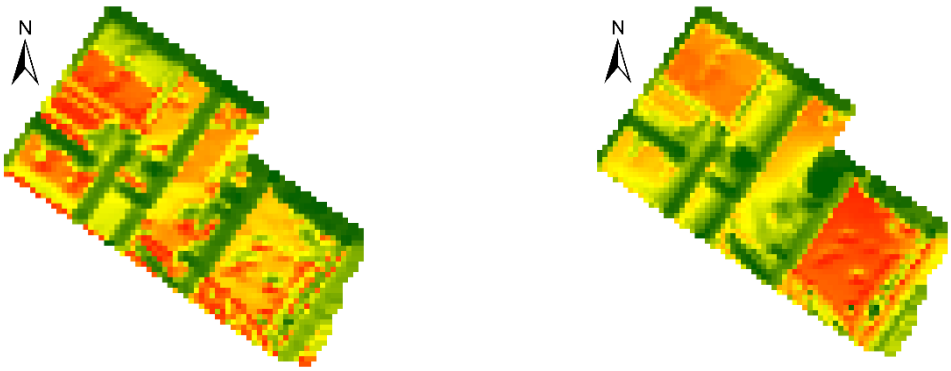
The solar irradiance received on each building rooftop was calculated, revealing the significant role of shadows in assessing rooftop solar energy potential. As illustrated in Figure 7, consider Building ID 19: in the scenario (a), without considering shadows, the total solar irradiance received by the building is 1.79×10^6kWh. However, when shadows are accounted in the scenario (b), this value decreases to 1.71×10^6kWh. With a total building area of 1,491.67 m², the average solar irradiance is calculated to be $1.20 \times 10^3 \mathrm{kWh/m^2}$. The ratio of irradiance in the shadowed scenario to the unshaded scenario is 95.53%, underscoring the considerable impact of shading on solar energy potential. These findings emphasize the critical need to incorporate shadow analysis in urban planning and building design, particularly for optimizing rooftop solar energy generation.



(a) (b)

Fig. 7: Solar irradiance on Building ID 19 (a) without shading and (b) with shading effects

Furthermore, for Building ID 39, the total solar irradiance is 2.62×10^6KWh in the absence of shadows, while it reduces to 1.95×10^6KWh when shadows are considered. The average solar irradiance per square meter for this building is $0.91 \times 10^3 \mathrm{KWh/m^2}$. The ratio of irradiance in the shadowed scenario (Scenario B) to the unshaded scenario (Scenario A) is 74.42% (Figure 8), indicating a notable reduction in solar energy potential due to shadowing.



(a) (b)

Fig. 8: Solar irradiance on Building ID 39 (a) without shading and (b) with shading effects

The analysis reveals substantial variations in shading impacts among the buildings studied. Building ID 19 experiences a 4.47% reduction in solar irradiance when accounting for shading effects, decreasing from 1.79×10^6 kWh to 1.71×10^6 kWh. A more pronounced effect is observed for Building ID 39, which shows a 25.58% decline in irradiance, from 2.62×10^6 kWh to 1.95×10^6 kWh. These differential impacts highlight the critical influence of building-specific characteristics and surrounding urban morphology on solar potential. At the aggregate level (Figure 9), Scenario A yields an annual irradiance of 1.48×10^8 kWh (averaging 1.23×10^3 kWh/m^2), while the shading effects of Scenario B reduce this to 87.13% of unshaded potential. This 12.87% overestimation carries material financial implications: assuming a 10 kW PV system with a $2,000/kW installation cost and $0.12/kWh electricity price, the shading-induced energy loss extends the payback period by 15–20% (e.g., 8 years vs. 6.5 years) and reduces the net present value (NPV) by approximately $5,000 over a 25-year lifetime. Such deviations underscore how unmodeled shading effects can distort feasibility studies and undermine investment returns, emphasizing the need for high-resolution assessments in urban solar planning.

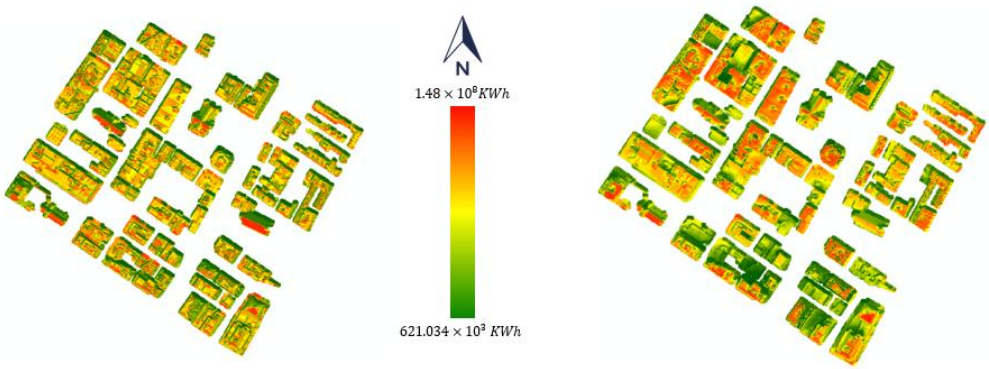


Fig. 9. The yearly distribution of solar irradiance on rooftops in the whole study area

The charts reveal (Figure 10) the substantial effect of shadows on solar irradiance throughout the year. By comparing monthly solar irradiance with and without shadows, it demonstrates a consistent reduction in potential solar energy due to shading. The impact of shadows is most pronounced in January with a 24.49% decrease in irradiance, while May shows the smallest difference at 8.51%, highlighting the variability of shadow effects across different months. This data underscores the importance of incorporating shadow analysis in solar energy assessments to accurately predict and optimize energy generation. The variability in shading effects across different buildings and seasons also emphasizes the need for uncertainty analysis in shadow modeling. Factors such as building height, rooftop features, and

surrounding obstructions can all contribute to variations in shading, which may affect the accuracy of energy predictions. Incorporating sensitivity analysis in future studies would help quantify the degree of uncertainty in shadowing effects, providing a more robust estimation of solar potential. From an urban planning perspective, these findings underscore the necessity of considering shadow impacts in the early stages of building design. Effective mitigation strategies, such as adjusting building orientation and height or implementing green roofs, could significantly enhance rooftop solar energy generation. Additionally, urban planners could focus on reducing shadowing effects by strategically placing solar installations and optimizing building layouts, ensuring maximum sunlight exposure on rooftops.

4. CONCLUSION & FUTURE WORKS

This study introduced a novel approach for accurately assessing rooftop solar energy potential in high-latitude urban environments by integrating deep learning techniques with LiDAR-derived 3D GIS models. The methodology effectively accounted for complex shading effects, rooftop obstructions, and seasonal solar variations, offering a high-resolution framework for optimizing photovoltaic (PV) installations. By analyzing 48 buildings in Montreal, Canada, the study demonstrated that neglecting shading effects leads to an overestimation of solar potential by 12.87%, highlighting the necessity of precise

shadow modeling in urban energy planning. The findings emphasize the significant influence of building morphology and inter-building shading on rooftop solar performance, particularly in dense urban settings. The simulation results revealed notable variations in solar irradiance across different rooftops, with shadow impacts fluctuating based on building height, surrounding structures, and seasonal sun paths. Monthly analyses further demonstrated that the shadow effect was most pronounced in winter months, whereas summer months exhibited the highest solar potential. These findings provide valuable insights for architects, urban planners, and policymakers, offering a data-driven approach to maximizing rooftop solar energy utilization.

Despite the advancements presented, certain limitations remain. The deep learning-based rooftop segmentation model is still in development, and further refinement is required to enhance its accuracy in detecting usable rooftop areas under varying lighting conditions. Additionally, the study primarily focused on a single geographic region, and its applicability to other high-latitude cities should be further explored. Future work will focus on expanding the deep learning framework by incorporating higher-resolution aerial imagery and diverse urban datasets to improve rooftop feature extraction. Moreover, integrating energy storage and grid-interconnection analysis will allow a more comprehensive evaluation of the feasibility of large-scale solar adoption in urban energy networks. Additionally, further research will explore mitigation strategies for shading effects, such as optimizing PV panel placement and developing dynamic solar tracking mechanisms for rooftop installations. By addressing these future research directions, this study aims to enhance the precision of rooftop solar potential assessments, supporting the transition towards sustainable and energy-efficient urban environments.

SUMMARY
Porous building materials control indoor humidity by absorbing and releasing moisture in response to changes in relative humidity and temperature. Recent studies show that incorporating superabsorbent polymers, such as bio-hydrogels, into traditional building materials can increase moisture capacity up to tenfold. However, current testing methods and simulations often neglect temperature effects, which significantly impact water vapor adsorption and moisture diffusion. Water vapor uptake and diffusion follow temperature-dependent behaviours, with adsorption isotherms and diffusivity exhibiting Arrhenius-type relationships. Ignoring temperature fluctuation induced by whether daily cycles, solar heating, or other building-specific factors, can lead to discrepancies between predicted and actual performance. This research develops a methodology to assess hygroscopic materials behaviour under non-isothermal conditions, using dynamic vapor sorption (DVS) analysis and polynomial interpolation. A differential equation model integrates moisture transport with indoor mass and heat balance, enabling real-world performance evaluation through an interactive optimization interface.

Keywords: innovative hygroscopic components, indoor moisture control, hygrothermal modelling.

1. INTRODUCTION

The Porous building materials interact dynamically with ambient air by adjusting their moisture uptake (the mass of adsorbed moisture relative to the dry mass of the material) in response to fluctuations in indoor relative humidity (RH) and temperature (T). Recent research has increasingly focused on identifying more sustainable and hygroscopic material that can buffer indoor RH variations caused by internal loads (Gentile et al. 2024; Zu et al. 2020). This buffering effect is achieved through the ability of buildings material to retain and release moisture, allowing indoor walls, ceilings and other partitioning elements to passively influence indoor RH. Such passive action is particularly valuable in mitigating moisture fluctuations around typical comfort values (RH~50%). The objective of this research field is to enhance indoor thermal comfort and air quality while reducing energy consumption for AC devoted for indoor RH control.

Traditional mineral based building materials used for indoor plasters, such as limestone and gypsum, exhibit moisture uptake values ranging from 0.1 to 2%, depending on the RH of the surrounding air (Yang et al. 2023). These values are relatively insignificant in achieving the dual objective of passive control of indoor comfort and energy savings. Recent experimental studies, however, have demonstrated that incorporating superabsorbent polymers such as alginate bio-hydrogels into conventional building materials like limestone, at mass fractions of 10-30%, can enhance moisture capacity by up to tenfold (Gentile et al. 2023). Other studies have attempted to similarly integrate sorption materials, such as MOF, zeolites and silica gel, into plaster compounds achieving improvements, but with lower magnitude (Qin et al. 2020). The main reason for this

limitation is the intralayer diffusive resistance of moisture, which reduces the active zone of material responding to RH fluctuations. As result, much of the "composite" plaster remains unexploited. In contrast, the introduction of hydrogels creates an interconnected moisture pathway through the material's thickness, effectively overcoming the diffusive resistance inherent in conventional building materials.

Those aspects are critical when simulating behavior of hygroscopic building materials in real environments. Experimental data and tests are essential to properly represent the material properties on simulative tools to understand their response to RH fluctuations and evaluate real effectiveness. The most important information is the equilibrium moisture uptake, typically measured using gravimetric methods, where stepwise changes in RH (while keeping constant temperature) allow for tracking mass variations between different equilibrium states. Depending on the material properties, reaching equilibrium can take several hundreds of hour, and standardized testing methods generally recommend a single testing temperature, typically between 23°C and 25°C. However, as well known in psychrometry, temperature has an intrinsic influence on moisture capacity. For instance, in air, the saturation vapor pressure (Pv_{sat}) of water increases substantially with temperature (e.g., $Pv_{sat} = a * e^{b*T/(T+c)}$).
Similarly, moisture uptake of porous building materials can vary significantly as the air/material equilibrium temperature changes. Despite the critical role of temperature in water vapor adsorption and moisture diffusion, most current testing methodologies and simulation tools for building applications often overlook this influence. Consequently, the common approach is to extrapolate material properties measured at 23-25°C across the broader temperature range encountered in indoor environments throughout the year, typically between 15°C and 35°C.

n	*Number of occupants*	$[-]$

Figure 1. On the left, a schematic representation of the mass fluxes analyzed in this scenario, along with the equations used to solve the mass balance between building materials, indoor and outdoor air, and the occupant. On the right, the table provides definitions for all symbols and acronyms used.

The scheme in Figure 1 presents a set of differential equations that represent the mass balance between the adsorbing materials present in buildings (e.g., in wall and ceiling plasters) as function of the indoor air at temperature T_i and water vapor pressure Pv_i. The scheme illustrates a scenario in which indoor building materials exchange water vapor with air at a rate G_{BUF}, while the

occupants act as water vapor sources with a generation rate G_{vp}. Additionally, air exchange between indoor and outdoor is considered, where outdoor conditions are defined by T_e and P_{ve}.

$$\begin{cases} \dfrac{\partial w_t(x,t)}{\partial t} = \dfrac{\partial}{\partial x}\left[D(w_t)\cdot\dfrac{\partial w_t(x,t)}{\partial x}\right] \\ \left.\dfrac{\partial w_t(x,t)}{\partial x}\right|_{x=0,t} = 0 \\ w_t(x=+s,t) = W_{t_{eq}}(t) \\ w_t(x,t=0) = w_{t_0} \end{cases} \tag{1}$$

$$\frac{V}{R_v T_i}\frac{\partial P_{v_i}}{\partial t} = \left(P_{v_e} - P_{v_i}\right)\frac{ACH * V}{3600\, R_v T_i} + G_{VP} - G_{BUF} \tag{2}$$

$$G_{BUF} = \frac{\partial w_t}{\partial t} A * s * \rho_d \tag{3}$$

$$G_{VP} = \frac{LHG}{2500}\frac{n}{1000} \tag{4}$$

The system of equation (1) defines the moisture diffusion transport (based on Fick's law) through the material thickness, in relation to the boundary conditions. Boundaries define the initial moisture concentration through material thickness, and also the concentration at the contact layer between air/material. In the hypothesis of a transport mainly constrained by diffusive resistance (hence minimal and neglectable influence from convection on the air side) it is reasonable to consider the persistence of a continuous equilibrium condition on the air/material contact layer. That is, whenever T_i and Pv_i changes over time, this point immediately reaches the equilibrium condition defined by the measured adsorption isotherm. The equations (2) and (3) represent instead the mass balance between air and the hygroscopic component. Equation (4) quantifies the vapor flux generated by internal loads, which depends by the type of occupant metabolic activity (LHG) and the total number of occupants.

Symbol	Definition	Units
W_t	Plaster Moisture Uptake	g_{water}/kg_{dry}
RH	Indoor relative humidity	%
T	Indoor air temperature	°C
D	Plaster Moisture Diffusivity	m^2/s
E_a	Adsorption activation energy	kJ/mol
Mode	shape of the RH solicitation 1-nordtest; 2-sinusoid; 3-skewed sinusoid; 4-triangular; 5-saw; 6-pulse	
t	time	s
RH_{high}	RH upper bound	%
RH_{low}	RH lower	%
duty cycle	$t_{sorption}/(t_{sorption}+t_{desorption})$	-
Period	single cycle duration (24 h for daily)	

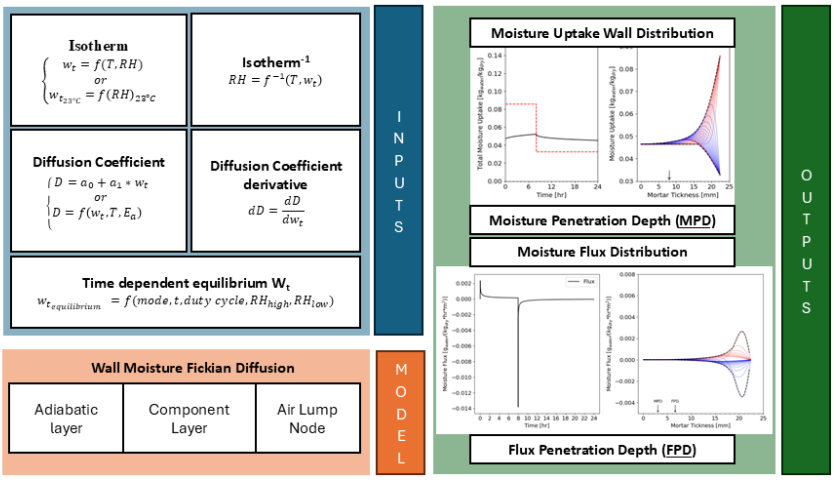

Figure 2. Required inputs and functions for solving moisture diffusion transport through the wall component, along with the outputs that can be derived from the simulation.

The most critical aspect of this set of equations concerns moisture transport through the hygroscopic component, as described in equation (1), particularly how its time derivative hinds the amount of adsorbed or released water vapor. To introduce a dynamic evolution, we implemented a time-dependent function for the equilibrium water uptake ($W_{t_{eq}}$) which updates the boundary condition at the building/air contact layer ($w_t(x = +s, t) = W_{t_{eq}}(t)$) at each time step (around 30-60 seconds). If $W_{t_{eq}}$ change over time due to variation of T_i or P_{vi}, the material reacts dynamically with a diffusive Fickian mass transport. Figure 2 provides a schematic visualization of this approach, in particular the temperature dependence of both inputs required for equation (1): $W_{t_{eq}}$, and the moisture diffusion coefficients (D). As previously mentioned, obtaining the numerical values of these functions requires experimental testing using a DVS analyzer, which measures mass response to stepwise increases in RH and T across the relevant operational range. When temperature dependence is considered, the data can be interpolated using a double-entry polynomial function, as in equation (5), allowing the identification of fitting parameters that describe a family of curves linking temperature (T), relative humidity (RH) and moisture uptake at the equilibrium($W_{t_{eq}}$). However, if temperature influence is neglected, the function simplifies to a single-entry polynomial (eq.6), where RH is the sole independent variable defining equilibrium moisture uptakes.

$$w_t(RH, T) = (d_0 RH^3 + d_1 RH^2 + d_2 RH + d_3) * (d_4 T^3 + d_5 T^2 + d_6 T + d_7) \qquad eq.5$$

$$w_t(RH) = a_0 RH^4 + a_1 RH^3 + a_2 RH^2 + a_3 RH + a_4 \qquad eq.6$$

A similar approach can be applied to moisture diffusivity, especially when temperature dependence is observed. In such cases, the Arrehnius type equation (7) can be used. The fitting parameters for this equation can be determined by interpolating trends from DVS data, using an optimization algorithm (e.g., square root minimization between experimental data and equation (1)).

$$D(w_t, T) = c_0 + c_1 T + c_2\, w_t\, e^{-\frac{E_a\, c_4}{T}} \qquad eq.7$$

$$D(w_t) = b_0 + b_1 w_t \qquad eq.8$$

If experimental data on moisture diffusivity are unavailable, or only a single isotherm has been measured, a simplified approach, such as the one described by equation (8), can be used. For typical building materials, the influence of T on moisture uptake in the interval of 15-35°C is often negligible, as variations in water uptake remain below 1%. In other words, the diffusivity coefficient is assumed to be constant.

The time-dependent variations of those material properties are introduced using a temperature dependent variable over time (which can also be applied to other model inputs). Since the primary focus is building applications, the topology of these functions over time (Figure 3) was chosen to reflect common trends in building physics: *i*) *step function* typical of Nordtest protocols used to evaluate moisture buffering capacity of materials and components (e.g., Moisture Buffering Value) and also representative of occupancy scheduled of tertiary buildings such as offices; *ii*) *sinusoidal function* typical of daily and seasonal temperature fluctuations; *iii) regulated response*, with a triangular or pulse shape, which mimics the temperature control operated by active systems, such as air conditioning units, or impulsive loads that introduce fast and sudden variations of sensible/latent heat into an environment; iv) *occupancy-based variation*, with skewed shape, similar to the step function but with fluctuations that introduce disturbances typical of random

events that generates unpredictable variations in indoor conditions. This pattern is particularly useful for studying the impact of stocastic disturbances on indoor environments.

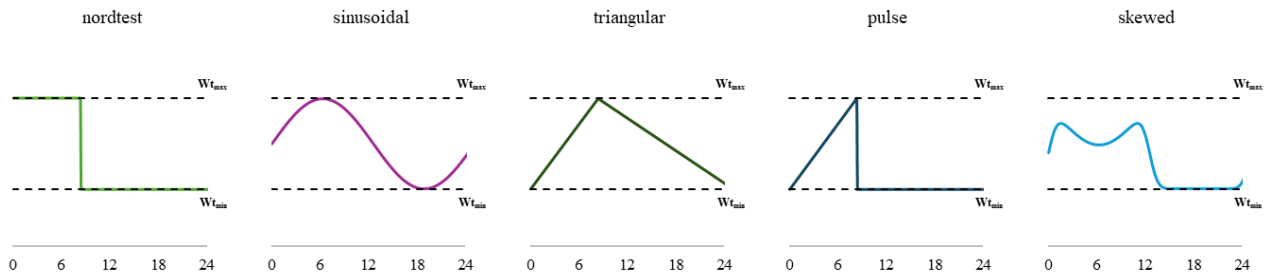

Figure 3. Topology of the forcing function used to simulate the temperature variation over time.

By solving the system of equation (1) to (4) using a forward Euler approach (while the diffusive model relies on iterative resolution algorithm), it becomes possible to obtain the evolution over time of both *Moisture Uptake Distribution* and *Moisture Flux Distribution* (outputs of Figure 2). This analysis is particularly useful for assessing the actual penetration depth in the presence of fluctuations, for example induced by the temperature, this information is essential for determining the optimal thickness of the hygroscopic material/component.

3. RESULTS

3.1. Influence of temperature on moisture exchange with air

For conventional materials, where water uptake variations are in the order of 1% (e.g., concrete, limestone, gypsum), the common approximation of "collapsing" all the adsorption isotherms within the 15-35°C range to a single reference curve at the intermediate value of 25°C does not introduce significant errors (or inaccuracies). The overall mass of water vapor involved in the exchange between the materials and the indoor air is, in these cases, very low.
However, when analyzing innovative, high-performing materials suitably designed to control indoor RH fluctuations, neglecting the influence of temperature can lead to substantial underestimations or overestimations of exchanged water masses. Water vapor adsorption isotherms are intrinsically linked to temperature, and within the typical temperature operational range in building environments, significant variations in moisture uptake at different RH levels can occur. For instance, Figure 4 shows the plot of isotherm function in equation 5 for the lower, the average, and the upper value of the considered range of variation of temperature. It is possible to see that variation of the moisture uptake of about ±30% occurs when the temperature swings between 15°C and 35°C. This effect is observed in both a traditional limestone indoor plaster (Figure 4a), commonly used for building retrofits, and in the same plaster enhanced with hygroscopic calcium alginate beads (Figure 4b). However, in the first case the variation of the moisture uptake is only few grams per kg.

In the first case (limestone) joining the different isotherms at the intermediate value of 25°C generates an error that is in the order of few grams also in the worst case of high RH values (specifically, between 1.6-4 grams when RH ranges between 40 and 95%). On the contrary, using the same approach in the more performing material (Figure 4b), where the enhanced plaster reaches moisture uptake close to 20% at the maximum RH, will induce an error whose is close to 100 grams per each kilos of used material in a room. Comparing this value with the latent load

associated to an occupant seated or doing light work (LHG = 75W) resting mode easily clarify the unacceptability of this approach when for example material is simulated over different seasons of one year.

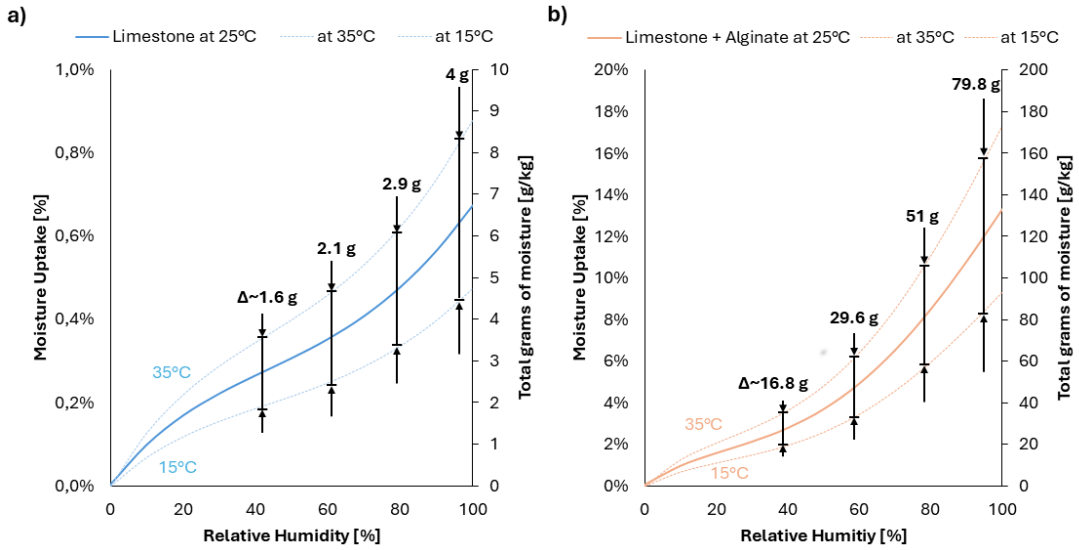

Figure 4. Comparison of equilibrium moisture uptake between unmodified limestone plaster (a) and the same plaster doped with 10% calcium alginate hydrogel beads (b), as the equilibrium temperature varies between 15°C and 35°C (the center, continuous, line correspond to a T=25°C).

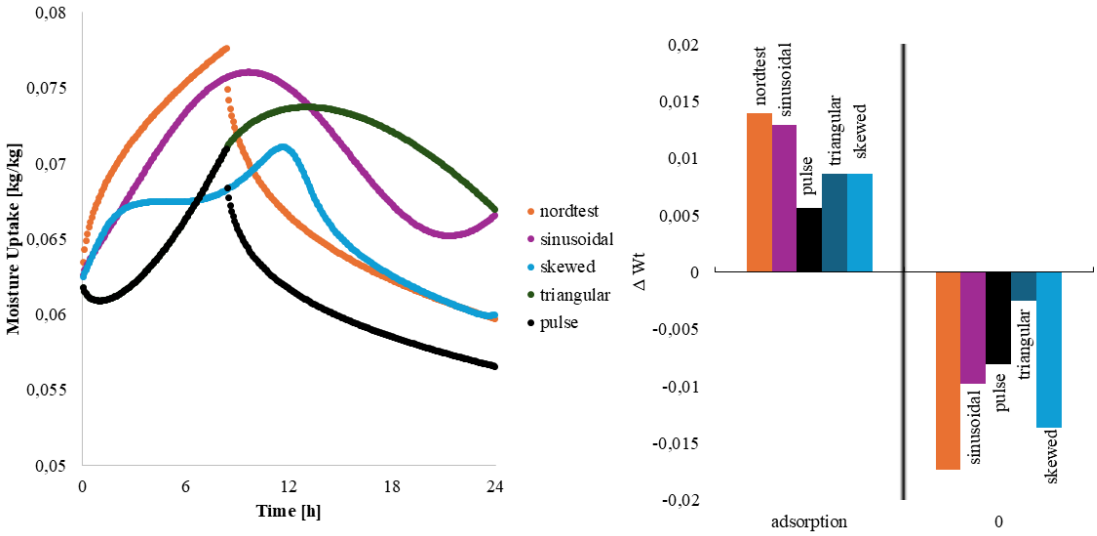

Figure 5. Results of the dynamic model under different temperature forcing functions. The left plot shows the total moisture uptake across the full thickness of the material over time. The right plot presents the total mass of moisture uptake adsorbed and released during the first 8 hours and the last 16 hours of the cycle, respectively.

Figure 5 presents the results the dynamic model related to a daily cycle where RH is maintained constant at 50%, while temperature varies over 24 hours according to the different forcing functions shown in Figure 3. The air change rate is set at 1 h^{-1}, and the room is occupied by a single

person. The plot on the left illustrates the variation in moisture uptake over time under different forcing functions, all applied with an 8/16h duty cycle. Since RH remains constant, temperature fluctuations directly influence vapor pressure variations, shaping the material's response to thermal changes. The response pattern closely follows the shape of the imposed temperature variation. The largest differences between moisture adsorption and desorption occur with the step function (Nordtest). Additionally, some forcing functions lead to a net moisture gain at the end of the 24-hour cycle, while others result in a net loss. This is further clarified in the right plot, where each bar represents the difference in moisture uptake between the start and end of each phase of the cycle (first 8 hours vs. last 16 hours). It is interesting to see that the triangular and sinusoidal functions cause a net increase in moisture content, indicating that at the end of the cycle, the material retains more moisture than at the beginning. Differently, the other shapes of the forcing functions generate a deficit at the end of the day. In general, cycle duration of 24 hours unlikely generate a balanced net mass variation, and the "average" response to a periodic solicitation would require several days to obtain a stable indication.

3. CONCLUSIONS

In conclusion, considering 1 kg of material, this dynamic approach, despite the material not reaching full equilibrium with the surrounding air within each phase, results in moisture variations ranging between ±5 and 15 grams. When extrapolated this information to the entire surface available in the simulated room (3×4×3m³, with 5 out of 6 surfaces covered in the enhanced hygroscopic plaster, totaling 66 m² of exposed surface, a plaster thickness of 2 cm, and a density of 1783 kg/m³), the total moisture exchange between the plaster and indoor air fluctuates between ±11 and 35 kg per cycle. These results highlight the significance of accounting for temperature influence in highly hygroscopic materials and the potential errors introduced when neglecting this factor in long-term simulations.

SUMMARY
The growing demand for human activities has led to increased scale and depth of underground buildings, thereby heightening the need for heat and moisture regulation in their envelopes. Influenced by semi-infinite rock bodies and diverse environmental factors, heat and moisture transfer (HMT) in underground building envelopes presents a complex issue. Firstly, this paper gathers engineering cases and literature related to HMT from Web of Science, expanding the search from both micro and macro perspectives, with a focus on theoretical models, experimental studies, and numerical simulations. Secondly, the literature analysis reviews classical theoretical models of HMT in porous media, predominantly focused on the ground envelope. Finally, the analysis of experimental and numerical simulation studies reveals that experimental studies are scarce and the available numerical models are inadequate. Future research directions encompass understanding the HMT mechanism under multi-factor coupling, enhancing the computational model, and achieving technological breakthroughs in practical applications.

Keywords: Heat and moisture transfer; Underground Enclosure Structure; Environmental Control

1. INTRODUCTION

Amid increasing surface land scarcity, the rational development and utilization of underground space are essential for sustainable urbanization and enhancing urban resilience. Underground space utilization addresses urban land scarcity, traffic congestion, and environmental pollution while also reducing energy consumption, enhancing carbon sinks, and facilitating carbon sequestration (Qin Boyu et al., 2024; Zhao et al., 2016). Progressive urbanization and industrialization have driven the continuous expansion of underground buildings in scale and depth, intensifying environmental regulation challenges. Heat and moisture transfer (HMT) in underground building envelopes is a critical component of internal environmental research. The distinct environmental boundary conditions of underground enclosures result in fundamental differences in their HMT mechanisms compared to aboveground structures. However, the majority of existing studies continue to concentrate on aboveground buildings, resulting in a relative paucity of systematic research and reviews concerning underground enclosures.

Utilizing “underground” and “heat and moisture transfer” as search terms, 33 highly relevant articles were retrieved from the Web of Science database and subsequently clustered using VOSviewer. VOSviewer was used to cluster the articles. As depicted in the keyword distance-density map presented in Fig. 1., research in the field of heat and moisture transfer in underground

enclosure structure primarily concentrates on three salient directions: “environmental factors and material properties” (Chen et al., 2009; Klemczak, 2011; MATSUMOTO, 1995; Shi et al., 2024), “practical engineering problems and moisture transport properties” (Chen et al., 2024; Li et al., 2020; Maliki et al., 2015; Yu et al., 2022; Zhou et al., 2023), and “simulation and analysis of heat and moisture coupling effects” (Chen et al., 2009; Li et al., 2022, 2021; Maliki et al., 2015; Park and Nagai, 2007; Zhao et al., 2020).

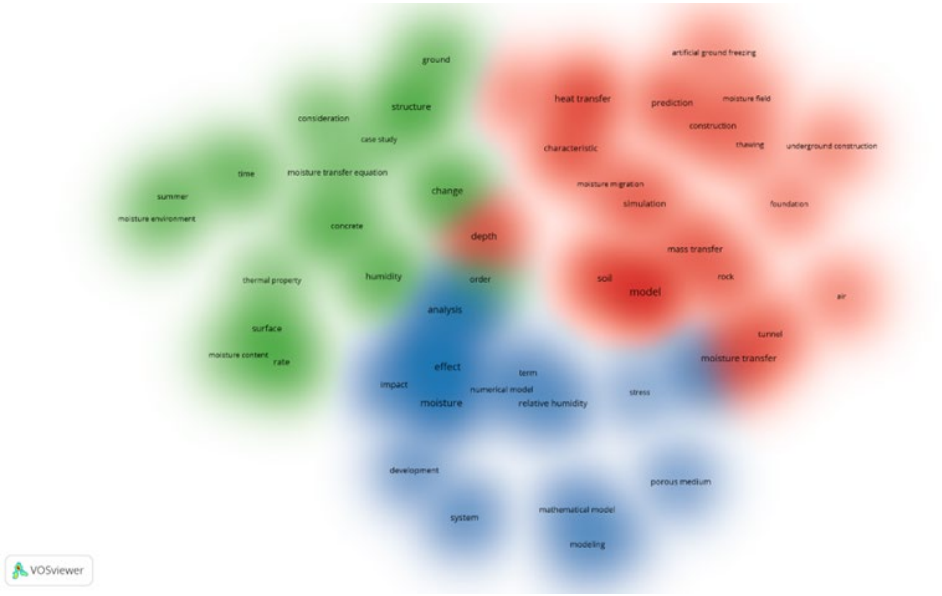

Figure 1. Distance-density view of keywords related to HMT in underground building envelopes.

Given the limited studies on HMT in underground building envelopes, this paper aims to analyze the HMT mechanism from a microscopic materials perspective and summarize research on HMT in practical engineering applications from a macroscopic environmental perspective. The article begins with key research points, expands the search scope, and provides a comprehensive summary of the current research status. The article aims to guide future research on heat and moisture coupling transfer in underground building envelopes and the regulation of underground building environments.

2. MICROSCOPIC PERSPECTIVE: HMT MECHANISM IN POROUS MEDIA

The difference in HMT between underground and surface building envelopes is mainly due to the presence of semi-infinite surrounding rock around underground envelopes (Liu Xichen, 2014) and the influence of complex factors such as burial depth(Liu Xichen, 2014; Stetjukha, 2023)and ground temperature distribution (Wei et al., 2024). The surrounding rock and underground enclosure structures are porous media, and understanding HMT principles within these media is essential for elucidating the formation mechanisms of the heat and moisture environment in underground buildings. The solid part of the porous medium, known as the solid-phase matrix, is distributed throughout the medium. The remaining part constitutes the pore space, which is filled with gas or liquid. Part of the pore space is interconnected (Bear J, 2013). Porous media can be categorized into three types based on moisture content:(1) wet saturated porous media, with pore space entirely filled with liquid; (2) unsaturated porous media, with both liquid and water vapor in

the pore space; and (3) dry saturated porous media, with only water vapor in the pore space. In underground envelope, the most common situation involves HMT in unsaturated porous media. The mathematical models of the coupled HMT process in porous materials are roughly Luikov only theory and Whitaker volume average theory.

2.1 Classical transfer theory

In 1934, Luikov introduced the concept of migration potential, recognizing the interrelation between HMT. Based on this concept, he integrated mass transfer effects into the Fourier heat conduction equation and incorporated heat transfer into the Fick diffusion equation, establishing a two-parameter coupled HMT model for porous media using temperature and volumetric humidity content as variables. Furthermore, he proposed a three-field driven model, where temperature, humidity content, and pressure act as migration potentials (Luikov, 1975). Although Luikov's phenomenological wet migration theory provides a mechanistic and realistic representation of wet migration in porous media, its governing equations rely on complex thermal and humidity parameters that are experimentally challenging to determine, limiting its practical applicability. The Whitaker volume averaging method models porous medium as a virtual continuum by selecting a representative unit cell that is sufficiently large to capture macroscopic transfer phenomena and encompasses all phases of the medium. As a result, the averaged properties and HMT phenomena within this volume are both continuous and representative. This method has become a standard and widely adopted approach for studying HMT in porous media. Furthermore, numerous researchers have extended the Whitaker model to explore various driving mechanisms (Ilic and Turner, 1989; Nasrallah and Perre, 1988; Peishi and Pei, 1989; Wei et al., 1985, 1985). However, the model exhibits several limitations. For instance, the transport and control mechanisms are inadequately described, particularly in expressing the equilibrium relationships among various forces (Liu Xichen, 2014). In porous media, HMT results from the combined action of multiple transport mechanisms. No single theory can comprehensively summarize the HMT behavior of porous media under all conditions. The development of the theory of coupled HMT in porous media has roughly gone through three stages. Initially, the pure vapor diffusion theoretical model dominated. Subsequently, theoretical models that account for evaporation and condensation were introduced. Finally, a comprehensive theoretical model of coupled HMT was developed.

2.2 Thermo-humidity coupled transport theory

In 1957, Philip and De Vries pioneered a dual-field coupling model incorporating temperature and humidity gradients, demonstrating their influence on gas and liquid transport(Liu Xichen, 2014). Luikov later expanded this framework by integrating irreversible thermodynamics, macroscopic conservation laws, and migration potential into heat and moisture transfer (HMT) theory, formulating a dual-drive model driven by temperature and humidity gradients (Liu et al., 2006). Subsequent advancements have refined thermo-humidity coupling models, with extensive research focusing on coupled heat-moisture transfer in porous media, particularly within enclosure structures. The thermo-humidity coupling model proposed by Häupl et al. (1997) correlates temperature and volumetric humidity content, utilizing the hygroscopic equilibrium curve to describe the relationship between pore-space humidity content (per unit volume of liquid water) and relative humidity in porous media. The moisture absorption equilibrium curve of the porous material is illustrated in Fig. 2. N. Mendes(N. Mendes et al., 2002) analyzed the impact of latent heat on thermal conductivity during moisture transfer in building envelopes using the dual-field coupling model by Philip and De Vries. In this model, thermal conductivity, mass transfer

coefficient, and specific heat are expressed as functions of the porous medium's moisture content. The results indicate that gas diffusion and seepage coefficients depend on the porous medium's microstructure and gas properties.

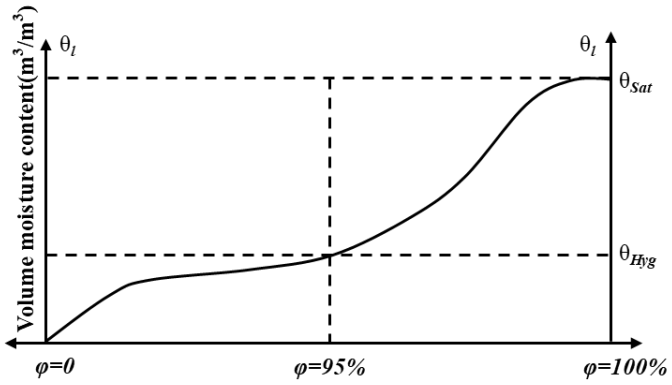

Figure 2. Moisture absorption equilibrium curve of porous materials.

Although more studies have been conducted on the mechanism of HMT in unsaturated porous media, most focus on small-scale porous materials, i.e., HMT over short distances and durations. Additionally, most studies on HMT in enclosure structures concentrate on above-ground buildings, with limited research on underground structures. Since these micro-mechanisms are influenced by boundary conditions, construction methods, and the coupling of multiple factors in the operating environment in macro-engineering applications, the following sections will discuss HMT in enclosure structures from the perspectives of engineering environment regulation and experimental monitoring.

3. MACRO PERSPECTIVE: HEAT AND HUMIDITY ENVIRONMENT CREATION

In addition to research on the heat and humidity coupling mechanism based on material properties, many scholars have also conducted research on HMT in underground buildings for the purpose of environment creation. Yu et al. (Yu et al., 2020) reviewed 107 studies on underground buildings and found that field experimental methods and numerical simulation methods are the primary approaches for studying underground buildings. In this paper, we focus on these two types of research methods and generalize and summarize the studies on HMT in the envelopes of underground buildings.

3.1. Field experiments and parameter testing

3.1.1. HMT of soil, surrounding rock, and lining material (SSL)

Underground buildings are typically surrounded by semi-infinite soil or surrounding rock, and the thermal and moisture properties of these materials significantly influence HMT in underground structures. As early as 1980, Shipp et al. (Shipp et al., 1980) conducted field experiments on heat flux through the walls of underground buildings and the surrounding soil temperatures and moisture content at the University of Minnesota. They highlighted that soil moisture content and surface conditions are key factors affecting soil thermal conductivity, and changes in this coefficient significantly impact heat transfer in the underground building envelope. Around 2000, Japanese scholar Daisuke Ogura (Ogura et al., 2000) conducted a one-year study on HMT

behaviors in underground buildings and their surrounding foundations in Tsu City, Japan. He reached similar conclusions and emphasized that ventilation is an effective means of regulating heat and humidity coupling in underground structures. Zhao et al. (Zhao et al., 2021) conducted a 68-day field monitoring experiment in a typical Nanjing Metro subway section to measure subway tunnel wall temperature (STWT), tunnel air temperature, and wall heat flow. They studied the heat absorption rate (SHAR) of the STWT and surrounding geotechnical soil, as well as their impacts on the subway system's thermal environment and energy consumption. They concluded that train operation, tunnel air temperature, and surrounding geotechnical soil temperature are the primary factors influencing STWT and overall thermal environment and energy consumption. The thermal and moisture characteristics of soil and surrounding rock significantly impact HMT in underground building envelopes. However, due to experimental challenges, field experiments in this area are relatively limited.

The heat and moisture parameters of SSL are crucial for simulating HMT in underground building envelopes, as these materials are predominantly porous media. Since the 1980s, several large-scale testing projects have been conducted in Europe and the United States to investigate the hygric properties of common building materials, including IEA Annex 14 (HENS, 1992), IEA Annex 24 (Canada, 2025), ASHRAE1018-RP (K, 2006), and NRC-IRC MEWS (Walls et al., 2003)35]. These projects have established isothermal moisture absorption and release curves, water retention curves, hygric permeability coefficients, hygric diffusion coefficients, and other hygric parameters for hundreds of porous building materials, forming a comprehensive database to support the simulation of HMT in underground structures. However, these tests have primarily focused on general building materials, with limited specific investigation into the heat and humidity parameters of underground SSL. Further analysis and categorization are still required. In recent years, the China Academy of Building Research and other organizations have actively accumulated data on the hygric properties of porous building materials and have achieved some progress (Feng Chi et al., 2016). However, the current tests on porous materials in China are not yet comprehensive, with limited testing related to the thermal and humidity parameters of SSL. Consequently, a more complete database of thermal and humidity parameters for porous materials has yet to be established.

3.1.2 Exploration of the Interaction between SST and Internal Environment

Excessive moisture is a prevalent issue in the internal environment of underground buildings, and studies on the thermal and humid environments within these structures often necessitate the exploration of dehumidification and moisture prevention strategies. Zhang et al. (Zhang et al., 2017) conducted a one-year field study on two typical underground civil defense works (CADWs) in Beijing. Their research elucidated the mechanisms underlying the thermal and humid environments in these CADWs and provided a foundation for developing appropriate dehumidification solutions. They also emphasized that different types of CADWs necessitate distinct moisture control measures. Ma et al. (Ma et al., 2022) conducted winter and summer tests on the hot and humid environments in three CADWs to characterize the heat and moisture exchange patterns between the underground intake tunnel envelope and the air. Yu et al. (Yu et al., 2022) conducted both short-term and long-term measurements at two subway stations on Tianjin Metro Line 5. They found that while the air temperatures in the stations were relatively stable, the humidity levels varied significantly. Notably, the relative humidity at the platforms was classified as “wet” or “very wet” for 30% of the test duration, indicating a high risk of condensation. Kim et

al. (Kim et al., n.d.) conducted a one-year field study of two typical underground parking lots in Seoul to investigate the phenomenon of moisture condensation and identify the most suitable conditions for condensation prevention. In recent years, with the proliferation of numerical simulation research, fewer studies have focused solely on field experiments. Instead, more research has integrated field experiments with numerical simulations or employed micro-experiments to validate numerical models.

3.2 HMT modeling and numerical simulation of envelope structures

Zhang et al. (Zhang et al., 2010) developed a novel heat-humidity model to describe the coupled HMT process involving water vapor diffusion and liquid water migration in underground building envelopes, based on Philip and De Vries' two-field coupling theory. Liu (Liu Xichen, 2014) established a mathematical model of HMT in an underground plant envelope, using liquid water volumetric moisture content and temperature as driving potentials. He introduced the concept of "cell partitioning" into the solution process for air parameters in longitudinally ventilated, deeply buried underground ducts. He also used coupling as an entry point to investigate the dynamic HMT of the plant envelope, revealing the relationship between air parameters and air temperature. The dynamic HMT of the plant envelope was investigated using coupling as an entry point, revealing the intrinsic connection between air parameters and wall HMT, and proposing a simplified formula for predicting year-round dynamic heat and humidity uptake and discharge of the envelope. Zhong et al. (Zhong et al., 2014) investigated the condensation of basement walls in Chengdu using EnergyPlus simulation software. They proposed condensation is influenced by the combined effects of thermal resistance, air change rate per hour, and heat gain. Huang (Huang, 2023) established a HMT model for underground envelopes using COMSOL Multiphysics software, based on Liu's model and incorporating measured temperature and humidity parameters from Xi'an subway station. He highlighted that an accurate heat and humidity coupling transfer model is crucial for simulating and predicting the heat and humidity distribution in subway station enclosures, as well as for improving air quality and extending the service life of equipment. The primary differences among these models and simulation approaches lie in their specific assumptions. Owing to the complexity of moisture transport theory, which involves multiphase and multilayer pore structures, variable boundary conditions, material properties, and highly nonlinear governing equations, no single model is suitable for all applications. In fact, simpler models, such as Fourier's one-dimensional heat transfer model and Glaser's vapor diffusion model based on Fick's law (Branco et al., 2004), remain popular and widely used in civil engineering.

4. CONCLUSION

This paper systematically reviews the research progress on HMT in underground building envelopes from both microscopic and macroscopic perspectives and obtains the following conclusions:

(1) The HMT process in underground enclosure structures exhibits multiple coupling properties and is influenced by multi-factor coupling, unlike above-ground buildings. Existing simplified or single-phase models are insufficient to accurately reflect this process. A reliable theoretical basis for regulating and designing the underground environment can only be provided by fully considering the pore structure of materials, phase changes, and multi-phase flow characteristics.

(2) Existing engineering practices must enhance the integration of parameter determination and multi-scale numerical simulations. Integrating on-site measurements of underground thermal and humidity environments with microscopic tests can better calibrate and validate model parameters, providing scientific support for optimizing engineering design schemes.

(3) As the potential value of underground buildings in urban complexes, public transportation, and energy utilization becomes more prominent, future research should deeply explore the influence of multi-field coupling (heat, moisture, stress, and chemistry) on the performance of underground structures. Further improving the thermal-humidity coupling model can help achieve energy savings and emission reductions in underground buildings, enhance indoor environmental quality, and meet the needs of sustainable urban development.

SUMMARY
Rising temperatures are leading to an increase in the cooling demand of buildings. Electrochromic (EC) glazing can be a promising solution for controlling solar heat gains while maintaining outdoor views. This paper presents the results of the monitoring of prototype panels of a novel type of inkjet-printed EC glass under real use and weather conditions in a small office building in the Netherlands. This building contained two identical west-facing meeting rooms of which one was equipped with EC triple glass IGUs and the other with normal triple glass IGUs. Each room was equipped with local heating/cooling units of which the energy use was monitored, and with an extensive environmental sensor network. Sensor and calendar data was fed into an energy balance model for each of the rooms for the entire measurement period, allowing to correct for differences between the two rooms with respect to heat losses and gains and use conditions. The results of the monitoring showed that in the meeting room with EC glass IGUs, the heating demand increased by 34% in Jan.-Mar. 2024 while in Sept. 2023 the cooling demand decreased by 3%. The main reason for the increase in heating demand was found to be the lower g-value of the EC glass IGUs in clear state as compared to the normal IGUs. The almost similar cooling demand was a result of a trade-off between the lower direct solar transmittance of the EC glass IGUs and the heating up of the absorptive layer inside the IGUs. Furthermore, an experiment with participants showed that in general in dark state, satisfaction with view clarity, daylight colour and daylight availability was higher for the EC glass IGUs. In transparent state, no significant difference was perceived between the EC glass IGUs and standard IGUs, except for view clarity.

Keywords: Electrochromic glazing, energy performance, monitoring.

1. INTRODUCTION

Rising temperatures are leading to an increase in the cooling demand and overheating risk of buildings. Dynamic switchable glazing, like Electrochromic (EC) glazing, can be a promising solution for controlling solar heat gains and daylight admittance while maintaining access to outdoor views. By applying a small electric potential, the transparency of the glass can be adjusted to modify the visible light and direct solar transmittance. It can be switched over a range between a clear state with high transmittance, and a tinted state with low transmittance. To produce EC glass, a thin-film EC coating is placed on a glass panel. The coating consists of several layers: at the centre, an ion-conducting electrolyte sandwiched between an active EC layer at one side and a passive counter-electrode layer at the other side. Transparent conductors form the outermost layers (Lee et al., 2006). The thin film deposition can be based on several methods. The selected method affects the production costs and the durability of the end product (Kelly Waskett, 2016). The current high costs hinder the widespread application in buildings. Recently, a cost-effective type of EC glass using inkjet-printing was developed. Its effect on the cooling and heating demand and how it holds under real use and weather conditions is still uncertain.

Several earlier studies have investigated the performance of traditional EC glazing based on field test experiments or energy performance simulations. These studies examined possible energy savings based on different control regimes, environmental conditions or building types (Chambers et al., 2019; Piccolo & Simone, 2015; Papaefthimiou et al., 2006; Li et al., 2023; Klems, 2001); or compared the performance of EC glazing to other solar control devices (Fernandes et al., 2013; Kwee, 2020; Krarti, 2022). One study also included user satisfaction (Kelly Waskett, 2016).

The objectives of the present study, the Windows to the Future project, were: 1) to upscale the production facilities of inkjet-printed EC glazing, 2) to understand and overcome the key bottlenecks when integrating the technology into facades, 3) to understand to what extent the EC glass impacts the cooling and heating demand, as compared to regular high-performance triple glass for office spaces in temperate climates, 4) to explore the satisfaction of the technology by users, and 5) to understand to what extent the EC glass transmits daylight into the workplace and how the colouring of the daylight affects user perception. This paper will mostly address the objective 3 and includes some of the results related to objective 5. More results related to objectives 4 and 5 can be found in Luna-Navarro et al. (2024) and Chiucchiu et al. (2024). The EC glass used in this project was developed by Brite Solar.

2. MATERIALS AND METHODS

2.1. EC glass prototypes

The experiments were done in the OfficeLab at The Green Village on the TU Delft campus, the Netherlands. This building is equipped with HR+++ triple glass with a U-value of 0.6 W/(m^2K), a g-value of 0.48, and a light transmittance (t_{vis}) of 0.73. In the experimental room, the existing insulating glass units (IGUs) were replaced with IGUs with an EC layer. The thermal insulating properties of these IGUs were selected to correspond to the existing triple glazing. Furthermore, the thickness of the new IGUs matched the existing IGUs. The U-value of the EC glass IGU was measured to be 0.60±0.02 W/(m^2K); the light transmittance (t_{vis}) for the clear state between 0.40±0.05 and for the tinted state between 0.08±0.02; and the solar transmittance (t_{sol}) for the clear state 0.18 and for the tinted state 0.004. The software WINDOW was used to assess the g-value of the glass in clear and tinted state, which were respectively 0.35 and 0.34 (if the EC coating is placed on the innermost pane) or 0.26 and 0.04 (if the EC coating is placed on the outermost pane).

Due to the Covid-19 pandemic, the full-scale production line for the EC glass panes was inaccessible. As a result, the EC glass panes had to be produced by a lab printer with much smaller dimensions. The dimensions were therefore limited to 50 x 50 cm. As a consequence, the smaller EC glass panes (two sheets of 3 mm glass with in-between them the active layers) had to be laminated onto a 5 mm glass pane of the full window size (approx. 1 x 2.6 m). This ±11 mm thick glass laminate was used as one of the three glass panes of the IGU. The fixed windows in the façade were subdivided into 12 smaller panes while the operable window was subdivided into 10 panes (Figure 1). Even though the EC glass panes (by lamination) were integrated into a full size triple glass unit, sealing stripes were visible between the smaller EC panes. Table 1 provides the layering of the glass. It is important to mention here that the glass in the fixed windows had the EC glass laminate on the inside while in the operable window it was on the outside. The manufacturer recommended, as a precaution for this experimental version, to place the EC coating on the warm side of the glass to prevent a too low temperature of the coating in winter. However, as sun-shading, the coating should ideally be as close to the outdoor environment as possible.

Table 1. Layering of the triple glass IGUs.

IGU configuration	Existing triple glass IGU	EC glass prototype fixed window	EC glass prototype operable window
Outer pane	6 mm Stratobel laminated 33.1: 3 mm Planibel Clearlite / 0.38 mm PVB clear / 3 mm iplus 1.1. pos.2	5 mm iplus 1.1 (or equal)	11 mm laminated EC glass
Cavity	15 mm argon 90%	13 mm argon	13 mm air
Centre pane	4 mm Planibel Clearlite	5 mm iplus 1.1 (or equal)	5 mm iplus 1.1 (or equal)
Cavity	15 mm argon 90%	13 mm air	13 mm argon
Inner pane	6 mm Stratobel laminated 33.1: 3 mm iplus 1.1. pos.2 / 0.38 mm PVB clear / 3 mm Planibel Clearlite	11 mm laminated EC glass	5 mm iplus 1.1 (or equal)

Figure 1. West façade of the experimental room with EC triple glass IGUs (left) and of the control room with standard triple glass IGUs (right). In the operable window, six of the small panes faced material leakage issues resulting from the lamination process due to improper sealing and could not be used.

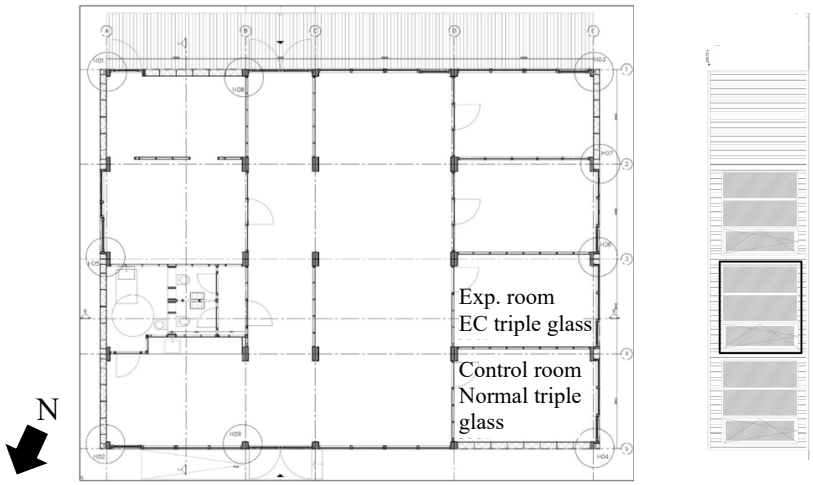

Figure 2. Floor plan and West façade of the OfficeLab. The windows highlighted contain the EC glass IGUs.

2.2. Test rooms set-up

The test building is a lightweight single-storey office building with a timber frame construction. Two similar meeting rooms, with a floor area of 17 m² each, at the western façade are part of the experimental setup: one control room where the original triple glazing is maintained and one experimental room where the original glazing is replaced with the prototype EC glazing (Figure 2). The two rooms have equal window areas with two fixed windows and one operable window.

2.3. Local heating and cooling units

To assess the heating and cooling demand, dedicated local heating / cooling units (portable air conditioner Whirlpool PACW212HP) were placed inside the two rooms and set to the same set-point temperatures (25ºC in cooling mode and 21ºC in heating mode, with a dead band of 1 ºC on both sides, from 3 am till 6 pm). Each unit was connected to a thermostat which was mounted on a wall. The electricity use of the heating / cooling units was measured with SXD10/5 0-10 ampere clip-on CTs attached to the electricity cable of each device and connected to an Eltek GD40A transmitter. The COP for heating was 2.8 and the EER for cooling 2.6.

2.4. Hourly heat balance corrections

The difference between the cumulative heating or cooling output of the local heating / cooling unit inside the two rooms provides an indication of the energy saving potential of the EC glass. However, differences between the two rooms (occupancy, ventilation rates, opening of doors and windows, electric lighting use, infiltration rate, and heat losses in general) will occur. To correct for these effects, a heat balance model was set up for each room for each hour of the full measurement period. This model was fed with data from environmental sensors, the outlook calendar of the rooms and the properties of all surrounding materials. It includes heat transmission through the floor, the roof, the opaque façade, the glass, and the partition walls; infiltration; heat transfer through mechanical ventilation; heat transfer through natural ventilation when the window was open (BLAST model); ventilative heat transfer to the main office when the door was open (stack model); internal heat gains from people, equipment, and lighting; solar heat gains through the glass. The energy use of the air-con unit in the two rooms was then compared and corrected for differences in the heat balance which were not a result of the glass, for every hour of the measurement period. This enabled us to correct for the different position of the rooms (corner versus centred) and differences in use. Also, pyranometers mounted behind the glass of each room ensured that the real solar gains were used in the analysis.

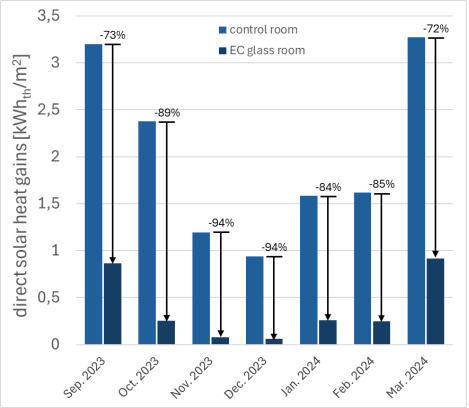
2.5. Sensors and data acquisition system

The meeting rooms and the offices next to them were equipped with multiple sensors to measure environmental variables. The actual monitoring campaign took place from Aug. 15, 2023 till March 31, 2024. Because the OfficeLab was undergoing construction works from April 2024 till Oct./Nov. 2024 the sensors had to be removed. Table 2 provides an overview of the installed sensors. All Eltek transmitters transmitted their data to an Eltek Squirrel RX250 receiver.

Table 2. Overview of installed sensors and transmitters.

Measured property	Sensor	Transmitter	Position
Direct solar transmission through glass	Thies GSM 10.7 pyranometers	Eltek GenII GS-44	behind the glass at 1.1 m above the floor (same height as outdoor one)
Outdoor solar radiation	Thies GSM 10.7 pyranometer	Eltek GenII GS-44	in front of the façade, outdoors, at a height of 1.4 m above the ground
Outdoor weather	Vaisala WXT536D	Eltek TMET	in front of façade at 1.5 m height
Indoor temp. and RH	Eltek GC-10 T and RH sensors and transmitters		at a height of around 1.5 m
Amount and temp. of mechanical air supply	E+E576 air flow sensors thermocouples type T	Eltek GS41AV and GS24 transmitters	inside the supply ducts
Window and door states (open/closed)	magnetic contact sensors	Eltek GenII GC60 transmitters	On openable windows and doors. The doors had automatic closers.
EC glass IGU surface temperature	thermocouples type T	GS24 transmitter	On indoor and outdoor glass surface at a height of approx. 1 m
EC glass IGU heat flux	Hukseflux HFP01	GS44HD transmitter	Same as above

The use of the electric lighting could not be monitored. Lighting use was estimated based on occupancy of the rooms (only then the lights were switched on in reality) and the installed power (65.6 W). The heat gains by equipment were considered small compared to the heat gains by people and lighting and were estimated from the number of people present, assuming 50% of the people brings a laptop with them. Since not everything could be monitored for practical reasons or because of privacy concerns, the following were estimated from the Outlook calendars of the meeting rooms: the time and duration of meetings in the meeting rooms and the number of people present; the time and duration when the flexible partition wall between the two meeting rooms was open.



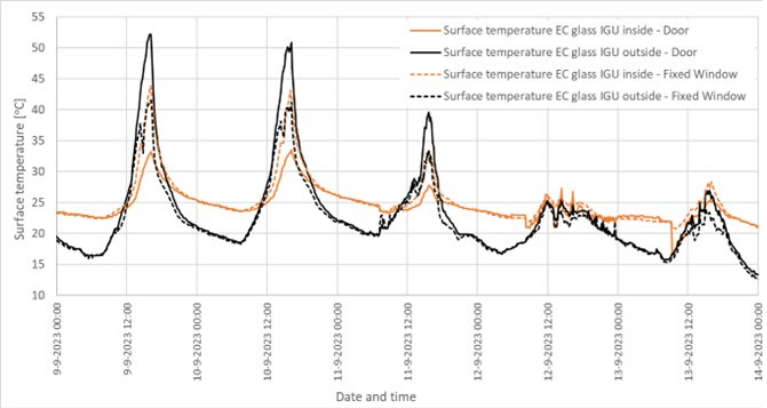


Figure 3 (left). Direct solar heat gains into the EC glass room and control room from Sept. 2023 - March 2024.
Figure 4 (right). Inside and outside surface temperature of the EC glass IGU installed in the middle window (EC coating on glass pane closest to the indoor environment) and in the door (EC coating on glass pane closest to the outdoor environment), for five selected days in September 2023.

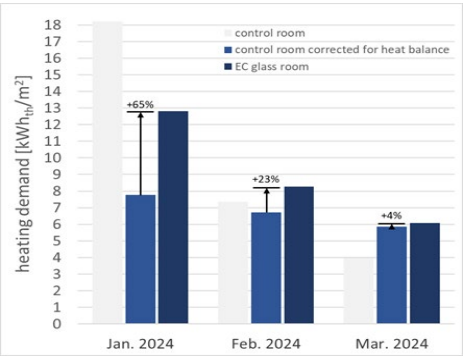
3. RESULTS AND DISCUSSION

3.1. Incoming solar radiation and surface temperatures

The direct solar heat gains for the months Sept. 2023 till March 2024 are presented in Figure 3. These results are based on the output of the indoor pyranometers behind the glass and normalised by the floor area of the room. The direct solar gains through the EC glass IGU are much smaller than through the standard IGU. On average, this difference is 81%, with monthly variations from 72-94%. This means that t_{sol} of the EC glass IGU is much smaller than of the standard IGU. However, this does not reflect the difference in total solar heat gains, for which also the indirect component due to absorption and re-emission of heat by the EC coating needs to be considered.
Therefore also the indoor and outdoor surface temperature of the EC glass IGUs were monitored. Figure 4 shows five selected days in September 2023. These measurements show that the absorptive EC coating heats up when exposed to direct solar radiation. During the entire measurement campaign, for the IGU with the EC coating integrated into the glass pane closest to the indoor environment, a peak indoor surface temperature of 49.1 ºC and a peak outdoor surface temperature of 45.7 ºC were measured, but not at the same time. For the IGU with the coating integrated into the glass pane closest to the outdoor environment, a peak indoor surface temperature of 33.5 ºC and a peak outdoor surface temperature of 55.7 ºC were measured, also not at the same time. These high temperatures were recorded when the glass was in tinted state. As a result, the indirect solar gains can be high and, even though the direct solar transmission may be limited, the overall solar heat gain coefficient can still be high.

3.2. Effect of EC glass on heating demand

The months January till March 2024 gave the most reliable data regarding the energy demand for heating. In December 2023, a better air temperature control algorithm was implemented. During these months the heating setpoints were working properly and the average air temperature in both rooms was close to identical, except for January (Figure 6). The heating demand of the room with the EC glass IGU was higher than of the corrected one of the room with the standard IGU, even though the U-value of both were identical. On average, the energy demand for heating in the experimental room was 34% higher than in the control room, with monthly variations from 4-65% (Figure 5). Besides, simulations in the software DesignBuilder v.7 were performed with a calibrated model of the test building and the exact same set-up of the experiment. These simulations showed for a full heating season that the EC glass IGUs increased the heating demand by 12% as compared to the original IGUs, assuming that in winter the glass was in clear state. The main reason for the increased heating demand is that the g-value of the EC glass IGU was lower than of a standard IGU. This reduces the solar heat gains in winter. This effect is stronger than the effect of the heating up of the absorptive layer. Besides, the smaller size EC panels with sealant seals in-between them reduced the 'transparent' area of the glass. The seams covered close to 10% of the glass. The impact of this on the U-value was small because they only appear in the innermost glass pane of the triple glass. However, they did reduce somewhat the direct solar gains.



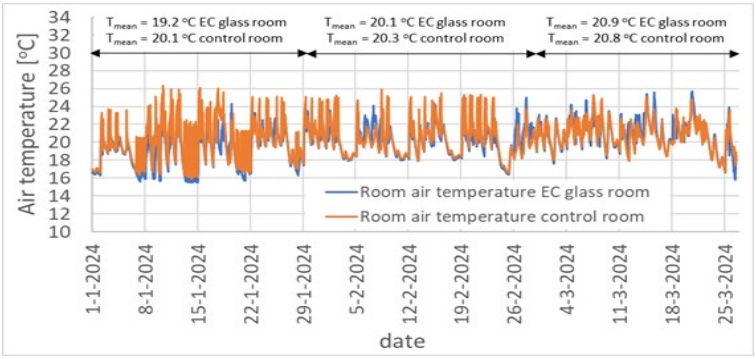


Figure 5 (left). Measured heating demand of the experimental and control room for January till March 2024.
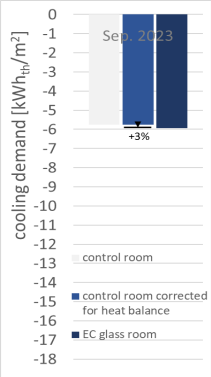
Figure 6 (right). Measured air temperature in the experimental and control room from January till March 2024.

3.3. Effect of EC glass on cooling demand

Unfortunately, no proper monitoring was possible for the summer months because the prototype of the EC glass IGU was only operational from September 2023 onwards and during spring and summer 2024 the test building was undergoing construction works. Luckily, September 2023 had summer-like conditions (av. monthly max. temp. of 23.1ºC). During that month, the cooling demand of the experimental room was similar to that of the control room (Figure 7). A difference of 3% was observed but the absolute value of this difference falls within the measurement uncertainties. Simulations with the calibrated model in DesignBuilder showed that for a full cooling season the EC glass IGUs decreased the energy demand for cooling by 9% as compared to the original IGUs without active sun-shading, and increased the cooling demand by 44% as compared to the original IGUs with active dark outdoor roller blinds (active if solar radiation on façade >125 W/m^2). These results are in line with other studies, albeit slightly lower. For instance, Chambers et al. (2019) found that EC glass could lead to a reduction of 11% in the cooling and lighting demand in Swiss office buildings. Krarti (2022) concluded that EC glass with optimal switching control could lead to an energy reduction of up to 20% for office buildings relative to static glazing. A point of attention in our study are the smaller than full size EC panes and the

resulting sealant seals between the panes. The impact on the cooling demand is difficult to assess because the direct solar transmittance and the temperature of these seams were not measured.



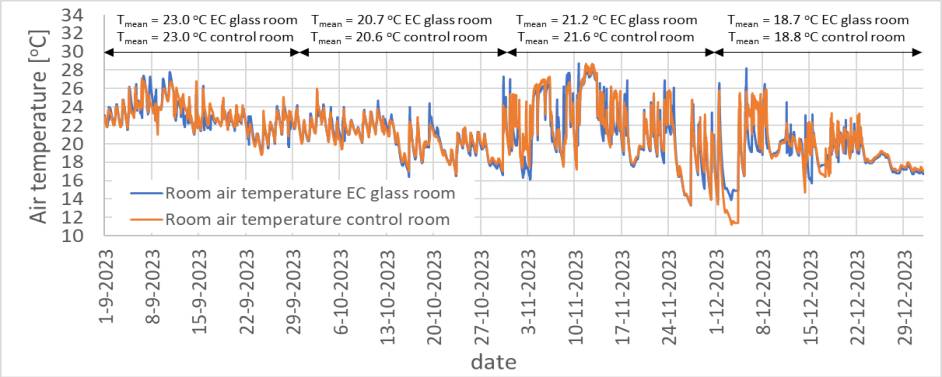


Figure 7 (left). Measured cooling demand of the experimental and control room for September 2023.
Figure 8 (right). Measured air temperature in the experimental and control room from Sept. till Dec. 2023.

4. THERMAL AND VISUAL COMFORT

Besides the extensive monitoring and simulation campaign, an experiment was done as a repeated measures "within subject" study with a total of 38 participants. The participants were spending in total two hours in the two rooms, i.e., the control and the experimental room. They were exposed to different conditions in random order and were working on a reading task. During the first 30 minutes, the EC glass was in clear state in the experimental room or the roller blinds were up in the control room, without sun in the field of view. Then the glazing was tinted or the blinds were lowered for another 30 minutes with the sun in the field of view. Then the glass was bleached and the blinds raised for another 30 minutes. At the end of each 30-minute session, the participants were asked to complete a questionnaire on their perceptions of the visual and thermal environment. The experiment showed that in general in dark state (EC glass tinted or blinds down), satisfaction with view clarity, daylight colour and daylight availability was higher for the EC glass IGUs (Figure 9). In transparent state (EC glass clear or blinds raised), no significant difference was perceived, except for view clarity. Overall, the EC glazing was perceived by the participants as a good alternative to dark roller blinds. More details can be found in Luna-Navarro et al. (2024).

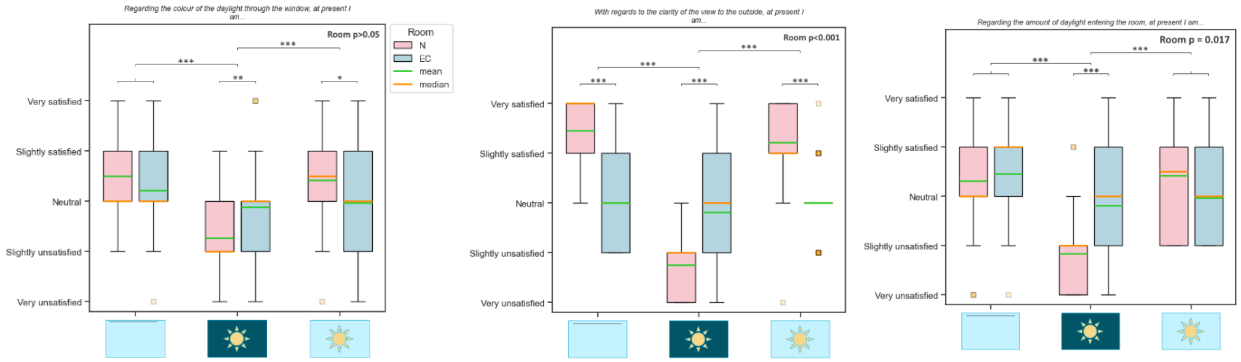

Figure 9. Results from the assessment of the user satisfaction with the visual environment. **left:** satisfaction with the daylight colour in the room; **centre:** satisfaction with view clarity; **right:** satisfaction with the amount of daylight in the room. The level of significance is: * = p-value < 0.05; ** = p-value < 0.01; *** = p-value < 0.001.

5. CONCLUSION

This paper presented some of the results of the Windows to the Future project, a project on the application of low-cost inkjet-printed electrochromic (EC) glazing and focussed on the results of the monitoring campaign. Prototype EC triple glass IGUs were installed in the west façade of a meeting room and the heating and cooling demand of this room were compared to that of a control room with standard triple glass IGUs. The results showed that the EC glass IGUs led to a higher energy demand for heating in winter. This is mainly due to lower solar heat gains through the EC glass. Under summer-like conditions, the energy performance of the EC glass IGUs was found similar to that of the standard IGUs. Even though the EC glass IGUs had much lower direct solar gains, the heating up of the absorptive coating resulted still in high (indirect) solar gains. A key point to mention here is that the EC coating in the triple glass IGUs was placed on the glass pane closest to the indoor environment. For better performance in summer, this coating should be placed on the glass pane closest to the outdoor environment. Besides, a larger dynamic range (especially towards the upper range, i.e. higher transparency) would improve the glass's performance under winter conditions. Also, a controlled experiment with participants showed that in general in dark state, satisfaction with view clarity, daylight colour and daylight availability was higher for the EC glass IGUs. In transparent state, no significant difference was perceived, except for view clarity. Overall, the EC glazing was perceived by the participants as a good alternative to dark roller blinds. Furthermore, future research should increase the length of the monitoring campaign, and test different room orientations and control strategies for the switching of the EC glass, as these were limitations of this study.

ACKNOWLEDGEMENTS

This study was made possible with the support of RVO within the TKI Urban Energy Program (TEUE219006). The authors are also thankful to Si-X for the glass integration and installation.

SUMMARY
In-situ building performance assessment is a main approach for delivering reliable insights into building operations and hindering environmental phenomena. This paper presents a detailed description of Villa SOBRE, a new full-scale research facility designed upon an existing building for multicriteria in-situ building performance assessments. The facility transformation involved envelope upgrades, advanced systems integration, and real-time monitoring. Over 100 sensors have been implemented to measure indoor and outdoor thermal performance, indoor air quality (IAQ), and energy performance and consumption, providing the building with comprehensive environmental data. Further, controlling mechanical ventilation, heating systems, and glazing alongside real occupancy in-situ simulation promotes building operation dynamics studies. The facility transformation features a new double-skin ventilated facade, advancing natural and hybrid ventilation studies, and inter-room slots for pollutant transport and air filtration research. Through adopting a frugal approach and combining a flexible design with fine instrumentation, the Villa SOBRE facility will provide insights into building multicriteria in-situ assessments, supporting future studies in sustainable new buildings and retrofits.

Keywords: Energy Retrofits, In-Situ Assessment, Building Operation.

1. INTRODUCTION

1.1 Context

Building retrofits have shown a significant capability in upgrading existing buildings' energy performance, accounting for 75% of Europe's building stock, with over 50 % built between 1970 and 1990 (Poel et al. 2007; European Comission 2024). Research within this field extends merely to energy consumption reduction and carbon footprint mitigation toward more comprehensive strategies that promote indoor environmental quality (IEQ), occupants' safety and well-being flexibility, and cost-effectiveness (HEART Project 2020; Pohoryles et al. 2020; Al Dakheel et al. 2024). Building operation assessment is required to prove the implemented strategies. The assessment is often conducted through building modeling or in situ measurement campaigns. However, extensive research has identified a performance gap between simulated and measured data, showing that modeling failed to represent the building's real operation. To foster confidence in numerical models, thorough calibration must be performed to minimize discrepancies in the modeling environment and strengthen its predictive capability (Cuerda et al. 2020; Vivian et al. 2023; Chiesa et al. 2025).On the other hand, in-situ measurement campaigns may be a better method for real performance evaluation, given that they provide direct empirical data accounting for the complexity of environmental conditions. Therefore, in-situ measurements remain crucial, despite ongoing advancements in the modeling techniques. Dedicated testing facilities were

established to enhance the flexibility of in-situ measurement campaigns. These facilities are classified based on their scale and exposure to outdoor conditions, ranging from full-scale test cells and buildings to controlled climate chambers (Berardi 2023). Several studies highlighted these facilities‘ potential and growing interest in real performance evaluation (Ascione et al. 2019; Pisello et al. 2021; Freppel et al. 2022).

1.2 Objectives

Considering the same interest, this paper introduces a new full-scale research facility, designed for building performance multicriteria in-situ assessments. This facility is mainly characterized by the integration of existing building characteristics and the exposure to real outdoor conditions. It will provide real-time monitoring of different performance metrics for building operations through a finely instrumented and flexible testing environment. The transformation process defined in the subsequent sections should enable a range of features, such as:

1) Real-time monitoring of both indoor and outdoor parameters, further the control of glazing, artificial lighting, heating set points, and ventilation rates.
2) Assimilation of different HVAC technologies for comparative analysis and demand-responsive control.
3) Advanced studies on pollutant transport and indoor air quality using inter-room slots and pollutant generators.
4) Experiment with hybrid, active, or natural ventilation strategies, using Double Skin Ventilated Facade and integrated systems.
5) Real occupancy through manual operation, or occupancy behavior modelling through systems control, pollutant generation, carbon dioxide, and humidity injection.

2. VILLA SOBRE AS AN EXISTING BUILDING

2.1 Location and Climate

Villa SOBRE is located on the National School of Public Works (ENTPE) campus in Vaulx-en-Velin, a suburb of Lyon, France (45.46°N,4.55°E), presented in Fig.1.Lyon lies between the Rhône and Saône rivers, influencing its microclimate. It falls within the Cfa/Cfb Köppen-Geiger climate zones and is classified as H1 (northeast) under French building regulation ,which features a temperate climate with warm summers and long, humid winters (Dubreuil 2022; Strohmenger et al. 2024).

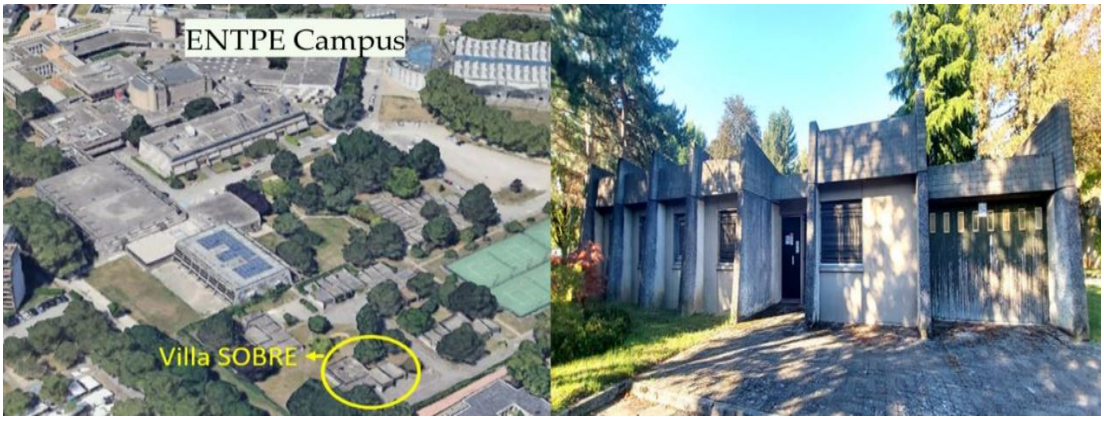

Figure 1. Villa SOBRE location in ENTPE Campus, Vaulx-en-Velin, France

Lyon's historical meteorological data exhibit significant daily thermal fluctuations. The prevailing wind has an azimuth of 340° (-20° from the north), with a monthly average speed of 1- 6 m/s. During the cooling season, temperatures range from 16°C to 27°C, peaking at 36°C with a relative humidity of around 65-70%. Winter temperatures range from 1 to 7°C, dropping extremely to around -7°C. The heating season is characterized by strong wind speeds reaching 17 m/s, and low temperatures with high humidity levels ranging from 76% to 90%, which can lead to significant discomfort and health issues in buildings.

2.2 Building Design & Characteristics

Built in the 1970s as a residential building, Villa SOBRE operated as an experimental site for the Sustainable Construction Research Team at LTDS ENTPE over the past two decades. A 90 m² area, featuring three exposed facades, has been turned into the test facility. The facade walls, partitions, ceiling, and roof are primarily composed of Machefer Concrete, a lightweight material widely used in the 1970s, particularly in the Rhône region. This concrete is composed of metallurgical incineration in various aggregate sizes, combined with lime or cement. (Sadineni et al. 2011; Carnus 2018). The existing doors are wooden, and the windows feature single glazing with metallic frames, each measuring 2.20 m × 1.23 m with a total surface of 2.706 m².

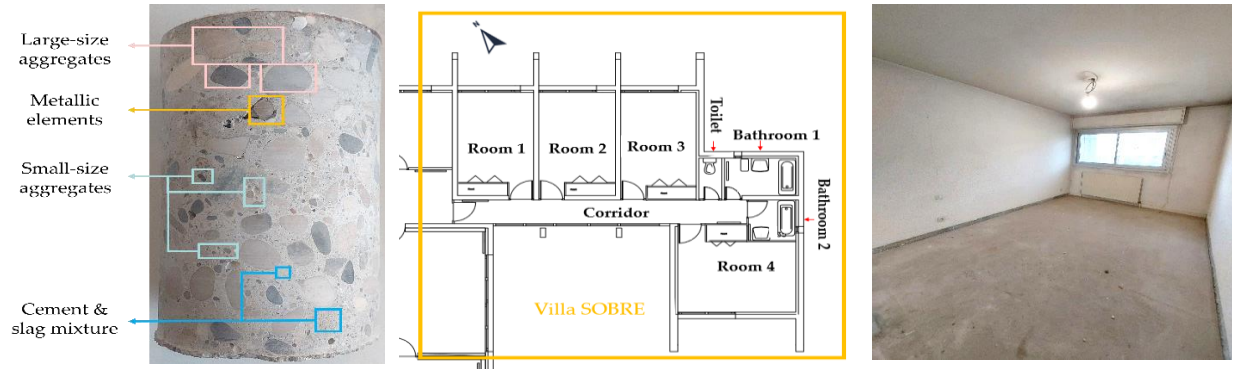

Figure 2. Villa-SOBRE before retrofit: Facade walls sample (**left**), plan view (**middle)**, and indoor rooms (**right**)

2.3 Choice of Retrofit Measures and Systems

The transformation aims to establish a novel experimental research facility that showcases high-performance buildings, applicable to both new constructions and energy retrofitted structures. An initial energy diagnosis using infrared thermography revealed thermal bridges throughout the rooms, localized dampness, cracks, particularly in partition walls, and significant heat loss through window frames. In parallel, the growing interest in multicriteria studies has sparked the importance of IAQ, prompting the design of solutions that control pollutant transfer between spaces and improve the airtightness of the facility components. To address these issues and meet performance objectives, the following measures were considered:

1) Insulation of the facade, ceiling, and floor to enhance the building envelope
2) Upgrading the window systems to reduce thermal losses
3) Improving airtightness, notably through insulated partition walls and airtight doors to enable pollutant transfer studies
4) Adoption of an energy-efficient heating system
5) Integration of a natural ventilation system to explore natural and hybrid ventilation scenarios

2.4 Choice of Sensors

The decision on sensors was guided by the need to gather critical data across multiple performance aspects in the different spaces of the building. The covered metrics are related to the occupant's

thermal comfort perception, indoor air quality, and other operation strategies. Furthermore, accurate boundary condition data were needed for a thorough calibration of building numerical models. Finally, outdoor sensors, comprising the ones measuring meteorological and air quality parameters, were selected to identify the external environmental impact.

2.5 Choice of Strategies

In the absence of occupants, in-situ modelling of occupancy behavior is significant for realistic operation scenarios. This includes opening control, presence patterns, and interactions with building systems such as heating and mechanical ventilation. To replicate real-world scenarios, control strategies were implemented to mimic how occupants typically operate these systems. Moreover, simulated presence needed to account for internal emissions generated by typical occupant activities. Therefore, the integration of emission sources within the building systems was critical to accurately reflect occupant influence on indoor conditions.

3. RESULTS

3.1 Villa SOBRE Envelope after Retrofit

During retrofit, the interior layout was reconfigured, reducing the number of zones from eight to six for space optimization. The new layout features three identical rooms, facing northeast (10.71 m², 25.91 m³ each), a fourth room facing southwest (13.5 m², 32.63 m³), a monitoring room, and a 7.3-meter ventilated façade along the corridor. Structured insulated panels (SIPs) were installed on all indoor walls, floors, and ceilings. SIPs used are a polyurethane core panel sandwiched between two metallic layers. They have been mainly chosen for their high thermal and acoustic insulation, moisture resistance, and specifically for their ease of assembly.(Demharter, 1998;Sadineni et al., 2011;Somarathna et al., 2018).Fig.3 presents Villa SOBRE' 3D view after retrofits and the SIPs application. While the external façades remained unchanged to preserve the original structure, the window area was reduced by approximately 62% through the installation of NF220-certified double-glazed windows, ensuring high standards of thermal and acoustic insulation, air and water tightness, and wind resistance(CSTB 2021). Tables 1 and 2, respectively, list the thermophysical properties of the new walls and the characteristics of the new windows.

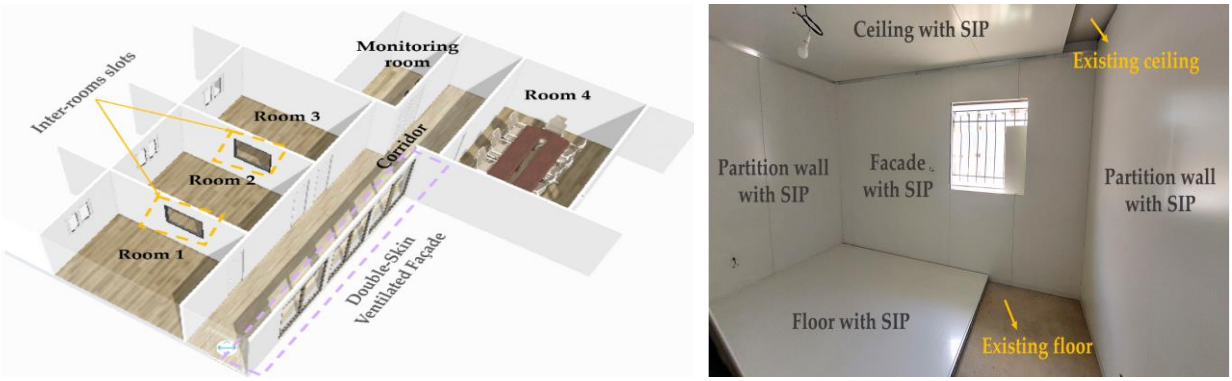

Figure 3. After retrofit 3D design' view (**left**) and the SIPs application on existing walls (**right**)

Table 1. Exterior and partition walls material configuration

	Configuration	Thickness [m]	Thermal conductivity $[W.m^{-1}.K^{-1}]$	Specific heat $[J.kg^{-1}.K^{-1}]$	Density $[kg.m^{-3}]$
Exterior walls	Render (outdoor)	0.01	1	750	800
	Machefer Concrete	0.2	~0.12	~850	~850
	Red brick	0.1	0.83	800	1500

	Plaster (Indoor)	0.01	0.35	1000	1500
	Air gap	0.15	0.02	1005	1.204
	Polyurethane panel	0.08	0.02	800	100
Partition walls	Plaster (Indoor)	0.01	1	750	800
	Machefer Concrete	0.2	~0.12	~850	~850
	Plaster (Indoor)	0.01	0.35	1000	1500
	Polyurethane panel	0.08	0.02	800	100
	Plaster (Indoor)	0.01	1	750	800

Table 2. New windows characteristics

Element	Dimension	Characteristics	Solar transmittance (at 90°) g-value	U value $[\mathbf{W.m^{-2}K^{-1}}]$	Filling gas
Double glazing	1.05 m × 0.98 m; Wsurface= 1.029 m²	4mm-16mm-4mm	0.79	1.2	Argon

For enhanced insulation and airtightness, room doors were replaced with SIP-based cold chamber doors featuring PVC frames and sealing gaskets. Airtightness measures included triple sealing, using polyurethane foam, metallic joint mastic, and gasketed corners to limit air leakage, thermal bridging, noise, and moisture transfer. Additionally, airtight electrical junction boxes were also installed to prevent leakage through the joints.

3.2 Implemented Systems and Strategies

Glazing control is managed by motorized systems: electric chain motors operate the room windows, while a rack-and-pinion motor adjusts the glazed area of the double-skin ventilated facade. Each room is heated by a 2000 W convector regulated through a closed-loop automation system, allowing dynamic power modulation from 0% to 100% to maintain thermal comfort. Fig.4 presents the implemented systems and strategies.

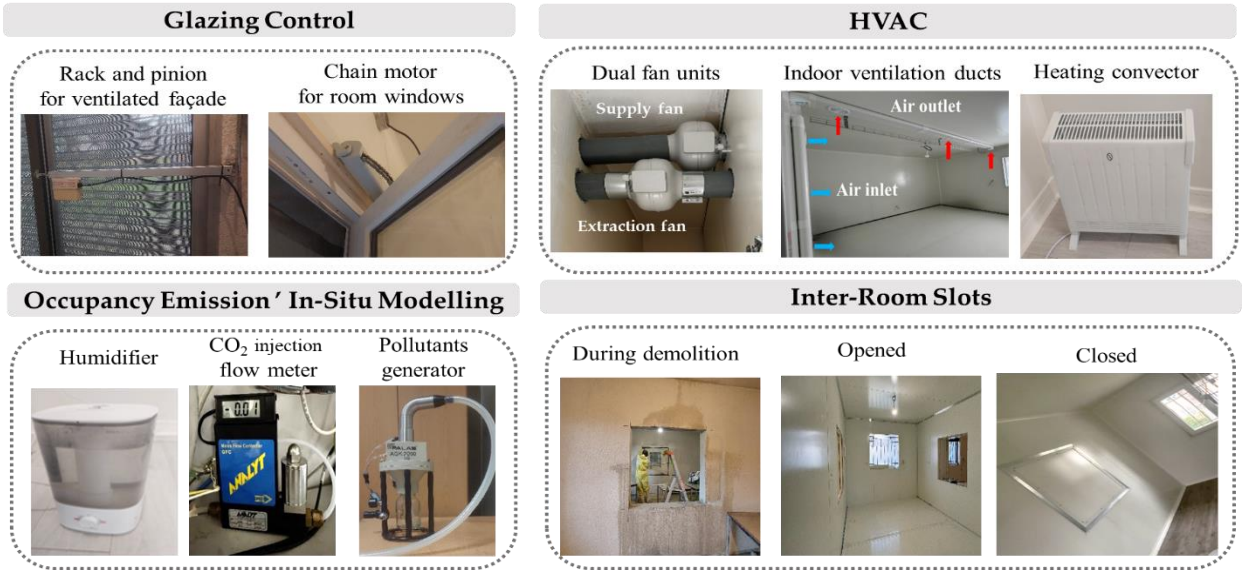

Figure 4. Implemented systems and strategies in Villa SOBRE

Mechanical ventilation relies on two Aldes VC MICRO WATT D125 fans per room (144 m³/h each), one supplying fresh air vertically and the other extracting stale air through top ducts, enabling single or double mechanical ventilation modes. Real occupancy is modeled in-situ, using humidifiers, CO_2 pumps, and flow meters for each room, humidifiers for humidity injection, and an AGK-2000 aerosol generator (5 nm–15 µm) to generate typical airborne pollutants of real

occupant activity, such as VOCs and PMs. Partition walls are modified to include configurable 1m×1m slots designed for experiments on thermal exchange, pollutant transport, and air filtration systems. For natural ventilation integration and investigation of hybrid ventilation strategies, a 7.3m × 2.3m double-skin ventilated facade was implemented in the corridor using SIPs as a second skin with adjusted top and bottom grilles. The double skin ventilated facade is presented in Fig.5.

Figure 5. Double skin ventilated facade (ongoing work)

3.3 Installed Sensors and Data Acquisition

Villa SOBRE has been finely instrumented with over 100 sensors, enabling comprehensive, real-time monitoring for multicriteria assessment of building performance. The monitoring system is categorized into four primary aspects: thermal performance, airflow and ventilation, indoor air quality, and energy use. The sensor's spatial arrangement within rooms is shown on Fig.6. and their specifications are detailed in Table 3.

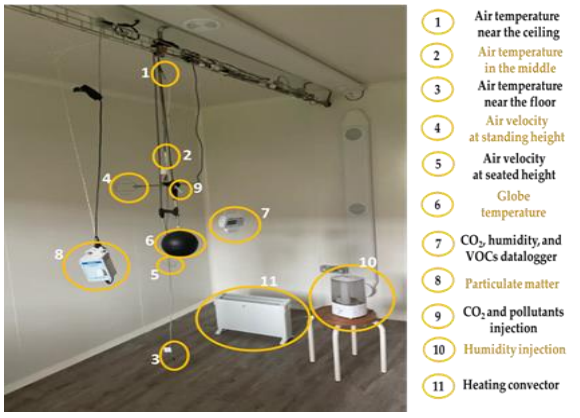

Figure 6. Implemented sensors and systems in rooms

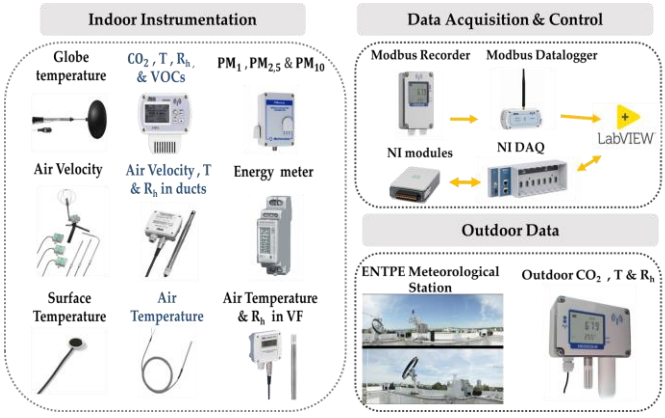

Figure 7. Installed indoor & outdoor sensors, and the data acquisition principle

For thermal monitoring, 33 surface temperature sensors are installed behind SIPs to characterize envelope boundary conditions, along with 4 heat flux sensors to evaluate thermal transmission. Airflow and ventilation are assessed through 14 wind velocity sensors positioned at seated and standing heights within rooms and behind the ventilated facade, 8 duct transmitters measuring air speed, humidity, and temperature to manage ventilation units, and 6 temperature and humidity transmitters for airflow monitoring in the ventilated facade. IAQ monitoring includes 5 particulate matter sensors measuring PM_1, $PM_{2.5}$, and PM_{10}, and 7 wireless data loggers that record humidity, CO_2, and VOC concentrations across the four rooms and central corridor. An outdoor sensor placed at building height measures ambient CO_2, humidity, and temperature, while meteorological

data such as wind speed and direction, and solar irradiation are recorded via the ENTPE weather station. Data acquisition is wireless via MODBUS recorders for giving the possibility of displacing the indoor sensors, except for fixed surface temperature sensors, which are wired through DAQ modules. A custom LabVIEW-based program with a user-friendly interface enables sensor communication, real-time data acquisition, and implementation of control strategies, such as heating setpoint adjustment, glazing opening percentage, and mechanical and occupancy emissions quantification.

Table 3. Characteristics of sensors installed in Villa SOBRE

Sensor type	Parameter	Measurement range	Accuracy
Probe RTD PT100 (SFCAR4F-P12)	Air temperature	-40 to +105 °C	±0.35°C at 100°C

6. CONCLUSION & FUTURE WORK

Villa SOBRE (Optimization Systems for Energy Renovated Buildings) is a full-scale facility

devoted to studying buildings' real performance during operation, evaluating advanced integrated systems, analyzing occupant-centric conditions, and developing new approaches for in-situ multicriteria assessment. Its originality lies mainly in the frugal approach adopted for design solutions and flexible design. Moreover, its multizone configuration and structure that showcase the real performance and climatic context of European and French existing building stock. The facility is also designed to remain adaptable for future upgrades and the integration of emerging technologies.

The next phase of work at Villa SOBRE will involve a diagnostic campaign to verify the intended performance outcomes of implemented retrofit measures. This includes infrared thermography, airtightness testing of Villa SOBRE spaces according to ISO 9972, and airtightness evaluation of ventilation ducts following applicable standards. In addition, newly developed HVAC systems from industry partners will be integrated for performance testing and comparative studies. Future developments also anticipate the incorporation of renewable energy systems for approaching Nearly Zero Energy Buildings for energy flexibility research.

ABSTRACT

The building sector accounts for approximately 30-40% of global energy consumption and nearly 40% of Greenhouse Gas (GHG) emissions, making building retrofits essential for achieving significant reductions in energy use and emissions. However, developing effective retrofit strategies requires careful consideration of several critical factors: the economic viability of each retrofit option, local climate, policies, incentives, energy prices, electricity grid emissions intensity, the embodied carbon emissions of materials and processes, and the operational carbon emissions resulting from each retrofit strategy. This study employs a micro-genetic optimization algorithm coupled with the Vertical City Weather Generator (VCWGv1.6.0) urban physics model to identify optimal retrofit strategies for residential buildings in Toronto. The goal is to help homeowners minimize cost, and the associated embodied/operational carbon emissions. The proposed approach offers a framework for sustainable building retrofits that balances energy efficiency, economic viability, and carbon emission reductions simultaneously in the context of evolving policy landscapes.

Keywords: Building Retrofit, Decarbonization, Economics, Micro-Genetic Alborithm (MGA), Optimization.

1. INTRODUCTION

As the global community faces the urgent challenge of mitigating climate change, the building sector has emerged as a critical area for intervention. Buildings are responsible for a significant portion of global Greenhouse Gas (GHG) emissions, both through their operational energy use and the embodied carbon in construction materials. Retrofitting existing building systems presents a unique opportunity to reduce emissions and improve energy efficiency, often at a lower cost and with fewer disruptions compared to new construction. Effective retrofits can address aging infrastructure while incorporating modern, low-carbon technologies that significantly enhance sustainability (Aliabadi et al., 2021; Moradi, 2021; Moradi et al., 2021, 2022; Safdari et al., 2024).

In addition to environmental benefits, cost considerations play a vital role in the adoption of retrofit strategies. The economic viability of retrofit measures is often evaluated through Marginal Cost Analysis (MCA), which compares the cost-effectiveness of various strategies for reducing emissions. Cost-effective retrofitting not only reduces operational and embodied carbon but also en-

hances property values and reduces energy bills, providing a win-win situation for homeowners. Understanding and optimizing these costs is essential to ensure widespread adoption of retrofit solutions (Madadizadeh et al., 2024). Furthermore, a critical aspect of building decarbonization is evaluation of Social Cost of Carbon (SCC) savings achieved through building retrofits. The SCC represents the economic cost of the damages caused by one additional tonne of carbon emissions. By reducing emissions, retrofits contribute to significant SCC savings, which translate into societal benefits.

When considering retrofitting, there are several key aspects to address. The first is carbon emissions savings and the associated environmental benefits, and the second is the cost factor. An effective retrofit strategy should achieve the highest possible emissions savings while minimizing costs or even generating financial returns. To identify the optimal strategy, optimization algorithms are a suitable approach. In particular, Micro-Genetic Algorithm (MGA) is an excellent choice due to its ability to quickly identify quasi-global optimal solutions and their computational efficiency (Aliabadi et al., 2023).

This study investigates the potential of retrofit measures to maximize GHG emissions saving and minimize marginal costs in the residential building sector. Through the application of MGA, we explore optimized retrofit strategies for a typical detached two-storey residential house in Toronto (2020) that balance environmental and economic benefits.

2. METHODOLOGY

2.1. Vertical City Weather Generator (VCWGv1.6.0)

The Vertical City Weather Generator (VCWGv1.6.0) as an urban physics model is used to simulate the performance of residential buildings in Toronto under different retrofit strategies (Fig. 1). VCWGv1.6.0 integrates local weather data, building design parameters, and energy consumption patterns to generate realistic, and high-resolution simulations of building energy use and carbon emissions. The model uses localized climate data for Toronto, accounting for variations in temperature, humidity, wind patterns, and solar radiation over the course of the year 2020. Also, the VCWG model simulates the energy consumption of the building with and without retrofit strategies, considering factors such as thermal insulation, heating and cooling efficiency, and energy consumption patterns. The model calculates both operational carbon (based on energy consumption) and embodied carbon (based on materials used in retrofits) emissions. The total carbon footprint is tracked for each retrofit solution.

2.2. Micro-Genetic Algorithm (MGA)

The Micro-Genetic Algorithm (MGA) is employed to search for optimal retrofit solutions. MGA is a computationally efficient version of traditional genetic algorithms, designed to solve problems involving multiple conflicting objectives. The algorithm operates by evolving a population of potential solutions (5) (representing different retrofit strategies) over a series of generations (5), selecting the best individuals based on the lowest fitness according to the defined objective functions.

The primary goal of this study is to identify retrofit strategies that maximize operational carbon saving ($\mathrm{GHG}_{o,s}$) over $N = 20$ years, embodied carbon emission (GHG_{e}) over $N = 20$ years, and

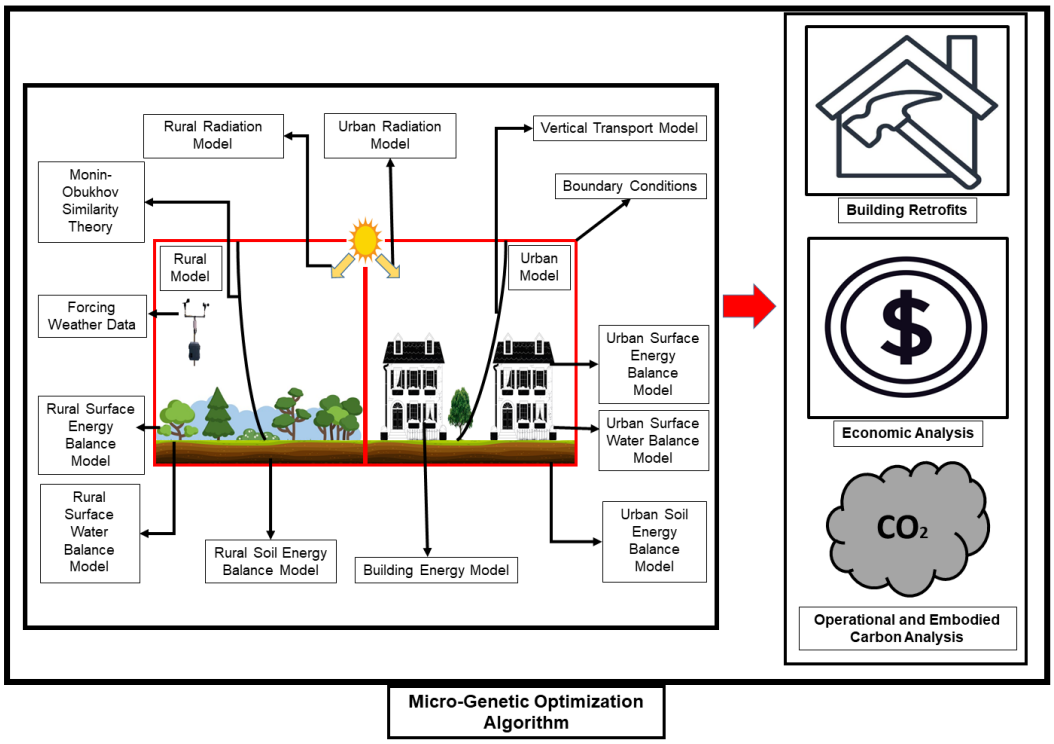

Figure 1. Vertical City Weather Generator (VCWGv1.4.6) and the associated sub-models.

the annualized marginal cost saving (C_s) of each retrofit strategy (Eq. 1). These objectives are considered simultaneously in the optimization process using weighted sum, which is to be minimized:

$$F = -w_{o,s}\frac{\mathrm{GHG}_{o,s}}{\mathrm{GHG}_{0o,s}} + w_e\frac{\mathrm{GHG}_e}{\mathrm{GHG}_{0e}} - w_{C_s}\frac{C_s}{C_{0s}} \tag{1}$$

Since all three objectives are equally important for our analysis, we assign the same weights to each, such that $w_{o,s} = w_e = w_{C,s} = \frac{1}{3}$. $\mathrm{GHG}_{o,s}$ [kg-CO_2], GHG_e [kg-CO_2], and C_{0s} [\$] represent the operational carbon savings, embodied carbon emissions, and marginal annualized cost savings, respectively. These values are derived from the solution of the first iteration of the optimization process. The optimization itself is conducted over a set of retrofit parameters with predefined discrete ranges and intervals, as listed in Table 1.

2.3. Economic analysis

The equations in this section are adapted from Aliabadi et al. (2023). For calculating the annualized cost of residential building retrofits, the following equation is used,

$$C = C_I + C_F + C_E + C_{OM} + L - C_S, \tag{2}$$

Table 1. Optimization variables with minimum value, maximum value, and variation interval: Building Integrated Thermal Energy Storage (BITES), Solar Thermal (ST), Wind Turbine (WT), PhotoVoltaic (PV)

Variables	Minimum	Maximum	Interval
Volume of BITES (V_{bites}) [m^3m^{-2}]	0.01	0.20	0.01
Roof Albedo (α_R)	0.1	0.7	0.05
Working Fluid Flow Rate for ST ($\dot{m}_{\text{st,f}}$) [$\text{kg s}^{-1}\text{m}^{-2}$]	0.0001	0.002	0.0001
Collector Area for ST (A_{st}) [m^2m^{-2}]	0.2	0.6	0.05
Roof Thermal Resistance (R_{roof}) [$\text{m}^2\text{K W}^{-1}$]	5.46	11.5	0.5
Infiltration Rate (V_{inf}) [ACH]	0.5	3.5	0.5
Wall Thermal Resistance (R_{wall}) [$\text{m}^2\text{K W}^{-1}$]	3.6	7	0.5
Ventilation Rate (V_{vent}) [$\text{L s}^{-1}\text{m}^{-2}$]	0.3	0.4	0.05
Glazing Ratio (GR)	0.1	0.4	0.05
Air Flow Rate for ST ($\dot{m}_{\text{he,st}}$) [$\text{kg s}^{-1}\text{m}^{-2}$]	0.001	0.02	0.001
Swept Area of WT (A_{wt}) [m^2m^{-2}]	0.05	0.2	0.05
Solar Heat Gain Coefficient (SHGC)	0.1	0.7	0.1
Collector Area for PV (A_{pv}) [m^2m^{-2}]	0.1	0.6	0.1

where C_I is the annualized initial investment, C_F is the annual fossil fuel cost, C_E is the annualized grid electricity consumption cost, C_{OM} is the annualized operation and maintenance cost, L is the annualized loan cost, C_S is the annualized income from alternative energy system salvage all in [$]. The annualized cost saving is given by:

$$C_s = C_{\text{Base}} - C_{\text{Retrofit}} + SCC_{saving}, \tag{3}$$

where C_{Base} [$] is annualized marginal cost for the base case without any retrofit, $\text{C}_{\text{Retrofit}}$ [$] is annualized marginal cost for each retrofit strategy, and SCC_{saving} is annualized social cost of carbon saving.

2.4. Environmental analysis

The environmental analysis involves the calculation of potential operational GHG emissions savings ($\text{GHG}_{o,s}$) and embodied carbon emission GHG_e through various building retrofit strategies. The embodied carbon emission is the summation of carbon emission of each retrofit strategy as shown in Eq 4:

$$\begin{aligned}\text{GHG}_e = {} & A_{\text{pv}}\text{ECF}_{\text{pv}} + A_{\text{wt}}\text{ECF}_{\text{st}} + V_{\text{BITES}}\text{ECF}_{\text{BITES}} \\ & + A_{\text{st}}\text{ECF}_{\text{st}} + R_{\text{wall}}A_{\text{wall}}\text{ECF}_{\text{Insulation}} \\ & + R_{\text{roof}}A_{\text{roof}}\text{ECF}_{\text{Insulation}} + \alpha_R\text{ECF}_{\text{CoolRoof}}\end{aligned} \tag{4}$$

where embodied carbon factor (ECF) for PV systems (ECF_{pv}) is 50 kg $\text{CO}_2\text{e}\,\text{m}^{-2}$), for wind turbines ($\text{ECF}_{\text{wt}}$) is 100 kg $\text{CO}_2\text{e}\,\text{m}^{-2}$), for the BITES system ($\text{ECF}_{\text{BITES}}$) is 30 kg $\text{CO}_2\text{e}\,\text{m}^{-3}$), and for solar thermal systems (ECF_{st}) is 40 kg $\text{CO}_2\text{e}\,\text{m}^{-2}$). Additionally, the embodied carbon factor for insulation materials ($\text{ECF}_{\text{Insulation}}$) is 10 kg $\text{CO}_2\text{e}\,\text{m}^{-2}$) and for the cool roof ($\text{ECF}_{\text{CoolRoof}}$) is 5 kg $\text{CO}_2\text{e}\,\text{m}^{-2}$).

The operational GHG emissions saving is the summation of GHG saving through a reduction of electricity and fossil fuel consumption. The fuel usage reduction is computed as

$$G_{\text{save}} = [G_{hB} + G_{whB} - (G_h + G_{wh})]A_{bld}N, \tag{5}$$

where G_{hB}, G_{whB}, G_h and G_{wh} [m^3 m^{-2}] are the natural gas usage for the base and retrofitted buildings for space and water heating, respectively. Then, the operational GHG emissions reduction potential in CO_2e associated with gas saving is estimated by,

$$GHG_{G_{\text{save}}} = G_{\text{save}} \rho_G \frac{MW_{\text{CO2}}}{MW_G}, \tag{6}$$

where $\rho_G = 0.669\ \text{kg}_G\ \text{m}^{-3}$ is the density of natural gas, $MW_{\text{CO}_2} = 44\ \text{g}_{\text{CO}_2}\ \text{mole}^{-1}$ is the molecular weight of CO_2, and $MW_G = 16\ \text{g}_G\ \text{mole}^{-1}$ is the molecular weights of natural gas. The electricity usage reduction is computed by,

$$E_{\text{save}} = [E_{cB} + E_{dB} - (E_c + E_h + E_d - E_{pv} - E_{wt})] A_{bld} N, \tag{7}$$

where E_{cB}, E_{dB}, E_c, E_h, and E_d [kW-hr m^{-2}] are the electricity usage for space cooling/heating and domestic appliance in base/retrofitted buildings, and E_{pv} and E_{wt} [kW-hr m^{-2}] are electricity generated by PV and WT, respectively, in the retrofitted building. Then, the GHG emissions reduction potential in CO_2e associated with electricity saving is found as,

$$GHG_{E_{\text{save}}} = E_{\text{save}} EI_E, \tag{8}$$

where $EI_E = 25\ \text{kg}_{\text{CO}_2}\ \text{kW-hr}^{-1}$ is the electricity grid GHG emissions intensity in Toronto in 2020.

3. RESULTS AND DISCUSSION

Fig. 2 illustrates the normalized overall objective function for three runs ((F-min)/(max-min)). It demonstrates that, for all runs, the objective function consistently decreases with each iteration. After more than 30 iterations, the function reaches a stable minimum value, indicating that the optimization process has made progress. This behavior highlights the efficiency of the MGA optimization algorithm in reaching an quasi-optimal solution.

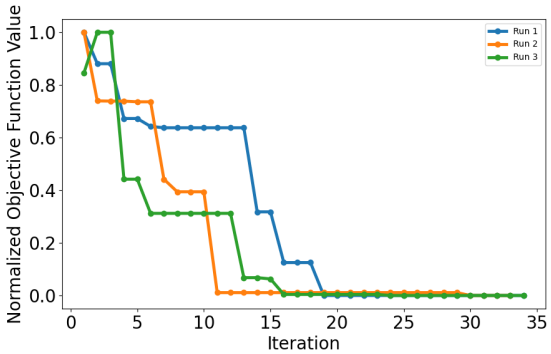

Figure 2. Normalized Best Overall Objective Function.

Table 2 shows best solution values of selected variables for optimization. The comparison between the initial setup of optimization variables (Table 1) and the optimized solutions (Table 2) reveals several key insights into effective retrofit strategies for Toronto. Some variables were maximized. The maximization of photovoltaic collector area (A_{pv}) suggests that integrating solar panels is a highly beneficial strategy for reducing operational carbon emissions, supporting the transition towards sustainable energy. Some variables were minimized, such as ventilation rate (V_{vent}), swept area of wind turbine A_{wt}. Other variables found an optimized value in the middle of their ranges (e.g. solar thermal collector area A_{st}, roof albedo (α_R), the infiltration rate (V_{inf}), Solar Heat Gain Coefficient (SHGC), Glazing Ratio (GR), and volume of BITES). Note that some optimization runs produced values in the entire range for some varaibles (e.g. infiltration rate).

Table 2. Optimized variables for each run

Variable	Run 1	Run 2	Run 3
V_{bites} [$\mathrm{m^3 m^{-2}}$]	5.00e-02	6.00e-02	5.00e-02
α_R	5.00e-01	5.50e-01	4.50e-01
$\dot{m}_{\mathrm{st,f}}$ [$\mathrm{kg\ s^{-1} m^{-2}}$]	5.00e-04	4.00e-04	6.00e-04
A_{st} [$\mathrm{m^2 m^{-2}}$]	2.00e-01	5.00e-01	4.00e-01
R_{roof} [$\mathrm{m^2 K\ W^{-1}}$]	1.146e+01	1.096e+01	6.96e+00
V_{inf} [ACH]	1.50e+00	5.00e-01	3.00e+00
R_{wall} [$\mathrm{m^2 K\ W^{-1}}$]	5.10e+00	5.10e+00	4.60e+00
V_{vent} [$\mathrm{L\ s^{-1} m^{-2}}$]	3.00e-01	3.50e-01	3.00e-01

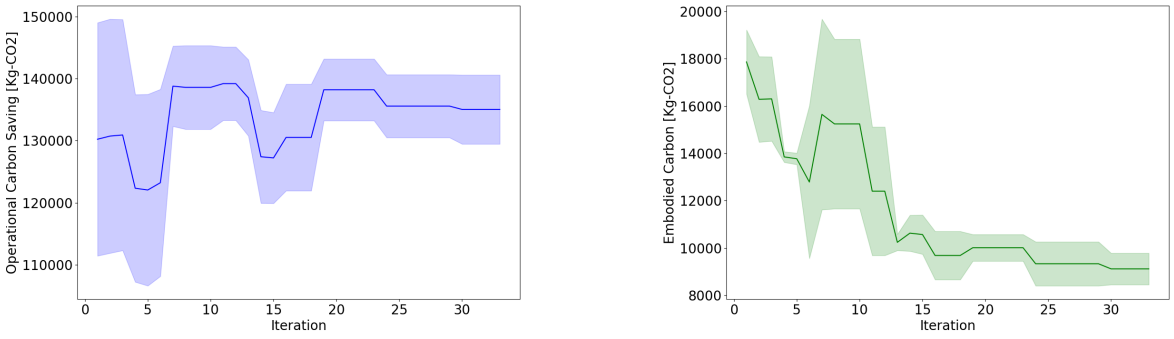
$\dot{m}_{\mathrm{he,st}}$ [$\mathrm{kg\ s^{-1} m^{-2}}$]	8.00e-03	2.00e-03	1.10e-02
A_{wt} [$\mathrm{m^2 m^{-2}}$]	5.00e-02	5.00e-02	5.00e-02
SHGC	2.00e-01	2.00e-01	1.00e-01
A_{pv} [$\mathrm{m^2 m^{-2}}$]	6.00e-01	6.00e-01	6.00e-01

Fig. 3a demonstrates the process of optimizing operational carbon emissions savings through retrofitting strategies, showcasing the potential benefits for homeowners. Initially, the carbon emissions savings are inconsistent, fluctuating between approximately 120,000 and 130,000 kg-CO_2, indicating instability in the sub-objective function. However, as the optimization progresses, the savings increase and stabilize around 135,000 to 140,000 Kg-CO-2 on average, with reduced variability, reflecting greater reliability and consistency in the solution. For homeowners, this translates into significant carbon emissions reductions, potentially saving an additional 10,000 to 20,000 Kg-CO_2 compared to the sub-optimal initial solution.

Fig. 3b illustrates the embodied carbon emissions associated with retrofit strategies over an optimization process. At the beginning, embodied carbon emission levels are notably high, approximately 18,000 Kg-CO_2. As the optimization progresses, significant reductions are noted, with embodied carbon emissions stabilizing around 9,000 to 10,000 Kg-CO_2. For homeowners, achieving this reduction means cutting embodied carbon emissions by nearly 50% compared to the initial solution.

Fig. 4 shows the marginal annual cost savings achieved through optimized retrofit strategies. For the initial solution, homeowners are subject to significant negative savings (or positive expenses), with losses exceeding $2,500 annually. However, as the optimization process progresses, the annual cost savings improve significantly, eventually stabilizing at approximately $500 per year. This indicates that implementing the optimal retrofit strategies can result in substantial financial benefits, allowing homeowners to save up to $500 annually on operational costs, while enhancing



(a) Operational Carbon Saving

(b) Embodied Carbon

Figure 3. Comparison of Operational and Embodied Carbon Savings.

energy efficiency and reducing carbon emissions.

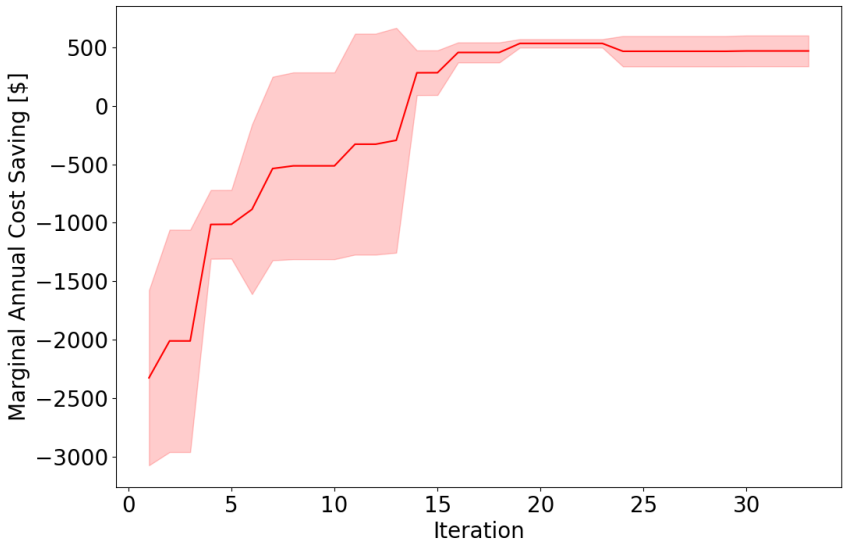


Figure 4. Marginal Annualized Cost Saving.

In addition to optimizing environmental and economic performance, this study also evaluates the savings associated with the SCC for each retrofit strategy. The SCC represents the societal cost of carbon emissions, encompassing the damages caused by climate change, such as extreme weather events, health impacts, and ecosystem destruction. By reducing carbon emissions through retrofits, this study calculates the annualized SCC savings, offering a valuable measure of the broader societal benefits. The reduction in carbon emissions for each retrofit strategy is calculated by comparing the operational and embodied carbon before and after the retrofit. The SCC is derived from existing studies and models that estimate the economic cost per tonne of GHG emissions avoided. Results show that the annualized SCC savings, calculated over 30 iterations, fluctuate between

$1,100 and $1,350. This amount of savings is of great importance as it highlights the potential for reducing the economic impact of emissions on society. The SCC savings underscore the long-term financial and environmental benefits of pursuing greener homes. By finding the optimal retrofit strategy, not only can we reduce emissions and mitigate climate change, but we can also see a financial return on these investments. Such strategies contribute to a more sustainable, resilient society, making the case for sustainable building practices both economically and environmentally beneficial.

4. CONCLUSIONS

The findings highlight the potential of MGA optimization for achieving comprehensive and sustainable building retrofit solutions. By balancing trade-offs between operational carbon emissions savings, embodied carbon emissions caused by retrofitting, and annualized cost savings, the proposed approach demonstrates a practical pathway for reducing upfront environmental impacts while ensuring long-term carbon benefits. Using the VCWG v1.6.0 urban physics model combined with economic analysis tools, the study optimizes retrofit strategies to maximize environmental and financial gains. Results show that retrofitting residential buildings in Toronto can lead to significant carbon emission reductions, up to 140 tonnes over 20 years, while generating annual cost savings of approximately $500. This outcome underscores the dual benefits of reducing carbon emissions and achieving financial savings, replacing high energy expenditures on electricity and gas consumption with sustainable and cost-effective solutions.

ABSTRACT

Frequent heatwaves pose significant threats to human health, making the accurate assessment of overheating risks on physiological health and safety in high-temperature environments crucial. Based on previous thermos-physiological experimental data, this study compares the predictive performance of the Two-Node model, JOS-3 model, and Predicted Heat Strain (PHS) model for core temperature, and water loss under various high-temperature conditions. The results show that the JOS-3 model performs best in predicting core temperature, with a root mean square error (RMSE) of 0.17°C. For water loss, the PHS model demonstrates higher accuracy under high metabolic rates but shows significantly increased RMSE in high-radiation and hot-humid environments, where the Two-Node model outperforms it. Overall, the JOS-3 model excels under sedentary and low-to-moderate metabolic conditions, making it suitable for assessing overheating risks in residential and office settings. The PHS model is more applicable for high-metabolic-rate scenarios, such as factory workshops and indoor sports venues. A combined application of the JOS-3 and PHS models can more accurately evaluate overheating risks in outdoor and high-radiation environments. This study provides a basis for selecting appropriate thermal response models to assess overheating health risks in high-temperature environments, contributing to the safety of buildings and urban thermal conditions.

1 INTRODUCTION

In recent years, the frequency and intensity of heatwaves have far exceeded baseline levels of the last century, evolving into a global climate disaster(UN, 2024). Prolonged heat exposure and improper thermoregulation can damage multiple organ systems and disrupt metabolic functions, leading to conditions such as heat-related illnesses (heat cramps, heat exhaustion, heat stroke), dehydration, fluid and electrolyte imbalances, sleep deprivation, cardiovascular diseases, kidney disorders, respiratory disease exacerbation, and even death(Obradovich et al., 2017; Sheridan & Allen, 2018; Winquist et al., 2016). Rapid urbanization has exacerbated the urban heat

island (UHI) effect in China(Yang et al., 2024). The combined impact of heatwaves and UHI has significantly intensified urban overheating issues, severely affecting residents' health, mobility, and safety. This is particularly critical in high-density cities, where heat risks are more pronounced(Ho et al., 2023).

Human tolerance to high temperatures has physiological limits. When a subsystem signals danger, the body enters a state of heat stress. These thermal safety signals primarily include two aspects: body temperature and sweat rate(Weng et al., 2017). In high-temperature environments, the body regulates heat through sweating to maintain metabolic function. However, excessive sweating without adequate fluid replenishment can lead to dehydration. When dehydration exceeds a certain percentage of body weight, various adverse conditions may arise. Additionally, when skin moisture approaches saturation, the body cannot dissipate excess heat through sweating, leading to an increase in core temperature and subsequent heat stress. According to ISO 7933-2023(Ergonomics of the Thermal Environment — Analytical Determination and Interpretation of Heat Stress Using Calculation of the Predicted Heat Strain, 2023), the thermal safety thresholds are defined as a dehydration rate of 3% and a core body temperature of 38°C.

Thermophysiological experiments and mathematical modeling are the two most common methods for studying human thermal responses, each with its advantages and limitations. Experiments provide extensive physiological data but face challenges such as large sample requirements, significant individual variability, risks associated with high-temperature environments, and poor reproducibility. On the other hand, mathematical modeling offers advantages in result reproducibility and flexibility, such as dividing the human body into layers or segments. However, most existing models are developed for moderate-temperature environments, and their applicability to high-temperature conditions remains to be further investigated. This is particularly important for assessing the health risks posed by overheating(Chen et al., 2024).

This study reviews three of the most widely used human thermal response models: the two-node model(Gagge A P et al., 1971), the JOS-3 model(Takahashi et al., 2021), and the Predicted Heat Strain (PHS) model(Ergonomics of the Thermal Environment — Analytical Determination and Interpretation of Heat Stress Using Calculation of the Predicted Heat Strain, 2023). Using data from thermophysiological experiments, the predictive performance of these models was compared under various high-temperature conditions. The applicability of each model was analyzed within specific scenarios, providing recommendations and a scientific basis for selecting an appropriate human thermal response model to accurately assess overheating risks in high-temperature environments.

2 METHODOLOGY

2.1 HUMAN THERMAL REPONSE MODELS

Gagge et al. (Gagge A P et al., 1971)proposed the two-node model, dividing the human body into the skin layer and the core layer. Based on this model, they introduced thermal comfort indices such as Effective Temperature (ET) and Standard Effective Temperature (SET). Due to its simplicity and practicality, Gagge's two-node model is still widely applied in the field of thermal comfort. Numerous researchers have refined components of the two-node model, including skin blood flow, shivering, sweating, and sweat evaporation efficiency(Ji et al., 2021). The development of the Stollwijk multi-node model(Stolwijk J, 1971) marked a significant advancement in the framework of human thermoregulation models, paving the way for more sophisticated multi-node, multi-segment, and non-uniform transient models. Building on Stollwijk's concept, Tanabe(Takahashi et al., 2021) developed the JOS-3 model, which divides the human body into 17 segments and 85 nodes. This model can predict localized core temperature,

skin temperature, and sweating rates while also accounting for the influence of age and gender on thermoregulation.

However, both the two-node and JOS-3 models are primarily applied in thermal comfort research. Their accuracy in assessing overheating risks under extreme heat conditions remains to be verified. To evaluate the risks of heat stress during prolonged work in high-temperature environments, the ISO 7933 standard(Ergonomics of the Thermal Environment — Analytical Determination and Interpretation of Heat Stress Using Calculation of the Predicted Heat Strain, 2023) introduced the PHS model. This model simplifies the two-node framework by predicting sweat rates, cumulative water loss, and changes in core and skin temperatures over time using the virtual sweat rate required to maintain thermal equilibrium. While the PHS model effectively quantifies heat strain in high-metabolic-rate occupational settings, its applicability to daily living environments is yet to be determined.

2.2 THERMOPHYSIOLOGICAL EXPERIMENTS

Thermophysiological experiments typically involve multiple participants undergoing tests in a climate chamber with controlled temperature and humidity. These experiments measure human thermophysiological parameters, such as skin and rectal temperatures, metabolic rate, and sweat production. Drawing on previous thermophysiological studies, this paper summarizes experimental conditions relevant to high-temperature environments in urban walking spaces and indoor buildings, as shown in Table 1. Case 1 to 5 were part of thermophysiological experiments conducted by Ooka's team at the University of Tokyo(Ooka et al., 2010), examining changes in thermophysiological parameters of Japanese university students under varying air temperatures, relative humidity levels, and activity states. Measurements included core temperature, skin temperature, and total body water loss (encompassing respiratory water loss and sweat loss). Case 6-8 were studied by André Dufour in France(Dufour & Candas, 2007), investigating thermophysiological responses across different age groups in high-temperature environments. Case 9-12 were experiments conducted by Stapleton in Canada(Stapleton et al., 2014), focusing on young and older adults under dry and humid heat conditions to examine thermophysiological responses.

Table 1 Thermal Physiological Experiments on Humans in High-Temperature Environments

Case	Subject	Met (met)	Clo (clo)	Environmental parameters				Time (min)
				T_a (℃)	MRT (℃)	RH (%)	V_a (m/s)

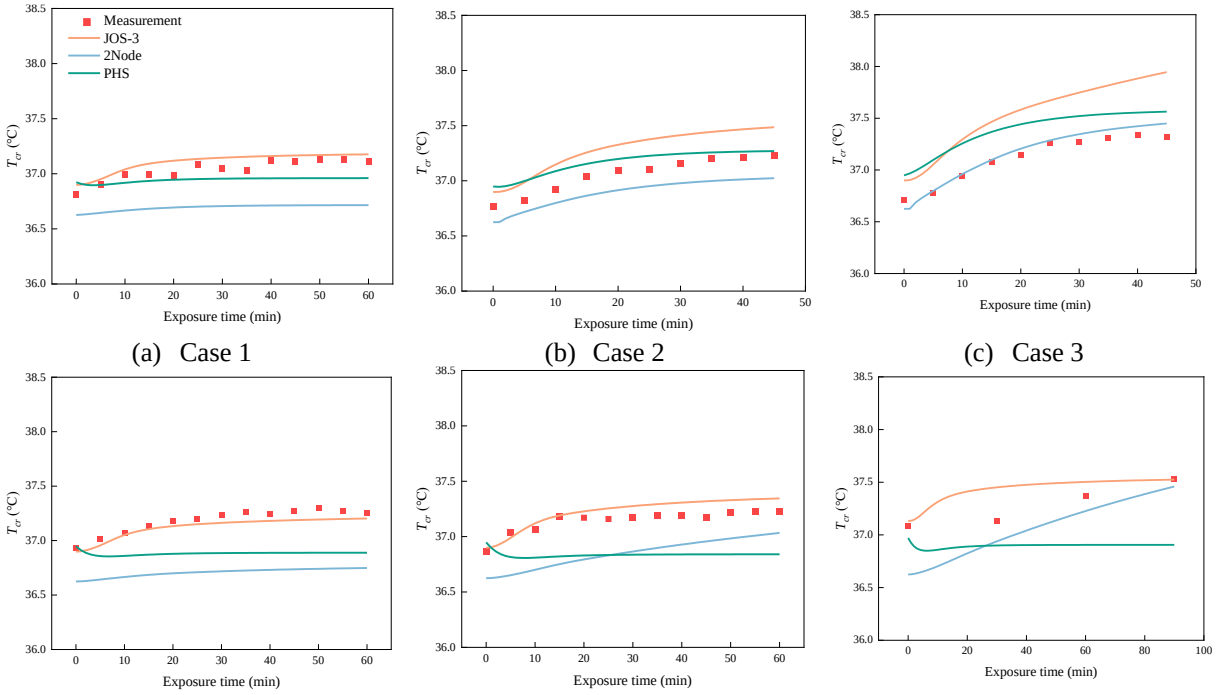
3 RESULT

To compare the accuracy of different models in calculating human thermophysiological parameters under high-temperature conditions, core temperature, and water loss data from

thermophysiological experiments conducted under 12 high-temperature cases were selected for validation. Localized sweat rates were not included, as they are challenging to compute using models and difficult to measure experimentally in isolation. Instead, total body water loss, which can be measured precisely using electronic scales to track body weight changes, was used. This measurement encompasses sweat evaporation and respiratory water vapor loss. Accordingly, only the per-unit-area water loss data from case 1 to 5 were validated, indirectly assessing the models' accuracy in calculating sweat rates. As each condition involved multiple participants, the experimental results shown represent the average physiological parameters of all participants. Similarly, the model calculations were performed using the average physical characteristics of participants as reported in the referenced studies.

3.1 CORE TEMPERATURE

Figure 1 illustrates the comparison between core temperatures predicted by thermoregulatory models and experimental measurements under various high-temperature conditions. Figure 2 presents the root mean square error (RMSE) of core temperature predictions by the JOS-3 model, the two-node model, and the PHS model across different conditions. Based on Figures 1 and 2, except for case 2 and 3, the JOS-3 model demonstrates the highest accuracy among the three thermoregulatory models in predicting core temperature, with RMSE values below 0.5°C for all conditions and an average RMSE below 0.2°C. When participants were engaged in physical activities with higher metabolic rates (case 2 and 3), the JOS-3 model overestimated core temperature compared to experimental results, making it the least accurate model in these scenarios. Additionally, for case 6 through 12, the JOS-3 model exhibited higher prediction accuracy for participants' core temperatures across different age groups compared to the two-node model and the PHS model. This can be attributed to the JOS-3 model's consideration of the effects of aging on metabolic rate. However, its accuracy in predicting core temperature for older adults was generally lower than for younger participants. For the two-node model and the PHS model, the predicted core temperatures were lower than the experimental results in nearly all conditions except for case 2 and 3. The average RMSE for the two-node model was 0.36°C, while that for the PHS model was 0.31°C.



(a) Case 1 (b) Case 2 (c) Case 3

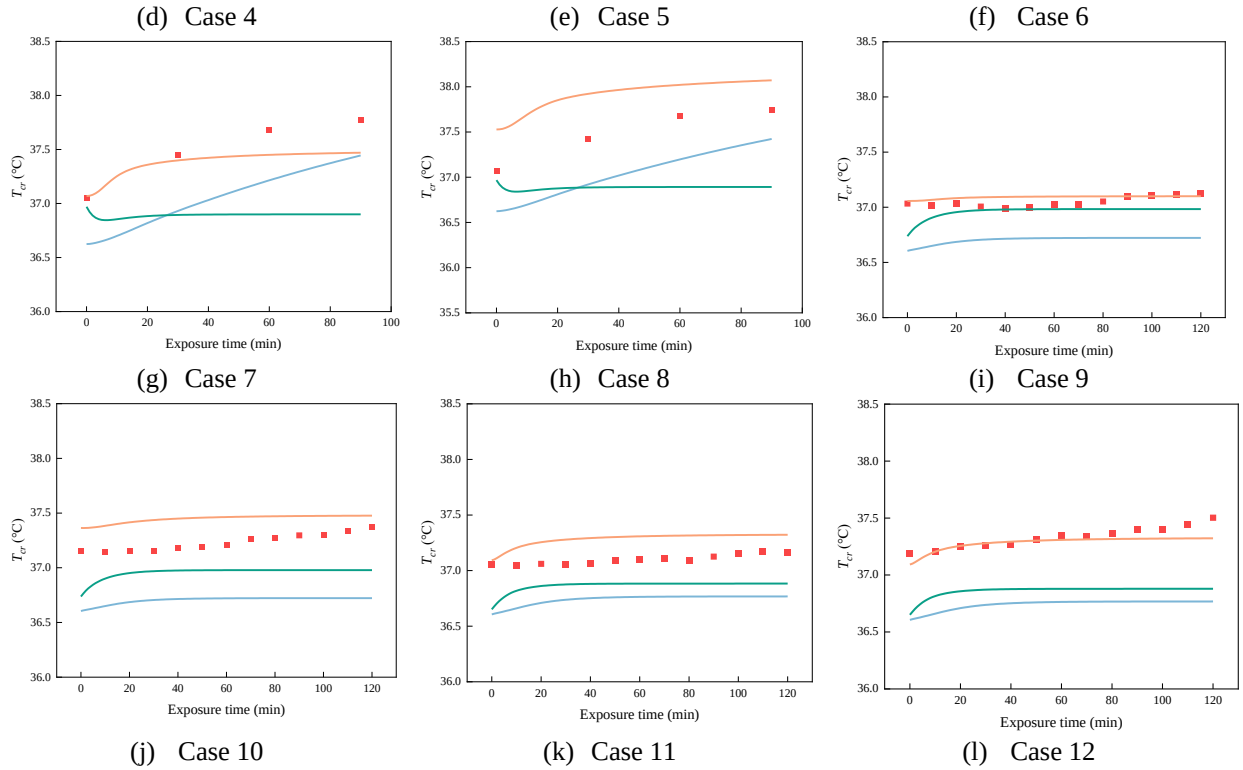


Figure 1. Comparison Between Experimental Results and Model Predictions of Core Temperature

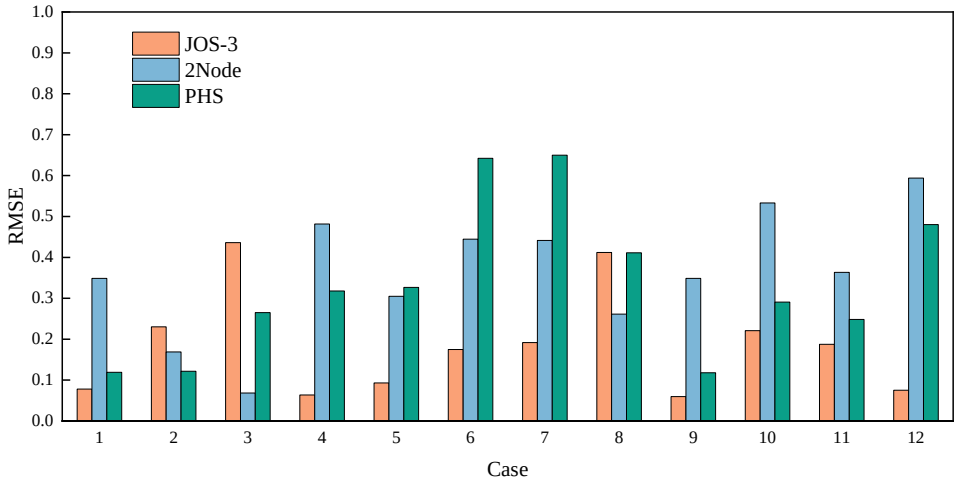

Figure 2. RMSE of Core Temperature Calculations Under High-Temperature Conditions

3.2 WATER LOSS

Figure 3 compares the experimental results of unit area water loss with model calculations, while Figure 4 shows the RMSE statistics of model calculations under different conditions. When the human body is in a sedentary state with a low metabolic rate (corresponding to Conditions 1, 4, and 5), the two-node model demonstrates higher accuracy in calculating water loss, as shown in Figures 3(a), 3(d), and 3(e). When participants are in motion with a higher metabolic rate (corresponding to Conditions 2 and 3), the PHS model provides the most accurate predictions of unit area water loss, while the RMSE for the two-node model and JOS-3 model increases. Particularly, the JOS-3 model significantly underestimates sweat production during physical activity, leading to an overestimation of heat storage in the body. This also explains why the JOS-3 model calculates higher core temperatures compared to measured values, as observed in Figures

1(b)-(c). When T_a and MRT rise to 40°C (case 5), the RMSE of water loss calculations by heat response models increases, especially for the PHS model, which tends to overestimate sweat production in high-temperature, high-radiation environments. This results in underestimating the body's heat storage and core temperature. Comparing Figures 1-4 and contrasting case 1 and 4, as well as case 9, 10 with case 11, 12, it is evident that in humid-heat environments, the accuracy of the PHS model in predicting water loss and core temperature is lower than in dry-heat environments.

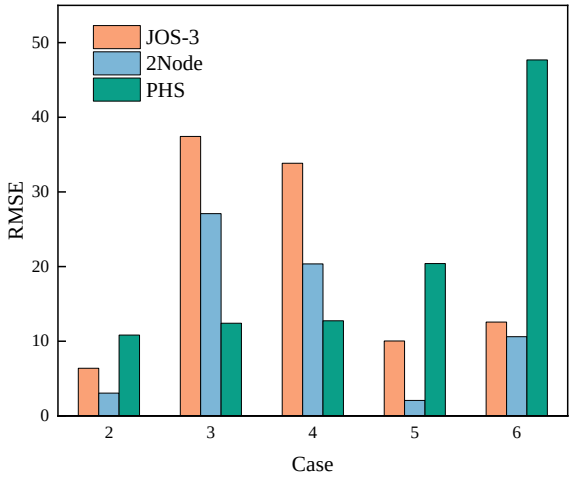

Figure 4. RMSE of Water Loss Calculations Under High-Temperature Conditions

4 DISCUSSION AND CONCLUSION

By comparing experimental results with simulation outputs, the study evaluated the accuracy of the two-node model, JOS-3 model, and PHS model in predicting core temperature and water loss under high-temperature conditions, leading to the following conclusions:

(1) The JOS-3 model achieved an RMSE of 0.17°C, outperforming the PHS model (RMSE: 0.31°C) and the two-node model (RMSE: 0.36°C). Under high-temperature conditions

with elevated metabolic rates, the two-node and PHS models showed higher accuracy in predicting core temperature. In other scenarios, the JOS-3 model demonstrated superior accuracy. Additionally, the JOS-3 model considers the impact of aging on metabolism, resulting in better prediction accuracy for individuals of different age groups.

(2) The PHS model showed high accuracy in estimating water loss under high-temperature conditions with elevated metabolic rates. However, its accuracy significantly declined in high-temperature and high-radiation environments (air temperature and mean radiant temperature reaching 40°C) or hot-humid conditions, where it performed far worse than the two-node model and JOS-3 model.

(3) The JOS-3 model is most accurate under sedentary conditions and low-to-moderate metabolic rates, particularly when accounting for age-related effects. It is suitable for evaluating indoor overheating risks in residential buildings, offices, and nursing homes. The two-node model and PHS model excel in estimating sweat production and core temperature under high metabolic rates, making them appropriate for assessing heat stress risks in factory workers performing high-intensity tasks and in indoor sports venues. For outdoor sports venues and construction sites with high temperatures, intense radiation, and significant physical activity, a combination of the PHS model and JOS-3 model should be used to evaluate overheating risks effectively.

SUMMARY
As the number of steel structures continues to increase, fire safety of steel buildings has been a subject of lasting interest due to the significantly decrease in steel strength in high temperatures. Therefore, in this study, numerical simulations were carried to explore the fire behaviour of steel factories with high fire loads. Software FDS was used to reconstruct the full-size room-fire scene and obtain the time variation of temperature of indoor air and steel structure. Then, finite element software ANSYS was employed to conduct thermo-solid coupling analysis to analyse the structural behaviour. The properties of structural components and materials set in the simulation works are based on the measured data of common SN490B steel and the recommended values of Eurocode. The results show that the fire spread speed and flashover time will be different depending on the location of the fire source, as well as the intensity of fire load. Extremely high temperature fire smoke accumulates high in space; thus, beams and columns near the roof severely deformed. If firefighters break in to control the fire at this time, the influx of outside air will intensify the fire. The high temperature at this time possibly causes the roof panels and floor panels to collapse, causing serious casualties to people in the factory.

Keywords: fire, room fire, building, steel, flashover.

1. INTRODUCTION

Located on the circum-Pacific seismic belt, Taiwan has seen an increased demand for seismic construction. While light-steel construction is less effective in terms of noise insulation, wind resistance, and leak-proof performance, it offers several advantages, including lower costs, shorter construction periods, shock resistance, and recyclability. These benefits have led to a significant rise in light-steel construction in recent years, gradually replacing traditional reinforced concrete (RC) structures in housing design. According to government statistics, fires occurring in buildings with 1-5 floors account for approximately 90% of all reported incidents. When categorized by building use, fires in warehouses and factories represent about 25% of the total annually. Among the various causes, electrical equipment malfunctions are responsible for around 40% of all fires.

Therefore, in this study, numerical simulations were carried to explore the fire behaviour of steel factories with high fire loads. Software FDS was used to reconstruct the full-size room-fire scene and obtain the time variation of temperature of indoor air and steel structure. Then, finite element software ANSYS was employed to conduct thermo-solid coupling analysis to analyse the structural behaviour.

2. RESEARCH METHOD

2.1. Room fire simulation

The investigated subject is a steel-framed furniture factory with metal exterior walls, as shown in Figure 1, measuring 30m in length, 18m in width, and 9m in height. Each of the two sides is equipped with three sliding windows, each 0.5m wide and 0.75m high. The front of the building features a 3m-wide steel rolling door, which is closed at night but leaves a gap of approximately 10cm. The exterior walls are made of 5cm-wide steel corrugated panels. The flooring consists of 5cm-high steel corrugated panels overlaid with a 5cm-thick wooden layer. The column sections are H-shaped steel profiles, specifically H400×200×8×13mm and H250×125×6×9mm, while all beams are H250×125×6×9mm. All beams and columns are bare steel without any fireproof coating. The steel material used is SN490B, with properties aligned with the values recommended by Eurocode-3 (1995).

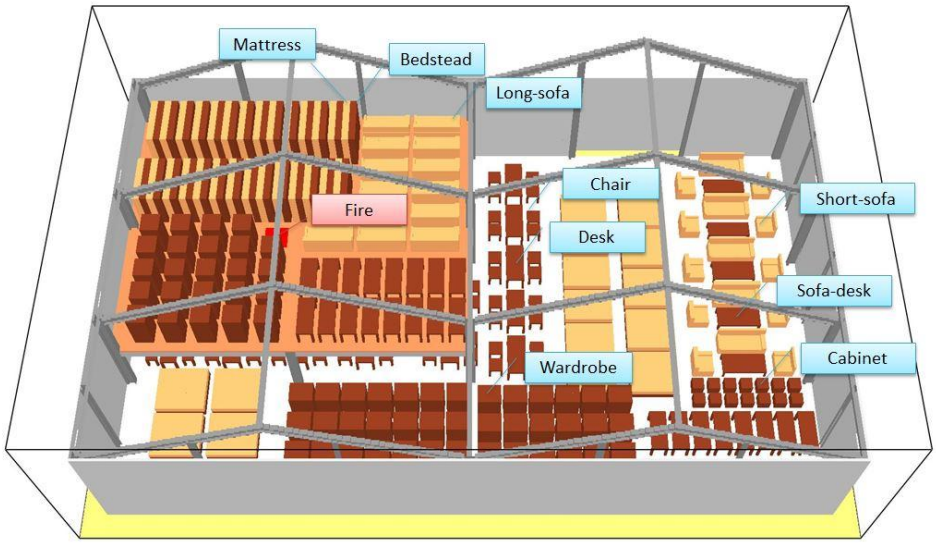

Figure 1. The investigated subject.

The simulation scenario involves an electrical wire short circuit leading to the ignition of a wooden cabinet. The heat release rate (HRR) of the fire source is set based on the burning characteristics of the wooden cabinet and converted into the fire source HRR input for FDS (Fire Dynamics Simulator). The initial simulation conditions include a temperature of 25°C, a relative humidity of 60%, and a simulation duration of 900 seconds.

The ignition point is located on the second-floor slab, where a 1m × 1m fire source replaces the wooden cabinet. The heat release rate per unit area is set at 3000 kW/m², with a maximum HRR of 3000 kW. In the FDS simulation, the HRR rapidly increases during the first 150 seconds and then stabilizes until the simulation ends at 900 seconds.

2.2. Structural behaviour in fires

This study employs the ANSYS transient thermal-structural coupling model for simulation. The analysis involves Thermal Analysis and Nonlinear Structural Analysis. The thermal loading temperature curve is applied to the structure based on the data obtained from the FDS analysis. The material properties are based on the values provided by Luecke (2005) and the European standard Eurocode.

3. RESULTS AND DISCUSSION

The simulation results (Figure 2) show that at 55 seconds, the flames began to spread, expanding the burning area, and the mattress near the fire source had already ignited. By 65 seconds, the mattress and bed frame area were burning. Initially, a large amount of heat energy accumulated on the left side of the roof. Once the heat energy reached a certain threshold, it started to extend toward the right side of the roof (at 65 seconds). Due to the effects of heat transfer through radiation, convection, and conduction, the high-temperature heat flow ignited the flammable furniture below, ultimately causing the entire factory to rapidly become engulfed in flames.

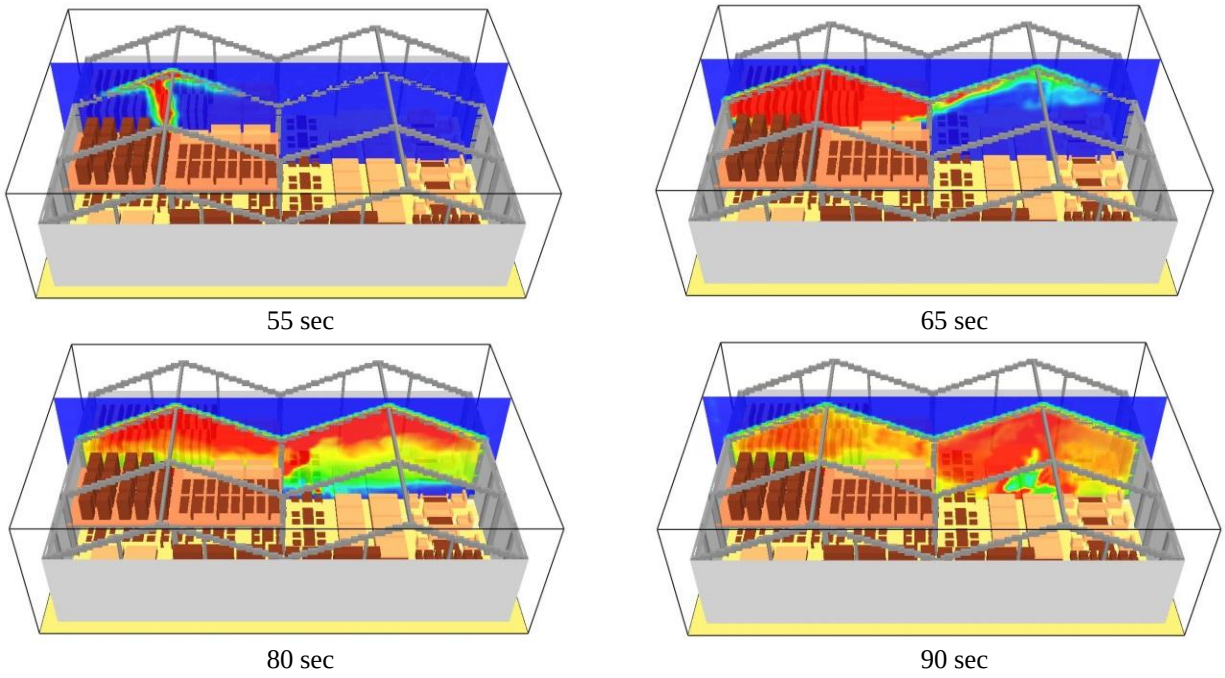

Figure 2. Fire spread (X-Direction).

Temperature measurement points were placed on all beams and columns, and after completing the FDS fire simulation, the measured temperature values were input into ANSYS for thermal analysis. As shown in the figure above, when the fire source begins to burn, the continuously accumulating heat energy causes the beams and columns on the second floor of the left side to rapidly reach high temperatures. As the fire progresses to its fully developed stage, it spreads from the second floor on the left side to the right-side space. In the right-side space, sufficient oxygen and combustible materials fuel extensive burning. The roof beams, subjected to high temperatures, experience thermal expansion as the temperature rises, increasing axial pressure. However, due to restraints at both ends, the beams initially deform in the Y-direction.

With the continued effects of high-temperature softening, axial pressure begins to decrease, leading to increased horizontal deformation of the components. The maximum deformation in the X-direction is 118.78 mm, in the Y-direction is 272.82 mm, and in the Z-direction is 214.51 mm, with an overall maximum total deformation of 273.22 mm. Between 90 and 100 seconds, as the fire reaches its peak intensity, significant deformations can be observed in the upper roof beams and the beams surrounding the second-floor slabs due to high-temperature softening. As shown in

Figure 3, these deformations can potentially lead to structural collapse, resulting in injuries or fatalities for personnel inside the factory.

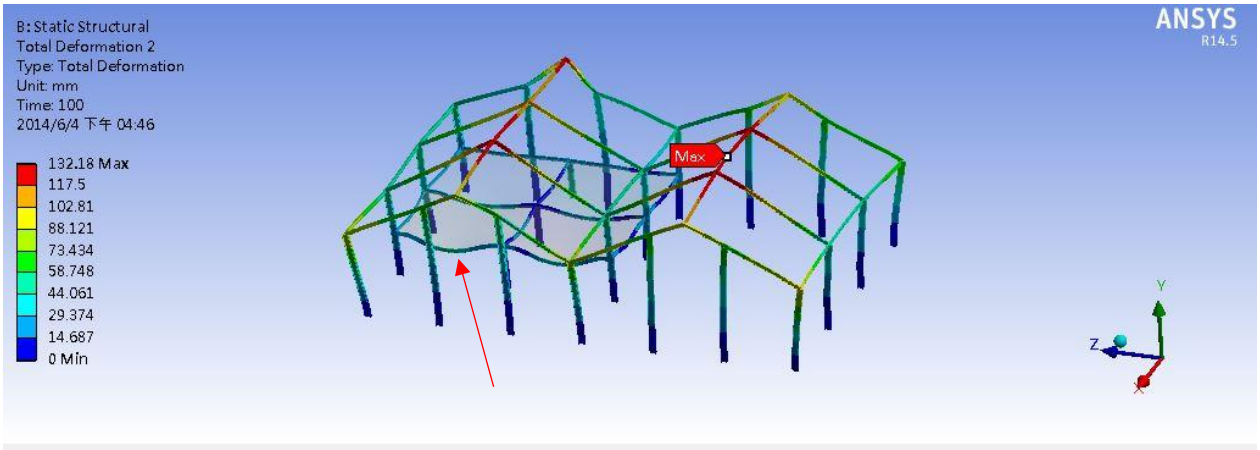

Figure 3. The deformation state of the structure at 100 seconds.

4. CONCLUSION

In the case presented in this study, the space contains a large number of wooden products, making it a high fire load environment. The time required for the fire to progress from the growth stage to the fully developed stage is extremely short. The accumulated heat energy and dense smoke within the factory cannot be effectively vented. If firefighters break in to extinguish the fire during this stage, the influx of air would cause the fire temperature to rise rapidly. The high temperatures would lead to more severe deformations of the beams and columns, potentially resulting in structural collapse, which poses a significant risk of injury or fatality to personnel entering the factory.

Explore health risks that the elderly face during heatwaves due to their degraded perceptual responses

Peiyang Du [1], Yongxin Xie [1], Jianlei Niu [1]

[1]*Department of Building Environment and Energy Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong*

SUMMARY
Elderly people are more likely to face heat-related health conditions when exposed to hot weather due to their low sensitivity. However, there is a lack of research in real environments to show the actual heat risks that low sensitivity brings to the elderly. In this study, subjects were asked to exercise on an outdoor treadmill for at a moderate intensity, during which physiological parameters and questionnaire survey were adopted. Results showed that both of the thermal sensation votes and thermal comfort votes of the elderly were higher than the young group, at the same time, the core temperature of the elderly gradually increased to 38°C, indicating that the elderly felt hot but were still comfortable, which means that the elderly had poor thermal sensitivity. The dehydration of the elderly reached 3%, but the thirst votes were lower than 4, indicating that they were not sensitive to their own dehydration status.

Keywords: Outdoor thermal health, High temperature, Senior, Thermal sensitivity.

1. INSTRUCTION

Globally, extreme heatwaves exceeding 40 °C have been recorded in recent years (Calvin et al., 2023). The warming trend in China is expected to accelerate in the future, causing cities in subtropical regions to experience more extreme hot days, posing a significant threat to human health (*Climate Issues to Watch in 2023*, 2022). Heatwaves have been found to increase the hospitalization rate and mortality rate (Conti et al., 2005). The impact of extreme heat is expected to be greater on the vulnerable groups, especially the elderly individuals (Hajat & Kosatky, 2010).

Hong Kong has one of the world's densest populations and limited living space (*Housing in Figures 2024*, 2013), so outdoor public spaces are often used as extensions of private living spaces. According to the previous study, although the Hong Kong Observatory issued "very hot weather warning", many residents still went out for activities, with 44% being elderly (Huang et al., 2022). The elderly group has a higher preference for warm environments than young people, and their thermal sensitivity is attenuated, resulting in the ability for them to remain in a thermally comfortable zone despite being exposed to a certain level of heat stress (Coates et al., 2014). Research has shown that the elderly reduce their activity outdoors only when air temperatures exceed 39°C (Huang et al., 2022). The elderly are less likely to perceive thermal changes than younger people. Therefore, senior individuals are more likely to be exposed to heat-related health risks without being aware of them.

It is a consensus that the elderly have lower thermal sensitivity and higher tolerance to high

temperatures, but there is currently no research that can accurately show the actual heat risks that this low sensitivity brings to the elderly. In addition, most studies are conducted in laboratories and lack experimental data in real environments. Therefore, it is necessary predict the thermal health risks of the elderly under heat stresses based on their subjective reactions and physical conditions, so as to guide the elderly in outdoor activities.

2. METHODOLOGY

2.1. Approach

This experiment was conducted on the outdoor terrace on the sixth floor of Block Z of the Hong Kong Polytechnic University. Nine seniors and three young subjects were recruited through posters distributed within campus, who were healthy and had no chronic diseases such as heart disease, emphysema, and hypertension.

At the beginning of the experiment, subjects were required to sit in the shade outdoors for 20 minutes for adaption. During this period, the subjects had to fill out a basic information questionnaire, including their physical health, exercise habits, etc. The subjects then put on wearable physiological instruments. After relax, the subjects filled out a subjective questionnaire and started walking on a treadmill at a constant speed of 3.5km/h to simulate moderate-intensity exercise. The subjects first walked for 20 minutes under sun exposure, and then walked for 10 minutes in shadings. This step was repeated twice, which meant that the subjects exercised for a total of 60 minutes. During the exercise, the subjects were asked to fill out the questionnaire survey every ten minutes, physiological parameters were measured simultaneously. During the experiment, subjects were told not to drink water as much as possible. The experiment will be terminated if any of the following three situations occur: (1) the subjects' core temperature reached 38.5℃; (2) the elderly's heart rate reached 130bpm or the young's heart rate reached 180bpm for three minutes; (3) the subjects voluntarily requested to stop the experiment. The experimental site is shown in Fig. 1.

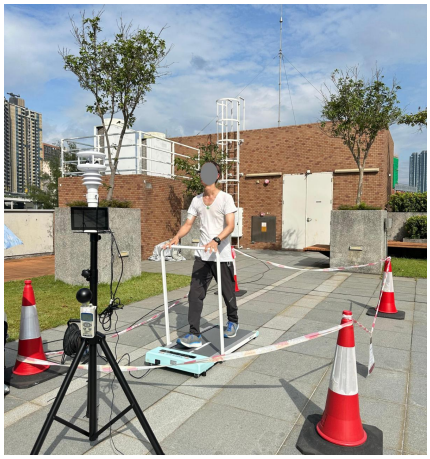

Figure 1. The experiment site.

2.2. Measurements

2.2.1. Physical measurements

The air temperature, relative humidity, wind speed, and wind direction in the shaded environment and the direct sunlight environment were continuously measured by two Mini-weather station (HY-WDS9, HONGYUV, Chengdu, China) during the whole experiment, and the black globe temperature was measured by black bulb thermometer (210SD, LUTRON ELECTRONIC, Coopersburg, USA).

2.2.2. Physiological measurements

Various physiological parameters including core temperature, dehydration status, heart rate, and blood pressure were measured during the experiment. Core temperature (A-166255, greenteg, Rümlang, Zurich), sweat volume (E01, NIX, Boston, USA), and heart rate (DSY-SP-W01F, Delsys, Natick, USA) were tested continuously during the entire experiment using wearable devices, and blood pressure (JPN610T, OMRON, Tokyo, Japan) was tested intermittently 6 times, after resting, after changing exposure conditions during exercise, and before the end of the experiment. The experimental process is shown in Fig 2.

The degree of dehydration of the subject can be expressed by body water loss (BWL). The calculation formula of BWL is as follows:

$$BWL = \frac{m_n - m_w}{m_0} (1)$$

Where m_n represents the total body dehydration of the subject during exercise measured by the wearable device, including sweating and respiratory loss. M_w represents the quantity of water the subject drinks during exercise. M_0 represents the body weights of the subjects before the experiment.

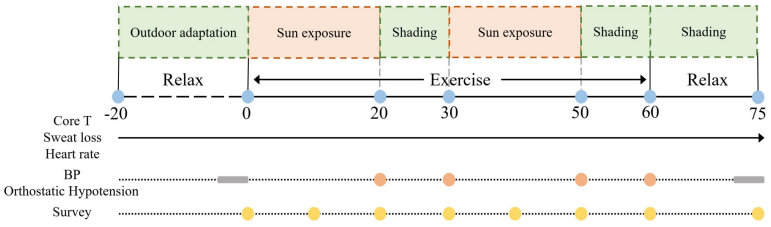

Figure 2. The experimental process.

2.2.3. Subjective measurements

The subjective evaluation was designed for collecting perceptual responses from human subjects, including heat-related and health-related issues. Heat-related questionnaires include thermal sensation vote and thermal comfort vote, both of which used the extended nine-point scale (Xie et al., 2019). The health-related questionnaire was summarized through a survey of heat-related health symptoms, including heat syncope, heat exhaustion, heat stroke, etc. It includes nine questions in total, namely the degree of sweating, thirst, fatigue, muscle cramps, headache, dizziness, palpitations, chest tightness and shortness of breath, and blurred vision of the subjects. Each question is a 10-point scale, with no symptoms (0), mild (1-4), moderate (5-7), and severe (8-10). The four levels of symptoms are described in detail. The subjects need to first select the degree of their symptoms according to the instructions, and then check the corresponding number.

3. RESULTS

3.1. The WBGT during experiments

The experiment was conducted in September 2024, and a total of nine experiments were conducted. The Wet Bulb Globe Temperature (WBGT) is a comprehensive indicators that considered temperature, humidity, solar radiation, and wind speed, evaluating the heat stress under high temperature and humidity. It is globally used to evaluate the heat-health risks of athletes and workers under heat exposure. Fig. 3 shows the WBGT of these nine experiments. It can be found that in each case, the WBGT has two peaks, which are the values in the direct sunlight environment, and the rest of the time are the values in the shadow environment. It can be found that the WBGT in the direct sunlight was basically over 31℃, while the WBGT in the shadings was basically between 28 ℃ and 31℃. According to the guidelines (*Heat Illness Prevention Information: About WBGT*, n.d.), when WBGT exceeds 31℃, it is considered dangerous. Even the elderly may face health risks in the rest room under such conditions, indicating that when subjects exercised under direct sun exposure, the heat stress that they faced was very high. When WBGT is greater than 28℃ and less than 31℃, it is considered a serious warning. It's recommended that everyone avoid direct sunlight when exercising under such conditions, indicating that when subjects exercised in shadings, the heat stress they faced was moderate.

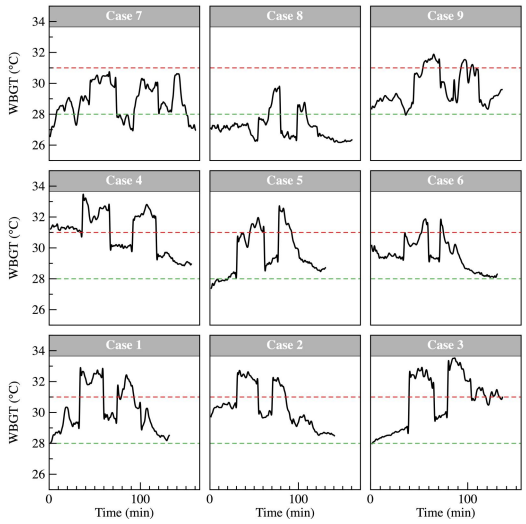

Figure 3. The WBGT during experiments.

3.2. Physiological and psychological responses during experiments

3.2.1. Core temperature and heat-related vote

Fig.4 shows the mean core temperature of both elderly and young group, the shaded area is the error band. It can be seen that after the start of exercise, the core temperature of young people rises faster than that of elderly people, but immediately reaches the threshold of thermoregulation and quickly begins to regulate the body temperature. The core temperature of the elderly

continues to rise during exercise, and the core temperature threshold of thermoregulation is slightly higher than that of young people. And after thermoregulation, their core temperature is still higher than that of young people, approaching 38°C in the later stage of exercise.

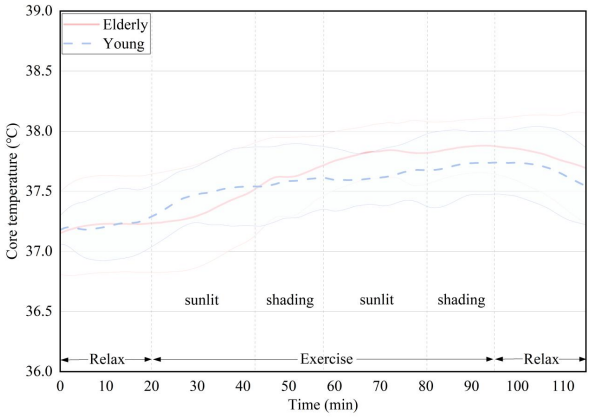

Figure 4. Mean core temperature during experiments.

Fig. 5 and Fig. 6 show the thermal perception votes and thermal comfort votes of the elderly and young people during the experiment respectively. The thermal sensation votes of the elderly and young people were similar, sometimes the elderly's thermal sensation was even higher than the young group, but the thermal comfort votes of the elderly were significantly higher than those of the young people, especially when exercising in direct sunlight. This shows that although the elderly feel that the environment is very hot, they still feel comfortable. It is worth noting that although the core temperature of the elderly was close to 38°C in the later stage of exercise, their thermal comfort voting values were still high, indicating that their thermal sensitivity was poor.

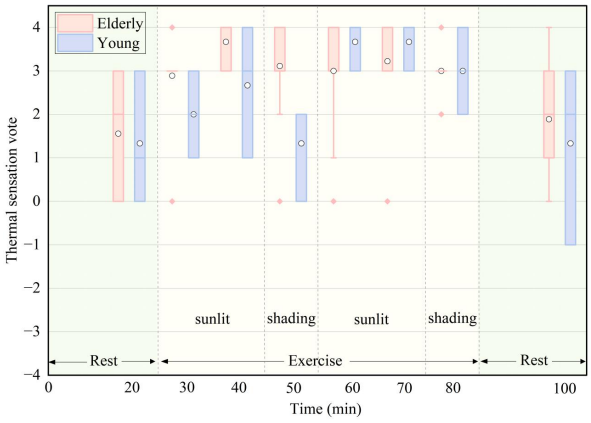

Figure 5. Thermal sensation vote.

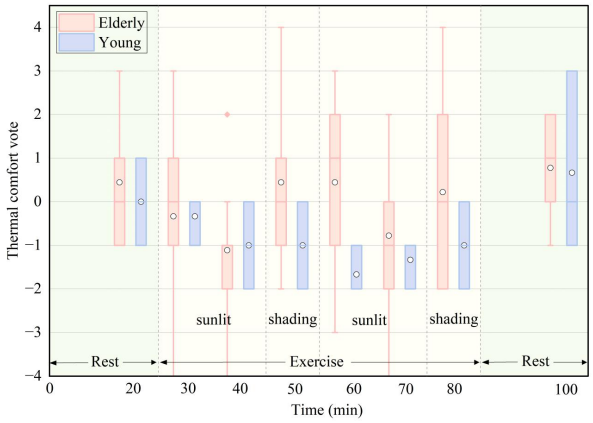

Figure 6. Thermal comfort vote.

3.2.2. Dehydration status and thirsty vote

Fig. 7 shows the degree of dehydration of the elderly and young people during the experiment. It can be found that there is a "scissors gap" between the dehydration of the elderly and the young people, that is, at the beginning of the experiment, the young people sweat more than the elderly, but as the exercise progresses, the elderly sweat significantly more than the young people. This indicated that the elderly's sweating threshold is lower than young group. During the exercise, the body water loss of the elderly reached 2%, and even reached 3% at the end of the experiment, while the body water loss of the young people during the entire experiment was always below 2%, indicating that when doing outdoor exercise under high outdoor heat stress, the risk of dehydration for the elderly is much greater than that for the young.

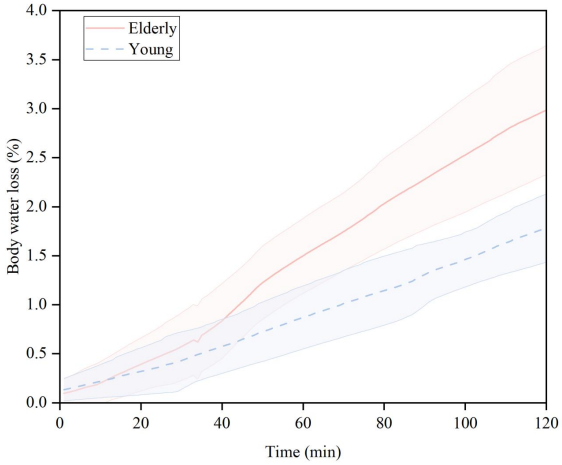

Figure 7. Mean body water loss of different age groups.

Figure 8 shows the thirst votes of the elderly and young people. It can be seen that during the entire experiment, the thirst of the elderly was always lower than that of the young people. As mentioned above, the scale of mild thirst is 1-4, and the scale of moderate thirst is 5-7. During the experiment, the average thirst vote of young people was basically around 4, which was mild thirst, that is, "it's okay not to drink water". In the later stage of exercise, the average thirst vote of young people was close to 5, which was moderate thirst, that is, "realizing that they should drink water, but they can still hold it in." For the elderly, the average thirst vote during the entire

exercise process did not exceed 4, which was mild thirst. After resting after exercise, the thirst even dropped significantly, indicating that the elderly are very insensitive to their own dehydration. The dehydration of the elderly is higher than that of the young, but the thirst vote value is lower than that of the young, which means that the elderly are at risk of dehydration when exercising in high temperatures outdoors because they are unaware of the lack of water.

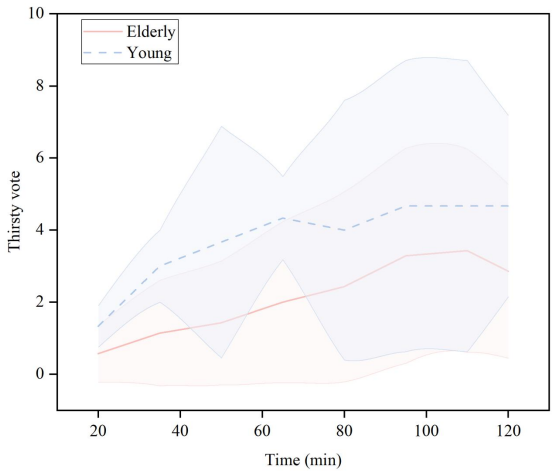

Figure 8. Thirsty vote of different age groups.

4. CONCLUSION

This study aims to investigate the differences in physiological responses and perceptions of the elderly in outdoor high heat stress environments. A total of 12 subjects were recruited to participate in the summer experiment. The subjects were asked to perform moderate-intensity exercise in direct sunlight and shaded environments, and vote on their thermal perception and health-related perceptions at specific time points. At the same time, the subjects' physiological data, including core temperature and sweat rate were collected, and the micro-meteorological station continuously measured the micro-thermal environment. This study shows that the elderly have a delayed perception of their own health status. In the future, the outdoor exposure risk of the elderly will be quantified, and indicators will be further established to regulate the outdoor exercise of the elderly to avoid the occurrence of heat health insurance related problems. The main conclusions are as follows:

(1) The thermal sensation votes of the elderly were similar to those of the young people, but the thermal comfort votes were significantly higher than those of the young people, which means that although the elderly feel hot, they were still comfortable.

(2) The elderly still had a high comfort rating for the thermal environment when their core temperature was dangerous (reach 38 °C), indicating that the elderly is not sensitive to changes of his body temperature.

(3) The sweating threshold of the elderly is lower than the young group. The elderly are more dehydrated than the young, but the thirsty vote of the elderly was always lower than the young group, indicating that the elderly are less sensitive to their own dehydration status and

may not replenish fluid on time, thus put themselves at risk of heat exhaustion.

SUMMARY
Rapidly developing societies face environmental challenges, notably air quality issues impacting public health, morbidity, and mortality, with significant socio-economic consequences. The growing awareness of air pollution's adverse effects increases demand for innovative mitigation measures. However, assessing on-site air quality strategies is complex due to fluctuating pollutant concentrations influenced by dynamic environmental factors. Computational fluid dynamics (CFD) simulations offer solutions to these challenges by addressing the limitations of full-scale measurements and enabling systematic scenario analyses. This work demonstrates the practical relevance of CFD simulations using steady Reynolds-averaged Navier-Stokes (RANS) models to study near-field dispersion and particulate matter (PM) mitigation. Despite inherent uncertainties, CFD simulations efficiently provide insights into real-world air pollution issues, supporting clear communication and decision-making. Practical examples highlight how stakeholders utilize these results, emphasizing CFD's vital role in designing effective mitigation strategies.

Keywords: air quality, pollution mitigation, CFD simulations, societal impact.

1. INTRODUCTION

Air pollution is composed of a dynamic mixture of gases and particulate matter (PM). Exposure to PM is widely acknowledged as a health hazard and is considered the main contributor to health effects associated with air pollution (GBD, 2024). A wide body of scientific literature documented positive health-effects and (socio-)economic benefits resulting from air quality improvements (e.g., Laden et al., 2006; Pope et al., 2009; Huang et al., 2018; Schraufnagel et al., 2019). Mitigation of air pollution, particularly PM, is therefore highly significant and of great importance.

Reduction or prevention of air-quality related negative health effects can - evidently - have a positive (socio-)economic impact. Scientific literature reports numerous positive health outcomes correlating to reduction of pollutant concentrations (e.g. Schraufnagel et al., 2019). Tools are available to assess health impact in a simplified way. Usually information is required regarding (spatial distribution of) the population that is being exposed to air pollutants, and evidently detailed spatial quantifications of the latter, to be able to assess the cost-effectiveness of mitigation strategies. Several studies show how geographic information systems can aid in this process (e.g. Bedach et al., 2020). Nevertheless, to calculate the spatial impact of mitigation measures on pollutant concentrations - being the core data for the assessments - additional tools are needed.

Near-field air pollution research can be conducted using either experimental or numerical methods. Experimental work typically involves (full scale) on-site field measurements or reduced scale wind tunnel experiments. Numerical approaches primarily include analytical plume-model based

calculations or computational fluid dynamics (CFD) simulations. Naturally, there are specific reasons to choose one method over the other, depending on the research objectives and constraints. Some advantages and disadvantages can be pivotal in shaping the selection of research methods, effectively ruling out certain approaches. Without delving deeply into the details of all available methods, it can be stated that experimental approaches can sometimes present challenges. For instance, due to scaling constraints it may not be possible to perform wind tunnel tests on complex objects, or it may be impossible to replicate certain key (technological) features. On the other hand, full-scale measurements entail the complexity of dynamic environments, where many conditions may not be controllable (i.e. wind, stratification, pollutant sources, etc.). This can make data interpretation - given a limited number of discrete measurement points - very challenging and occasionally even incomprehensible. As a result, long measurement periods or numerous repetitive tests are often required to achieve research objectives, which can become prohibitively expensive. Such circumstances are generally impractical for engineering practices, where research needs to be systematic and straightforward, avoiding disruptions to ongoing processes.

Testing and optimizing concepts in a 'virtual environment' without the need for expenditure or disruption in practice, could therefore be considered a highly suitable approach for industry. Practitioners often rely on standardized modelling methods to systematically perform scenario analyses (e.g. assessing the effect of mitigation measures). These models - with varying complexity - are mostly based on Gaussian plume and trajectory dispersion methods and operate at meso- (< 200 km) and microscale (< 2 km) levels, but are generally not capable of predicting detailed concentration distributions around (groups of) objects in e.g. an urban environment.

The nature of many engineering tasks related to air pollution (mitigation) often necessitates the use of more advanced, higher spatial-resolution calculation tools, such as CFD. CFD simulations are able to overcome most of the limitations associated with aforementioned methods. This article presents three case studies, with only a brief discussion of the numerical setup in the methodology section. In addition, some further perspective on suitability of quantification methods is given, by briefly addressing some of the experimental work that was done for these case studies. The goal of this manuscript is to illustrate how engineering practice can benefit from the application of CFD.

2. METHODOLOGY

This section outlines the research methodologies adopted. Only the main characteristics are mentioned for the sake of brevity; a detailed description of each distinct case study is not included.

2.1. Numerical

This manuscript presents case studies based on 3D steady RANS analysis in combination with the standard or realizable k-ε turbulence model, using either standard or scalable wall functions. Second-order discretization schemes were adopted for all modeling quantities. Simulations are conducted on highly detailed hybrid grids, partially structured and unstructured, based on manual and automated meshing procedures. The grids were created in accordance with best-practice guidelines (e.g. Franke et al., 2007; Blocken, 2015). Pollutant concentrations are calculated using Eulerian approaches; PM is represented by a passive scalar and modeled with an advection-diffusion equation and standard gradient-diffusion hypothesis, depending on the case, with or without gravitational settling and deposition (method adopted from Chen et al., 2006), using

constant turbulent Schmidt number (Sc_t) of 0.7. Such modeling procedures were previously validated and verified by e.g. Chen et al., (2006), Blocken et al., (2016) and Vervoort et al., (2019).

2.2. Experimental

The presented case studies also involved some on-site experimental activities. Measurements were conducted using 'Grimm EDM-164' high-resolution research-grade optical measurement equipment (Grimm & Eatough, 2009) and weather stations. Local PM concentrations, including particle size distributions, can vary greatly in time and space due to variations in environmental conditions and on-site processes and related emissions. Reference measurement methods rely on data sampling and integration over extended periods, which are not expected to provide a suitable temporal resolution necessary for the case studies presented. Use of low-cost PM sensors was purposely avoided because of the many well-known (potential) issues inherently related to the use of low-cost sensors (e.g. Karagulian et al., 2019; Alfano et al., 2020; Kuula et al. 2020).

3. CASE STUDIES

This paragraph demonstrates how CFD simulations are adopted in the mitigation of real-world air pollution issues. The case studies presented differ significantly in the nature of the pollution problems and situational conditions, covering (1) a bus terminal, (2) an industrial facility and (3) railway works. For each case, the pollution issue is outlined, followed by the rationale for using CFD simulations and a concise summary of key insights.

3.1. Bus terminal

This study focused on a bus terminal, with a capacity of 43 buses, which is being used by approximately 10,000 daily commuters, each spending about 30 minutes per day at the terminal (waiting for buses). In this building, short-term exposure risks are high due to the concentrated amount of people and the buses that emit pollutants in a semi-enclosed volume (empty ~30,000 m^3). To assess possibilities to alleviate exposure risks inside this building, a CFD analysis was conducted including nine high-capacity air purification systems (total ~66,000 m^3/h).

CFD simulations were selected to be the most appropriate method of analysis considering that this involves a highly complex case with a lot of uncontrollable and unregistrable variability, such as (1) moving and parked cars and buses, (2) presence and potential interference by people, and (3) the presence of ceiling-mounted air circulation units for which the control strategy was not clear. In addition, due to the open characteristics of the building and the relatively open upstream wind fetch, high wind-driven ventilation rates and limited percentual mean PM reduction levels are anticipated. All in all, this makes assessment based on full-scale PM measurements (pre- and post-mitigation) unfeasible when long-term measurements (i.e. min. several months) are ruled out.

A multi-scenario analysis was conducted using CFD simulations, covering several critical wind directions, variations in wind speed, and mechanical ventilation settings. The CFD model includes a detailed representation of the bus terminal as well as the main buildings nearby (Fig. 1a-d), which are expected to significantly influence airflow within the terminal (Fig. 1e-f). The study gave clear insight into the spatial performance of the purification units. Anticipated mean PM reductions were presented in the form of 2D contours and zonal quantifications (Fig. 1g-j), which can be adopted in socio-economic impact assessments. Additional suggestions, to improve the local effectiveness

of purification units, such as adapting the building envelope and implementing a targeted control strategy for the existing mechanical ventilation, were provided. Finally, the modeling approach was adopted by Oh et al. (2024) to conduct their own analysis.

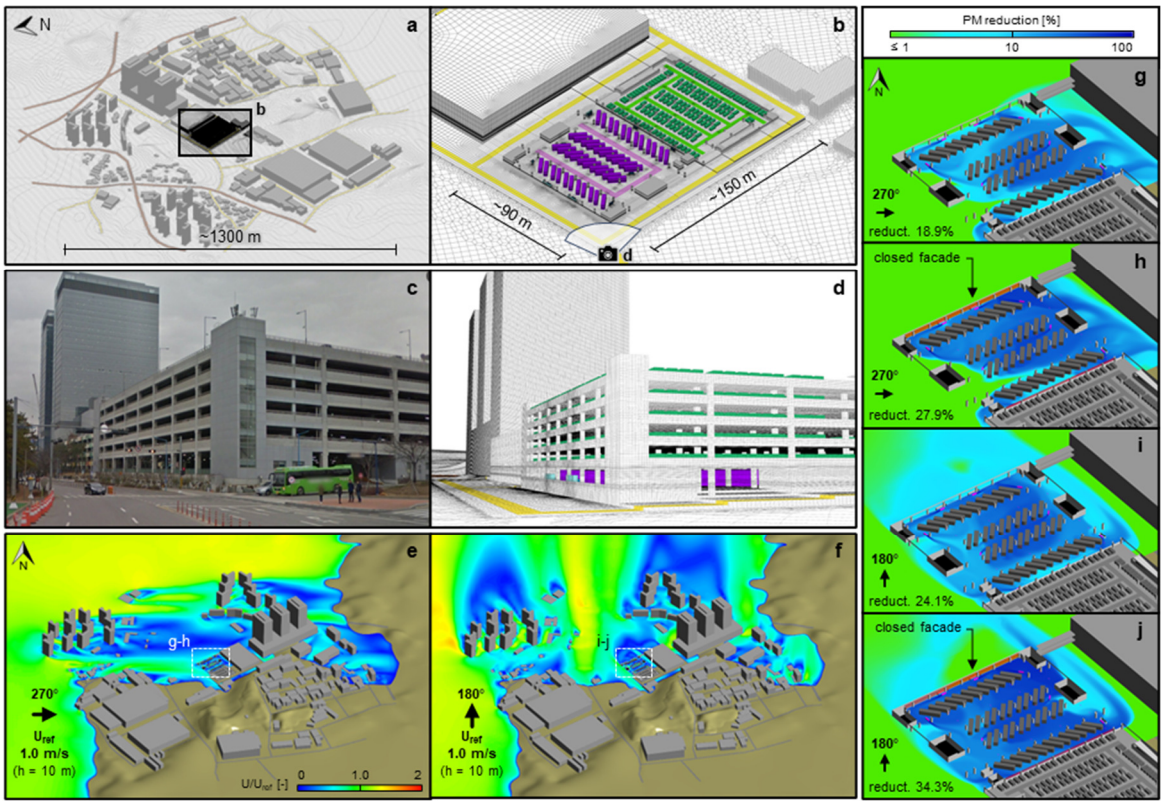

Figure 1. Overview of bus terminal case study: (a-d) computational grid bus station with surroundings, (e-f) flow entire domain for two wind directions and (g-j) PM reduction mitigation measure for two wind directions (g,i) including (h,j) façade adaptation. Contours are shown for the bus station ground floor at 1.1 m height (h = 23.1 m).

3.2. Industrial facility

This study focused on the working environment inside a large industrial facility consisting of several interconnected compartments with a total volume of ~280,000 m^3, partly naturally and partly mechanically ventilated. The scope of the study was to focus on one specific area within one of the sub compartments, where most of the labor takes place (thus exposure risks are most significant), and working processes evidently result in elevated PM concentrations.

Four weeks of full-scale measurements were conducted using four monitors in an attempt to identify the nature of PM-related issues within the facility. Because no permission was granted to install cameras to oversee processes within the facility, personnel were instructed to register the opening of large internal and external doors, working procedures, and any other events that may affect PM concentrations procedures. The measurement campaign and data analysis yielded several key conclusions: PM concentrations exhibited numerous high peaks, with significant variations between locations (Fig. 2a). Various processes across the facility contributed to concentration peaks, with some activities leading to persistently high background levels (Fig. 2b). However, dust-generating actions in the sub-compartment of interest occurred infrequently and were not the sole contributors to high concentrations. The complexity of airflow patterns in and

around the facility made it difficult to identify clear trends from measurement data. Furthermore, manually registering daily activities proved to be insufficiently accurate.

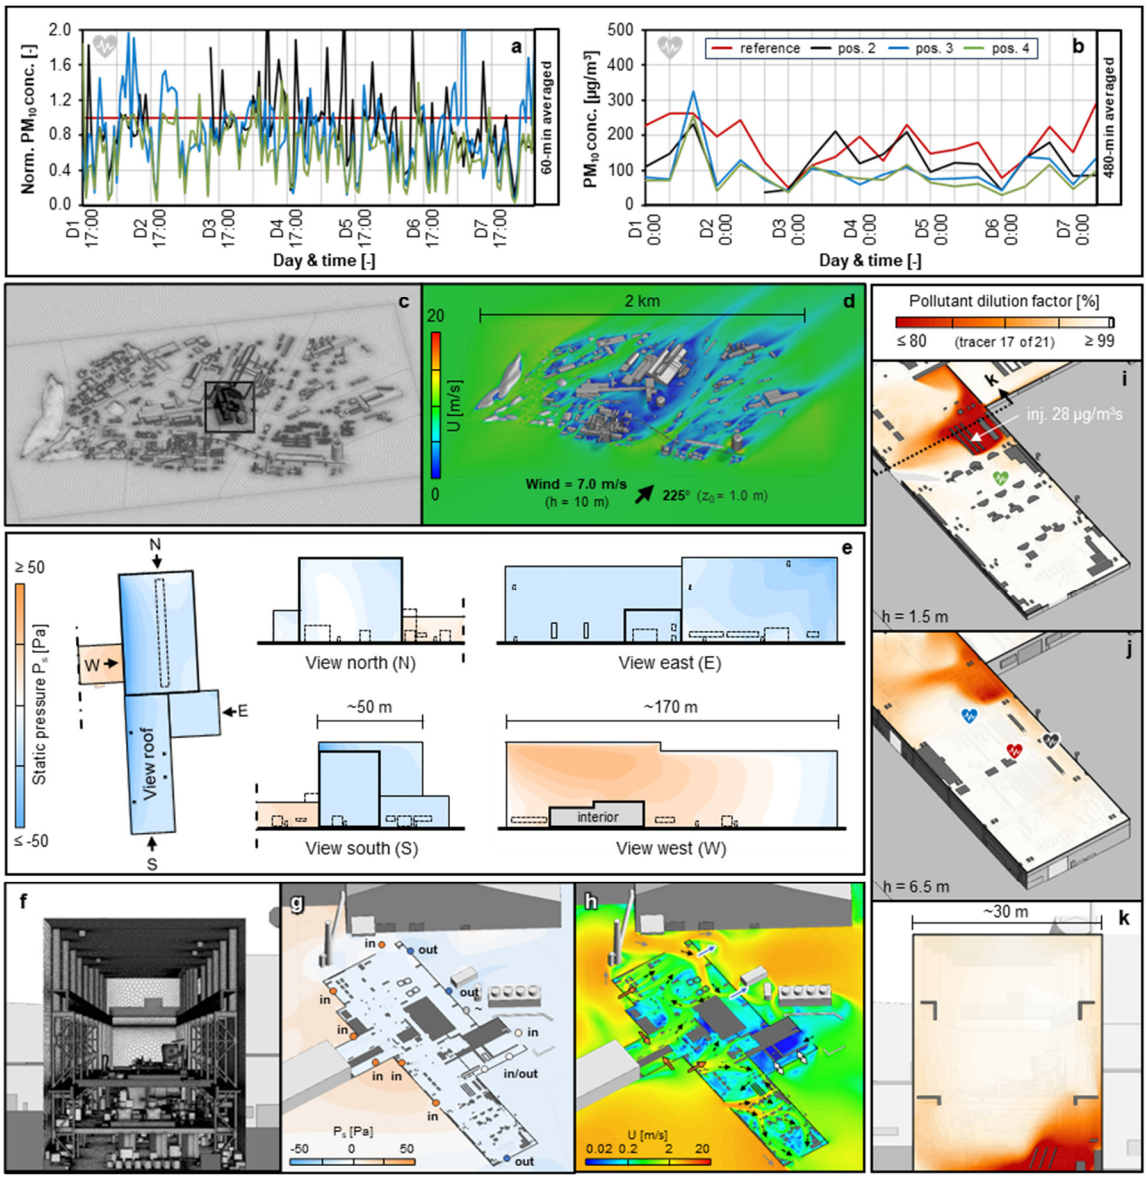

Figure 2. Overview of industrial facility case study: (a-b) One week of PM_{10} concentration measurements at 4 locations; (a) normalized 60-min and (b) absolute 480-min averages (date-time stamp at end of measurement interval), (c) computational grid surroundings, (d) airflow entire domain, (e) pressure faces building of interest, (f) detailed grid building, (g-h) airflow inside building, (i-k) dispersion pattern of one of the tracers injected inside the facility.

Therefore, CFD simulations were employed to gain a better general understanding of site dynamics. The analysis followed a multi-step approach, starting with modeling the airflow and pressure distribution around the building of interest (for a few critical wind directions; Fig. 2c-d). After obtaining information on the pressure distributions at façade openings (Fig. 2e), a more detailed analysis was conducted on the airflow inside the facility (i.e. ventilation effectiveness), considering several critical operational scenarios regarding e.g. mechanical ventilation settings and opening/closing of internal and external doors (Fig. 2f-h). Then several passive pollutant sources

were included at either (1) locations where large amounts of air are displaced or where air exchange occurs between different building compartments, or (2) at locations where employees indicated that a significant amount of dust is likely to be generated. The pollutant source locations were therefore chosen partly generically and partly with specific operational conditions of the facility in mind, primarily to map internal distribution pathways (Fig. 2i-k).

Based on insights from both measurements and CFD simulations, bottlenecks were identified, leading to targeted strategies to reduce PM exposure risks. Solutions ranged from relatively simple interventions, such as policies for workers, building compartmentalization, and optimization of existing building management systems, to more advanced technological interventions.

3.3. Railway works

This study involves a technical intervention to limit PM dispersion during railway works. Most railway tracks are laid on a bed of stones, so-called 'ballast'. However, various materials in this bed of ballast may pose health risks when inhaled, such as respirable crystalline silica (quartz). These risks are particularly high during railway works, as certain processes can erode the material and disperse PM into the surrounding environment (Fig. 3a). This case study involves a machine (SSP 110 SW) which is being used to distribute and profile ballast. A (concept) technological intervention was engineered aimed at limiting dispersion of airborne PM from a brushing compartment by generating a low-pressure zone inside it.

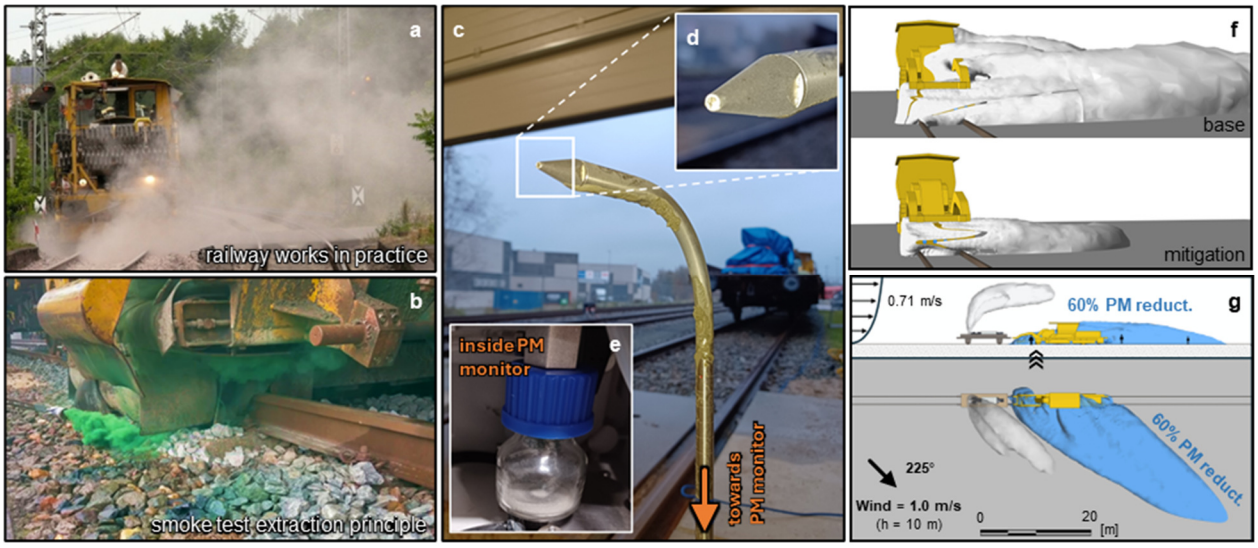

Figure 3. Overview of railway works case study: (a) SSP 110 SW railway works in progress showing the occurrence of a dust 'cloud'; (b) smoke test to assess mitigation extraction principle; (c-e) unsuitable conditions for in-duct isokinetic PM measurements with (c) mud- or cement-like material that deposits on the sampling probe, (d) leading to slippage of the sampling nozzle and (e) sand grain-sized particles accumulation inside the PM monitor (conditions qualified for causing serious damage to equipment); (f-g) indicative figures of CFD analysis effect mitigation measure.

In this case CFD simulations were combined with on-site experiments. Several factors influenced the decision not to rely solely on measurements: (1) The winter measurement period featured low air temperatures and even lower surface temperatures, leading to condensation on metal components and clogging of measurement equipment (Fig. 3c-e); (2) extremely high PM concentrations were present, ranging from a few to tens of mg/m^3, further exacerbates this issue.

(3) The available railway track for testing was limited to 75 meters, making long continuous brushing runs unfeasible (max. 5 min per run). (4) Wind conditions were rather unstable, with high velocities and strong gusts. (5) The available measurement window was restricted to a maximum of 1.5 working days due to scheduled railway works. These challenges, among others, made it difficult to obtain reliable data within the given timeframe.

A few targeted measurements were conducted to characterize (strongly varying) PM particle size distributions to be able to determine the single-pass purification efficiency of the purification chamber. Smoke tests combined with detailed airflow measurements (duct traversing) were performed to identify leaks, determine the total required extraction volume flow rate through multiple extraction openings, and control the respective airflow valves (Fig. 3b). These results were then incorporated into CFD simulations to assess the intervention's impact on the working environment around the machine and to evaluate its effectiveness in limiting the spread of (respirable) PM to the surroundings (Fig. 3f-g).

4. DISCUSSION AND CONCLUSIONS

Conducting full-scale assessments of mitigation measures presents significant challenges. The high costs associated with state-of-the-art equipment, the need for extended measurement periods to capture relevant environmental conditions, and the requirement for mitigation measures to already be in place, all contribute to the complexity of such studies. Additionally, there is a risk of data misinterpretation or a lack of comprehensive understanding of the underlying processes.

The presented case studies highlight the potential of high-resolution numerical analyses, such as CFD simulations, as a cost-effective and systematic alternative to traditional measurement-based assessments. Unlike point-based measurements, which provide limited data at specific locations, CFD simulations offer whole-flow field insights, leading to a more comprehensive overall understanding. It should be noted that the results are subjective to modeling simplifications. Nonetheless, CFD enables a broader perspective, including possibilities for socio-economic impact assessments. While CFD is a powerful tool on its own, it becomes even more valuable when combined with targeted measurements and practical tests, forming a robust methodology for addressing complex environmental engineering challenges

As Blocken (2018) noted, steady RANS simulations remain the workhorse of engineering practice. This article further demonstrates that 3D steady RANS simulations can provide valuable insights into various engineering challenges, particularly in cases where alternative methods - such as measurements or plume models - are either impractical or unsuitable. More computationally intensive approaches, such as large eddy simulation (LES) and Lagrangian particle trajectory modeling, were not feasible for the current case studies due to their scale and complexity. The primary objective of the simulations was to gain general, systematic insights by assessing mean quantities rather than precisely replicating pollution episodes. Given the inherent simplifications of the case studies, the use of higher-fidelity numerical methods would not have been justifiable.

It is important to acknowledge the limitations of the presented case studies, which are inherently linked to the applied numerical methodologies. These limitations are well understood by the authors but fall outside the scope of this manuscript. Nevertheless, CFD simulations have proven

to be a powerful tool for assessing and communicating the potential impact of mitigation strategies. CFD simulations can help bridge the gap between research and practical implementation, offering valuable guidance for reducing air pollution exposure risks in complex real-world scenarios.

ACKNOWLEDGEMENTS

The authors thank Alessio Ricci for his support in grid generation for the bus terminal CFD analysis. They also appreciate the collaboration with Strukton Rail Nederland and ProRail in the railway works case study.

SUMMARY
In high-altitude tunnels, due to the ambient pressure and density of air being different from those under normal pressure, the pollutant emissions caused by mechanical and electrical equipment varies under different operating conditions. As a result, the diffusion characteristics of pollutants in high-altitude tunnels are different from those in plain areas,and corresponding adjustments need to be made to the pollution sources when studying the ventilation environment in tunnels.The study is based on three-dimensional thermo-hydraulic Computational Fluid Dynamics simulations accounting for the actual fluid flow that occurs in the aforementioned environments, and analyze the diffusion characteristics of pollutants by comparing the pollutant concentrations, diffusion coefficients, and altitude correction factors in tunnels under normal pressure and high altitude.The work also presents novel relationships between pollutant concentration and atmospheric pressure that may be used in the analysis and design of tunnel ventilation system.

Keywords: pollutant dispersion, Plateau tunnel, Numerical simulation.

1. INTRODUCTION

In recent years, with the increase in high-altitude tunnel projects, some studies have begun to focus on the special effects of high-altitude environments on tunnel ventilation. Some studies have revealed the distribution patterns of pollutant concentrations after blasting operations in high-altitude tunnels through on-site monitoring (Zou et al., 2020). Meanwhile, numerical simulation methods have also been widely used to study the pollutant diffusion characteristics in high-altitude tunnels (Huang et al., 2020; Chang et al., 2020). Chang et al. studied the diffusion mechanism of harmful gases by simulating the tunnel flow field under different ventilation modes and derived a ventilation time estimation function.

However, existing studies still have certain limitations. Most studies have focused on the analysis of pollutant diffusion in ventilated tunnels, and relatively few studies have been conducted on the pollutant diffusion characteristics in unventilated single-ended tunnels under altitude changes. On the other hand, although some studies have considered altitude factors, the research on how altitude affects various coefficients and thus affects ventilation volume and ventilation time is not in-depth enough when establishing pollutant diffusion models, lacking a systematic mathematical model to accurately describe this process.

This study aims to fill the above gaps. Through detailed CFD simulations, the variation law of pollutant diffusion characteristics in unventilated single-ended tunnels with the altitude changing from 0km to 4km is deeply studied.

2. MODEL AND BOUNDARY CONDITIONS

The research object is the Huzhu Beishan extra - long tunnel. The altitude of the area where the tunnel is located ranges from 2,815 meters to 3,699 meters, belonging to a high - altitude region. This area has many characteristics such as low air density, low atmospheric pressure, low ambient temperature, low oxygen concentration, and a decline in human body functions. The ventilation environment is importance. During the tunnel construction, the area near the working face is the most polluted and the most difficult to ventilate. Thus, a model is established within a certain distance from the working face to the air supply outlet.

The boundary conditions and relevant parameters need to be set with reference to the real - world environmental conditions. Fluent is used to simulate the diffusion law of polluted gases near the working face. The boundary conditions are set as follows:

(1) Assume that the polluted gases generated during the working process are mainly CO and CO_2 gases, and there are no other pollution sources in the tunnel.(2) The outlet boundary is set as a pressure outlet.(3) For the fixed wall boundary, the working face and the tunnel surface are set as wall boundaries with no slip and no heat exchange.

2.1. GEOMETRIC MODEL AND MESH

According to the tunnel construction design plan, the geometric model for numerical calculation is set up as follows: The tunnel cross-section is a fan-shaped with a radius of 6 m. The tunnel entrance ventilation method is forced ventilation, with the ventilation duct positioned 15 m from the tunnel working face, installed at a height of 4 m, and with a duct diameter of 1.6 m. Fluent software is employed to simulate pollutant diffusion during high-altitude tunnel construction, ignoring the gantry and other special components during the construction period. The three-dimensional modeling software Space Claim is used to create the tunnel geometric model.

For the numerical calculation model of tunnel ventilation, the quality of the mesh significantly impacts simulation results, with structured meshes yielding more accurate simulation outcomes. Fluent Meshing software was used to generate three different mesh densities for the geometric model: Mesh 1 (373,453 elements), Mesh 2 (627,660 elements), and Mesh 3 (976,560 elements). Grid independence tests were conducted for these three different meshes, with results shown in Figure 2.

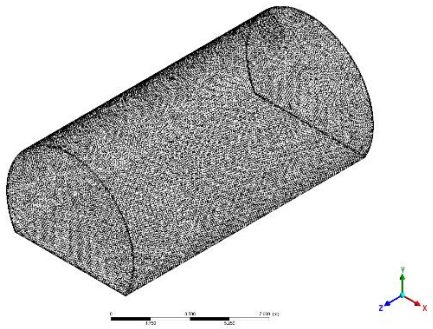

Figure 1. Geometry and face meshing of numerical model.

From Figure 2, it can be observed that the results from Mesh 2 and Mesh 3 are similar, with only Mesh 1 showing slight differences compared to Meshes 2 and 3. However, overall, these differences are relatively minor. Considering both computational performance and mesh quality, Mesh 2 was selected for mesh generation and calculations. When dividing the model mesh, boundary layers were set at the model interfaces to better reflect actual conditions. The final mesh count was 627,660 elements, with good mesh quality that satisfied the computational requirements of this study.

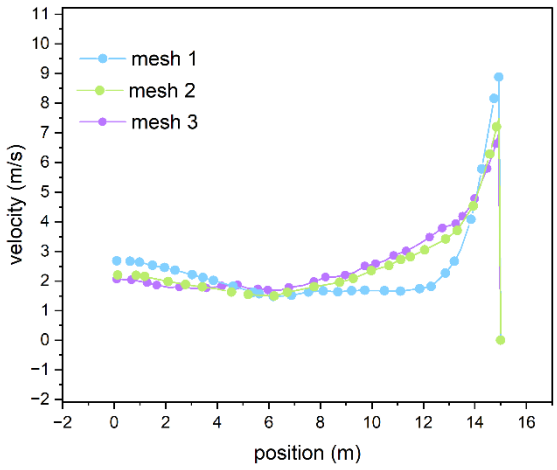

Figure 2. Grid independence.

2.2. BOUNDARY CONDITIONS

In order to carry out effective and reliable numerical simulation, the following assumptions were made in combination with the actual situation (Sun et al., 2018).

(1) The hazardous gases produced by blasting do not have chemical reaction and phase change reaction during diffusion. (2) The air and hazardous gases in the construction tunnel are idealized as three-dimensional viscous incompressible fluids. (3) Assume that all pollution sources release pollutants constantly and there are no other pollution sources in the tunnel. The mathematical model was based on the above.

Continuity equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_j}(\rho u_i) = 0 \tag{1}$$

Momentum conservation equation:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial P}{\partial x_i} + \frac{1}{\rho}\frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right] + g_i \beta_T (T - T_0) \tag{2}$$

Energy conservation equation:

$$C_p[\frac{\partial(\rho T)}{\partial t} + u_j \frac{\partial(\rho T)}{\partial x_j}] = \frac{\partial}{\partial x_j}(k \frac{\partial T}{\partial x_j}) + S_T \quad (3)$$

Species transport equation:

$$\frac{\partial(\rho Y_s)}{\partial t} + u_j \frac{\partial(\rho u_i Y_s)}{\partial x_j} = \frac{\partial}{\partial x_j}(\rho D_s \frac{\partial Y_s}{\partial x_j}) + S_{Y_s} \quad (4)$$

Compared with the Standard k-ε model, the Realizable k-ε model improves the calculation of turbulent viscosity and introduces a constraint on the ε equation to ensure that the turbulent normal stresses remain positive, thereby better capturing the characteristics of complex flows. The equations for k and ε are as follows:

$$\frac{\partial(\rho k)}{\partial t} + u_j \frac{\partial(\rho k u_i)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + G_k - \rho\varepsilon + G_b - Y_M \quad (5)$$

$$\frac{\partial(\rho \varepsilon)}{\partial t} + u_j \frac{\partial(\rho \varepsilon u_i)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right] + C_{1\varepsilon}\frac{\varepsilon}{k}(G_k + C_{3\varepsilon}G_b) - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} \quad (6)$$

where t is the time; u_i and u_j are the components of the velocity vector, m/s; x_i and x_j are the components of the coordinate system, m; ρ is the density, kg/m³; P is the pressure, Pa; g_i is the acceleration of gravity in i direction, m/s²; T is the temperature, K; μ is the dynamic viscosity, Pa·s; μ_t is the turbulent viscosity, Pa·s; C_p is the specific heat capacity at constant pressure, J/(kg·K); S_{Y_s} is the source term of the s component; Y_s is the mass fraction of the s component.

In this simulation study, we need to use local meteorological data as a reference, and apply relevant formulas to calculate and correct the physical properties of air at different altitudes, including atmospheric pressure, air density, environmental temperature, oxygen content, and other environmental parameters. Since the relationship between atmospheric pressure and altitude is non-linear and air is considered a compressible fluid within a certain height range, the calculation method for atmospheric pressure from sea level to 11 kilometers altitude is as follows:

$$P = 101325 \times (1 - \frac{H}{44329})^{5.2559} \quad (7)$$

where, P is the atmospheric pressure at altitude H, Pa; H is altitude, m.

In high-altitude areas, due to low oxygen concentration, combustion processes are often incomplete, resulting in emission chemical reaction equations that differ from those under standard atmospheric pressure. For diesel engines (commonly used in tunnel construction equipment), the incomplete combustion reaction at high altitudes can be expressed as:

$$C_xH_y + nO_2 \rightarrow aCO_2 + bCO + cH_2O + dC + hHC \quad (8)$$

Where n represents the theoretical amount of oxygen required for complete combustion. Ignoring HC and C emissions, the low oxygen partial pressure in high-altitude regions alters the mixing ratio of fuel and oxygen, leading to an increased CO/CO_2 ratio and higher emissions of unburned

hydrocarbons and particulate matter.

The chemical reaction equations for incomplete combustion are significant for accurately simulating the generation and dispersion of pollutants in high-altitude tunnels. Emission coefficients selected from previous research (Yan et al., 2021) are calculated and input into the CFD model as baseline data for pollution source terms.

The settings of other solvers are shown in Table 1.

Table 1. Major settings in numerical simulation.

Parameter	Values and settings

3. RESULT

3.1. ANALYSIS OF CO EMISSION PATTERNS

To study the diffusion patterns of polluted gases at different altitudes, the diffusion patterns of polluted gases near the working face were simulated at altitudes of 0 m, 1000 m, 2000 m, 3000 m, and 4000 m respectively, with other conditions and parameters kept unchanged. Due to the variations in environmental parameters, there were differences in the source intensity and distribution of polluted gases. Fig. 2 shows the differences in the source intensity of polluted gases at different altitudes.

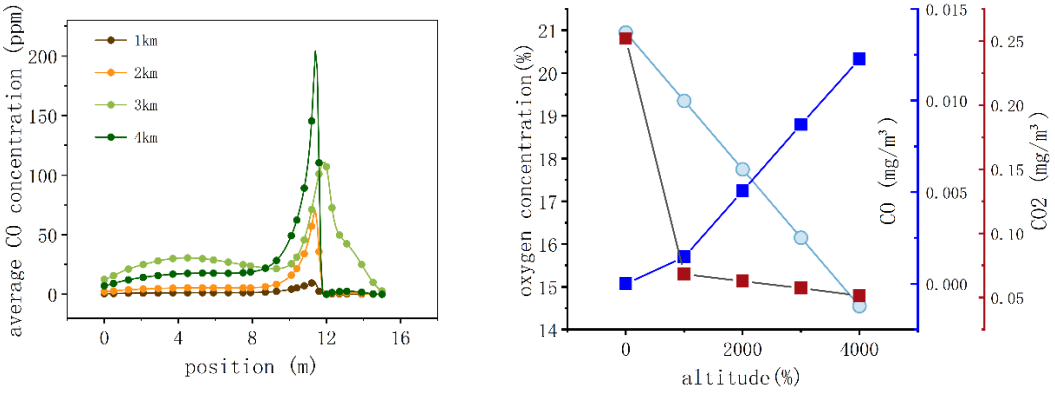

Figure 2. The concentrations of polluted gases at different altitudes.

Due to the changes in the physical properties of gases caused by the increase in altitude, the source intensities of pollutants in different altitude environments are different as calculated. To further study the diffusion levels of the same pollutant source intensity at different altitudes, CFD simulations were carried out. The concentration levels of the polluted gases after the simulations are shown in the Fig. 2 below.

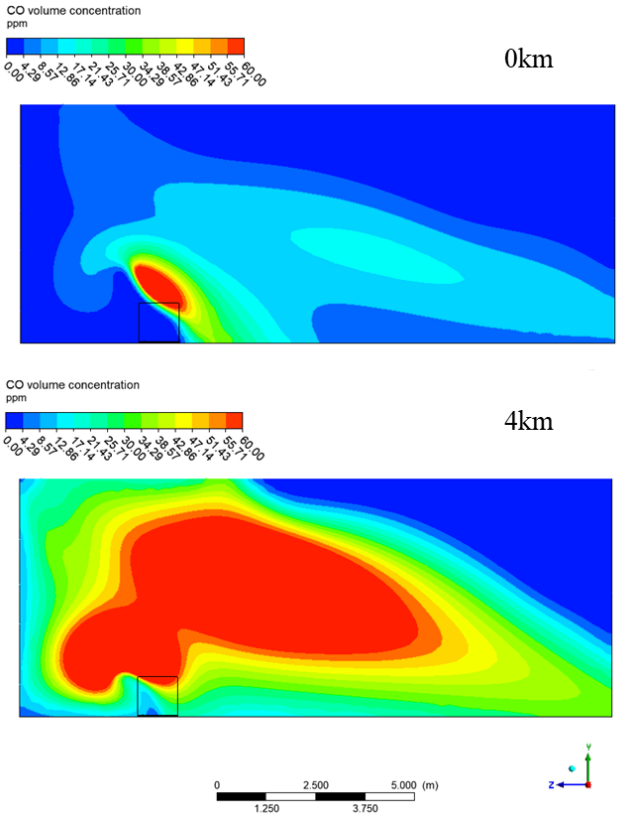

Figure 2. CO concentration distribution.

From the simulation results, even if the source intensity of pollutants remains the same, the concentration distribution of polluted gases varies under different environmental conditions. According to the previous analysis of the mathematical model, such differences are due to the fact that different environments affect the gas diffusion coefficient, thus resulting in differences in the pollutant concentration distribution. By using relevant analysis methods, the correlation between the diffusion coefficient and environmental conditions can be further analyzed.

3.2. ANALYSIS OF THE IMPACT OF ALTITUDE ON CO DIFFUSION

To study the impact of altitude on CO gas diffusion during high-altitude tunnel construction, the variation in tunnel CO mass concentration was calculated for five altitude scenarios (0, 1,000, 2,000, 3,000, and 4,000 meters). All parameters except altitude remained the same. The meteorological parameters used in the study are shown in Table 2.

Table 2. The meteorological parameters.

Altitude (m)	Pressure (Pa)	Air Temperature (℃)	Air Density (kg/m³)
0	101325	15	1.225
1000	89870	8.5	1.112
2000	79500	2	1.007
3000	70110	-4.5	0.909
4000	61640	-11	0.819

As altitude increases, various environmental factors in the atmospheric environment such as air

density, atmospheric pressure, temperature, and humidity will change. Even with the same source intensity, these changes cause the volume of pollutant gases to increase with altitude, resulting in differences in the mass concentration distribution of pollutant gases during the diffusion process in tunnel chambers. The change in atmospheric pressure is the main reason for ventilation differences in high-altitude tunnel areas. Changes in atmospheric pressure alter the static pressure distribution in tunnel chambers, affecting the tunnel's ability to remove pollutants (Cao et al., 2016). Therefore, when studying the impact of altitude changes on CO diffusion in tunnels, temperature and humidity changes are ignored, and only the two main factors of atmospheric pressure and air density are considered.

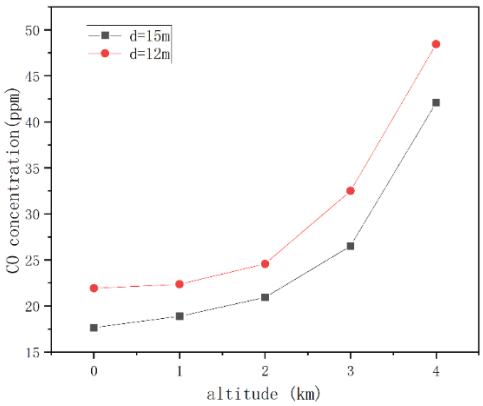

Figure 3. CO concentration at different altitudes.

During the ventilation process, vortex zones form near the tunnel face. Consequently, in the initial stages of CO diffusion, the distribution pattern near the face is highly complex due to the influence of vortices and airflow recirculation. Cross-sections at 12 and 15 meters from the tunnel face are selected to calculate the variation in CO mass concentration at different altitudes, as shown in Figure 3. It is observed that as altitude gradually increases, the CO mass concentration at the same measurement point in the tunnel rises.

To further investigate the relationship between CO mass concentration and altitude during the diffusion process, introduce an altitude-based correction coefficient for CO mass concentration. Under the same ventilation time and distance, assume that the CO mass concentration in a high-altitude tunnel is:

$$C_P = f(C_0,\ P) \tag{9}$$

Where C_P is the CO concentration at altitude p, and P is the atmospheric pressure.

Selecting monitoring planes at 3-meter intervals within the CO diffusion area, recording the average concentration on each plane, and calculating the variation of CO mass concentration with altitude in this region, the results are shown in Table 3.

Table 3. The meteorological parameters.

Altitude (m)	Plane 1	Plane 2	Plane 3	Plane 4	Plane 5
0	2.68	4.78	7.61	10.61	10.63

1000	2.73	4.72	7.30	10.24	7.58
2000	3.02	5.23	8.02	11.19	7.63
3000	4.06	7.17	11.31	15.73	15.54
4000	6.87	18.60	28..41	39.34	48.06

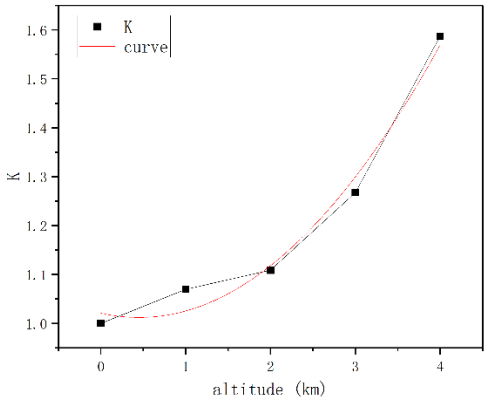

Figure 4. CO concentration at different altitudes.

By fitting the data in Table 3, the fitted curve is shown in Figure 4. It can be seen that the fitting degree R^2 of the equation fitted using the calculation results is greater than 95%, which demonstrates the accuracy of the prediction model. The equation for CO concentration based on altitude during the ventilation and pollution discharge process in tunnels at different altitudes is as follows:

$$\frac{C_P}{C_0} = 1.02071 - 0.03981H + 0.04423H^2 \quad (10)$$

At present, for long-distance tunnels at high altitudes, regulations do not provide clear definitions for ventilation volume and ventilation time. Therefore, the proposed CO concentration correction coefficient based on altitude during the ventilation and pollution discharge process in tunnels at different altitudes can serve as an excellent supplement. It has significant reference and guidance value for the preliminary design of ventilation systems and the estimation of ventilation time during operation in high-altitude areas.

SUMMARY
It is projected that by 2050 70% of the world population will be living in urban areas. Urban Heat Island (UHI) effect is a significant phenomenon that affects urban environments, exacerbating the already elevated temperatures in cities and leading to an increase in illness and mortality. By definition, UHI occurs when urbanized areas experience higher temperature compared to the surrounding. This phenomenon is associated with a closed circulation, characterized by an updraft at the city center and a downdraft at the edge of the circulation. In this study, first a validation of Computational Fluid Dynamics (CFD) simulations of UHI conducted using OpenFOAM is carried out by replicating the set-up of a temperature-controlled water tank experiment reported in Cenedese and Monti, 2003. Then the computational set-up is modified to appropriately conduct a full-scale simulation of convective currents due to UHI in a sample city.

Keywords: UHI effect, urban microclimate, heat transfer, climate change.

1. INTRODUCTION

The Urban Heat Island (UHI) effect is a significant phenomenon that affects urban environments, exacerbating the already elevated temperatures in cities and leading to an increase in illness and mortality (Beniston et al., 2007). By definition, UHI occurs when urbanized areas experience higher temperature compared to the surrounding environment. This is due to a modification in the energy balance accompanying the process of urban development (Oke, 1995). In unstable conditions, during the day, and stable conditions, during the night, and with no concurrent synoptic wind, the circulation associated with UHI effect is described by an updraft inside the city characterized by a convergence at the ground and divergence at the top and by a downdraft that occurs at the edge of circulation, generating a close wind flow.
By the end of the last century, with increasing awareness towards the environment and with the consolidation of the UHI effect as one of the most prominent consequences of urbanization and

climate change (Jamei et al., 2005), the number of studies on UHI and related effects have also increased. Some studies were carried out using numerical simulations (e.g., (Mei et al., 2025; Yoshikado, 1992)) while others were carried out through experimental analysis (e.g., Cenedese and Monti, 2003; Fan et al., 2019; Lu et al., 1997). A water tank model and the natural atmosphere are considered to be thermally similar if equivalent boundary layers occur at equivalent times in both situations (Yuan et al., 2011).
In this study, two different computational domains are being analyzed: the first one will serve as a validation using Cenedese and Monti, 2003 experiments, and therefore the same set-up is reproduced using Computational Fluid Dynamics (CFD). The second one will be a full-scale domain with building clusters. A brief description of the set up will be presented in the methodology and some preliminary outcomes of the study in the section to follow.

2. METHODOLOGY

Computational Fluid Dynamics (CFD) offers a unique opportunity to reproduce complex environmental phenomena at full scale. However, validation is required to prove that reliable and realistic results can be obtained. Accordingly, CFD simulations of the UHI effects experimentally investigated by Cenedese and Monti, 2003 have been carried out as reported in the following sections.

2.1. Experimental set up description

The experiment by Cenedese and Monti (2003) has been carried out using a temperature-controlled water tank of 0.96 m $\times$ 0.30 m $\times$ 0.095 m (respectively along axis x, y and z), as presented in Figure 1. The tank was originally divided in two sections, one representing the sea and the other one the land, but for the purpose of this research the part of the sea is neglected.
The temperature at the top of the tank was maintained at a constant temperature of 46°C (319 K) while on the bottom side a circular-shaped electric heater was place in order to simulate the temperature surplus associated with the UHI. The range of heat flux generated was between 300 $\mathrm{W/m^2}$ and 2000 $\mathrm{W/m^2}$. The temperature of the surrounding ground was maintained constant at temperature of 27°C (300 K) during the noctural simulation and 31°C (304 K) during the diurnal simulation.

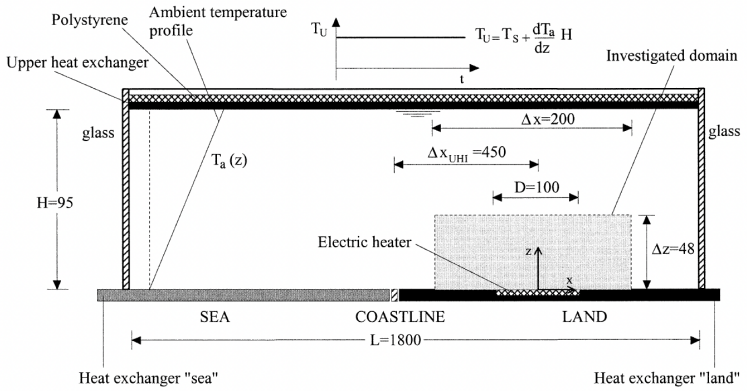

Figure 1. Experimental set up of the water tank. Lengths in mm. From Cenedese and Monti (2003).

2.2. Computational set up description

At first, the experiment of Cenedese and Monti (2003) (only the set up associated with land) is replicated at the same scale using the open source CFD software OpenFOAM (Figure 3a). The solver used for carrying out this simulation is `buoyantBoussinesqSimpleFoam`, based on the Boussinesq assumption. The same boundary conditions are maintained as well: `fixedValue` condition at the top and bottom of the domain, `fixedGradient` for the circular heat exchanger.

In the second part of the study, the domain in scaled by a factor of 10^4 in order to simulate a full-scale condition. Moreover, the fluid is changed from water (with Prandtl number Pr = 6.9, and thermal diffusivity,$\alpha = 0.14 \times 10^{-6} \mathrm{m}^2/\mathrm{s}$) to air (Pr = 0.71, $\alpha = 22.5 \times 10^{-6} \mathrm{m}^2/\mathrm{s}$) in order to represent a real atmospheric boundary layer.

Finally, the circular heater representing the city is replaced with a cluster of buildings corresponding to a neighborhood of the city of Genoa to study how the generated flow by the HIC interacts with the buildings (Figure 3b).

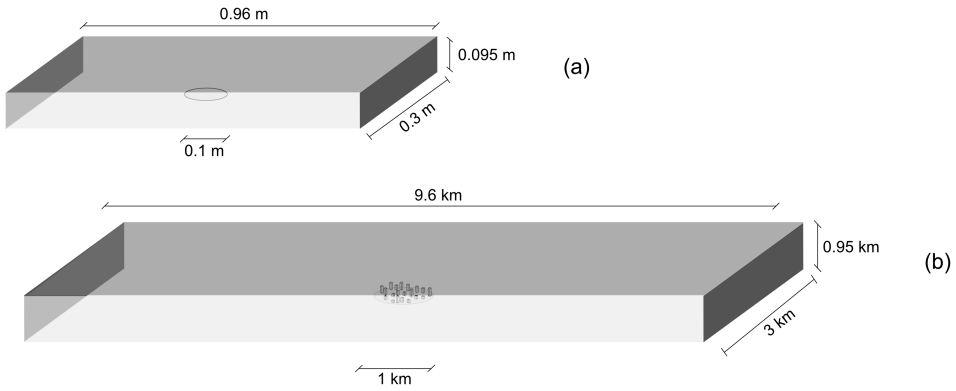

Figure 2. a) Computational domain of the water tank by Cenedese and Monti, 2003 and b) Computational domain full scale.

3. PRELIMINARY RESULTS

The comparison of the Cenedese and Monti (2003) experiment with the CFD shows a good agreement in terms of temperature profiles and flow fields. Figure **??** shows the normalized temperature profiles measured at different distances from the center of the heat exchanger. The profile measured at x/D = 0.75 (external from the circular heat source) shows the least agreement, which is probably related to a limitation of the solver, where conduction between layers is neglected. A good agreement is maintained also in the Heat Island Circulation (HIC) dynamics, where is possible to observe the peculiar shape of the urban heat island (Figure 3).

Further investigations are ongoing for fully evaluating the similarity between the small experimental simulation and the full-scale computational domain and will be presented at the conference.

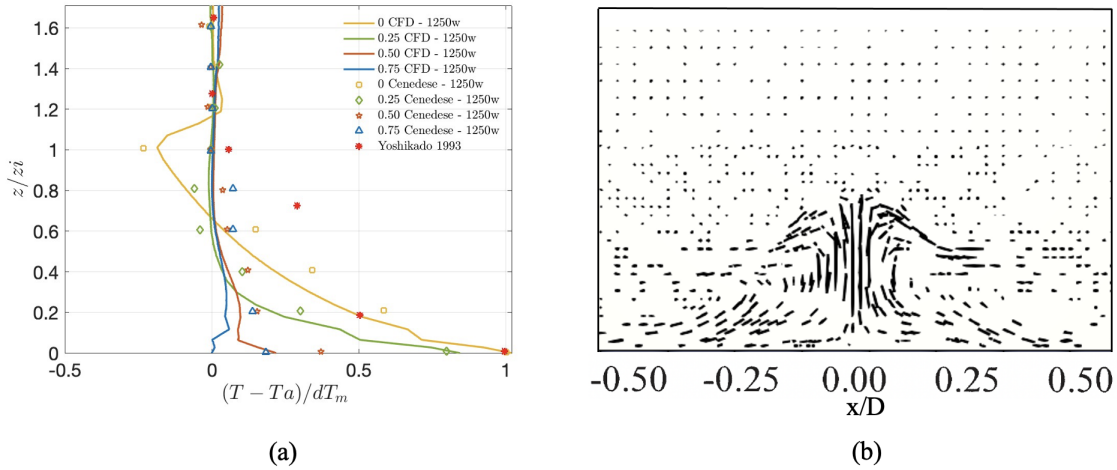

Figure 3. (a) Normalized mean temperature profiles as a function of the radial distance from the UHI center for case with heat flux = $1250W/m^2$ and the vertical displacement z with the mixing height z_i and (b) average velocity vectors for case with heat flux = $1250W/m^2$

SUMMARY
Buildings play a critical role in urban heat stress, particularly in dense metropolitan areas like Ahmedabad. The built environment's thermal properties significantly influence urban microclimate, with roof characteristics being a key factor in heat island mitigation. Using ENVI-met simulation software, three urban sites with varying built cover ratios (BCRs) of 20:80, 35:65, and 50:50 and solar reflectance indices (SRIs) were analysed. The study revealed significant air temperature reduction potential through cool roofs (CR), with the most substantial cooling observed at a 50:50 built cover ratio and a solar reflectance index of 110 (reflectance of 0.85; emittance of 0.95). Peak hour air temperature reductions reached (-)4.24°C, accompanied by space cooling energy demand reductions of up to 19.08%. Cool roofs offer urban planners in India a strategic solution to mitigate urban heat islands, improve public health, and enhance energy efficiency in sustainable city development.

Keywords: Urban Heat Island, Microclimate, Pedestrian Air Temperatures, Energy Consumption.

1. INTRODUCTION

Ahmedabad faces a critical environmental challenge with the Urban Heat Island effect (UHIE), driven by rapid urbanization and extensive construction ("Ahmedabad Records Hottest Day in Century as Mercury Hits 48 Degrees Celcius | Ahmedabad News - The Indian Express," 2016). In 2016, the city recorded its highest ambient air temperature in 100 years at 48°C, highlighting the severity of urban heat issues. UHI emerges from changes in surface energy balance, characterized by lower albedo and higher Bowen ratio compared to natural surfaces (Li et al., 2019). Urban areas absorb more solar radiation, leading to excessive daytime heat and prolonged night-time heat retention (Giridharan et al., 2004; Oke, 1981).

Cool Roofs (referred to as CR) are thermal management systems characterized by high solar reflectance and thermal emittance. They have emerged as a promising mitigation strategy for UHIE (Golden et al., 2007; Khare et al., 2021; Zonato et al., 2021). Direct benefits include significant indoor air temperature reduction, with studies showing potential decreases of 3-4°C (Vellingiri et al., 2020). They directly lower cooling electricity requirements and minimize sensible heat flux, providing immediate thermal comfort improvements (Wang et al., 2022). Co-benefits extend beyond individual building performance. CRs contribute to broader urban thermal management by decreasing outside ambient air temperatures. This improves the efficiency of air conditioning system by decreasing strain on the condensing units in the refrigeration cycle. (Santamouris et al., 2001).

2. PROBLEM STATEMENT

In the heart of Gujarat, Ahmedabad emerges as a microcosm of India's rapid urban transformation, embodying the complex interplay between economic development and environmental sustainability. The city's metamorphosis from the "Manchester of the East" to a diversified economic powerhouse reflects a broader narrative of urban growth that comes with significant ecological challenges. Between 2001 and 2011, the city's population surged by 51%, dramatically outpacing national growth rates. Studies by (Garg et al., 2018) and (Mohammad et al., 2022) reveal that open spaces have diminished by 7%, cropland by 36%, and water bodies by 2%, while built-up areas continue to expand. By 2021, Ahmedabad had lost 1.47km^2 of lakes, the heat sinks and natural stormwater management zones. The city's tree cover of 6.8 m^2 per person falls short of the WHO's 9m^2 recommendation, amplifying UHIE. Future projections are even more alarming: built-up cover is expected to increase by 13.08% by 2030, while cropland is predicted to decrease by 12.54% (Mohammad et al., 2022). With Ahmedabad projected to experience 225 days annually where maximum temperatures exceed 35°C (Mackres et al., 2023), and a Universal Thermal Climate Index (UTCI) above 46 points for 311 out of 365 days (World Bank and CEPT University, 2023), the urgency for innovative cooling solutions becomes paramount. By examining the interaction between CR technologies and Ahmedabad's diverse urban landscapes, this study aims to develop targeted interventions that can simultaneously address urban heat stress, energy efficiency, and sustainable urban development.

3. LITERATURE REVIEW

Elevated temperatures worsen health, energy use, and environmental conditions, intensifying heat waves, straining ecosystems, and worsening air pollution. Ahmedabad's roof area covered 41% of the city in 2020 and is projected to reach 48% by 2030 (Joshi et al., 2022). Conventional dark roofs absorb over 80% of solar radiation, worsening climate warming. CRs along with the appropriate level of insulation, can help cool buildings and cities.

3.1 Conventional Roofs vs Cool Roofs

Surfaces with low albedo absorb more solar radiation, increasing their surface thermal energy. Highly reflective and emissive surfaces remain at a lower surface temperature (ASTM International, 2001). By reflecting the heat-carrying radiation towards the atmosphere, CRs minimize heat absorption and maintain lower surface temperatures. Consequently, the reduced surface temperature of CRs leads to a two-fold benefit. Less heat gets transferred into the building interior via conduction, minimizing the heat gain within the occupied space. As wind flows over the cooler roof surface, the temperature difference between the surface and the surrounding air is minimized. This reduces the driving force for convective heat transfer, further contributing to a cooler ambient environment. The combined effects of selective reflectance and reduced conductive and convective heat transfer result in a cooler surrounding environment and a significant reduction in heat gain within buildings equipped with CRs.

3.2 Impact of Cool roofs on energy consumption

India's energy landscape faces a critical challenge: limited air conditioning penetration (7-9% of housing units) coupled with buildings consuming 33% of total electricity. Projections suggest a dramatic increase from 372 to 4,697 TWh annually by 2047, highlighting the urgent need for energy-efficient solutions. CRs emerge as a promising mitigation strategy. (Rawat & Singh, 2022) found approximately 15% energy savings with an average roof surface temperature reduction of 2.4°C. Microclimate studies provide compelling evidence. (Santamouris et al., 2020) revealed that

integrated reflective materials could reduce peak air temperatures by 2.5–3.0°C during summer. Reflective materials with high SRI values have been shown to reduce land surface temperatures by up to 10°C. The energy-saving potential is significant. (Goldstein et al., 2017) suggest that a 1°C temperature decrease can translate to a 3-6% reduction in cooling electricity demand. In Ahmedabad, (Joshi et al., 2022) estimated annual energy savings of 14.2 kWh per square meter through CR implementation. The effectiveness of CRs extends beyond simple reflectivity. Well-insulated designs outperform conventional roofs, with material composition, thermal emittance, and surface characteristics playing crucial roles in energy efficiency.

4. RESEARCH METHODOLOGY

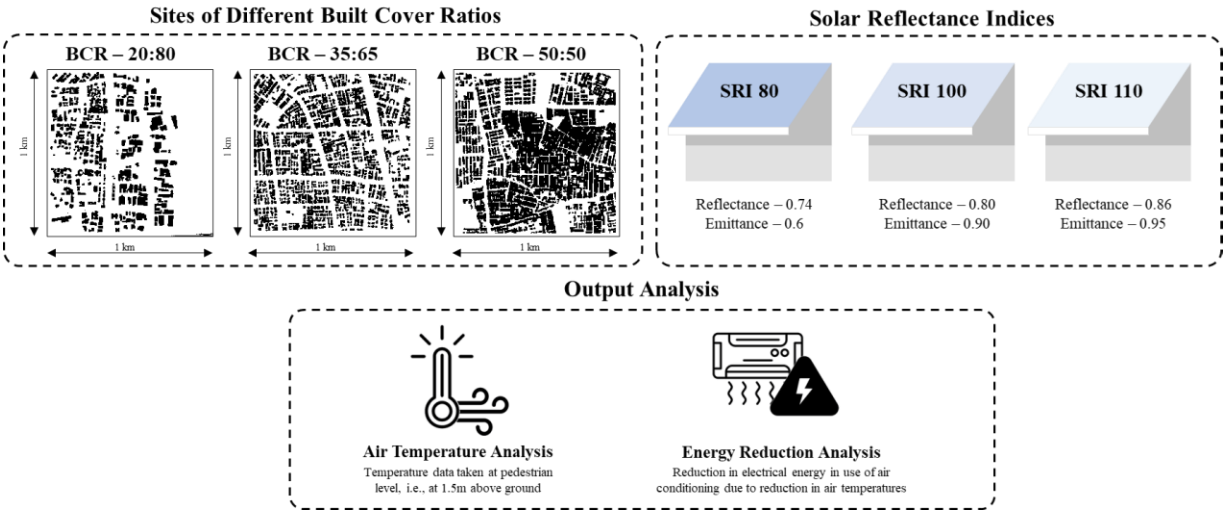

Figure 1. Infographic of methodology for different BCRs and SRIs proposed for the study

To assess the effectiveness of CRs for a reduction in warming due to the heat island effect, several methodologies can be employed. The research involves identifying the built cover ratio of areas for analysis and then identifying the SRI values for implementation on the roofs for modelling. Weather data sourced from the Energy Plus Weather (EPW) file is converted into a forcing file. Subsequently, ENVI-met modelling is conducted, followed by a detailed analysis.

4.1 Site Selection to obtain Built Cover Ratios (BCR)

Table 1. Description of sites with different BCRs chosen for simulation

BCR	20:80	35:65	50:50
Site Map			Description	The 1 sq. km. area is part of the Central Business District	The 1 sq. km area comprises a mix of business,	The 1 sq. km area is a mix of businesses, institutions,

	(CBD) of Ahmedabad. It is placed on the Sabarmati riverfront. 60% of the built cover comprises office spaces. The built cover ratio is 20:80, i.e., 20% is built while the remaining 80% is covered by roads and pavements (53%), green cover (9%) and water (18%).	institutional, healthcare and residential areas. The built cover ratio is 35:65, i.e., 35% is covered by built structures while the remaining 65% is covered by roads and pavements (55%) and green cover (10%).	healthcare facilities, and residential neighbourhoods. 50% of the area is covered by buildings, remaining 50% is a mix of roads and pavements (46%), and green cover (4%).

4.2 Modelling and Simulation Inputs

The model is made with the help of shapefile which has been taken from the Centre for Advanced Research in Building Science and Energy (CARBSE) database. The shapefile contains model information regarding the shape of the building, building height from the ground and the precise location of the building. The trees on the site have been marked with the help of Google Earth.

4.2.1 Weather Data

The Energy Plus Weather File (EPW) for Ahmedabad provided a detailed hourly weather data for May 20th (peak day according to Dry Bulb Temperature). A heat transfer lag of about 4 hours is observed between the DBT and the Global Horizontal Radiation. On this day, there is a significant temperature variation of 17°C between the maximum and minimum temperatures, with the maximum reaching 46°C at 5 PM. In contrast, solar radiation peaks at 972 Wh/m² at 1 PM.

4.2.2 Wall and Roof Construction

Energy Conservation Building Code (ECBC) sets out guidelines that define the minimum energy performance standards for buildings in India; considers for roof to be "cool", it must have an SRI of 80 or higher, with a reflectance of at least 0.7 and emittance of 0.75. Ahmedabad's hot and dry climate is considered, and the study explores CR materials with SRI values of 80, 100, and 110 with detailed physical properties given in Table 2.

Table 2. Physical properties of Wall and Roof used for simulations

Building Envelope	Wall	Roof		
SRI	44	80	100	110
Absorptivity	0.6	0.26	0.20	0.15

4.2.3 Trees, Grass, Soil and Road

In modeling the urban environment, indigenous vegetation was selected based on Central Pollution Control Board guidelines (CPCB, 2000). From 200 native Gujarat plant species, three trees were chosen considering height and crown surface area. Grass was selected from the ENVI-met library with a standard height of 0.25m. For soil and road materials, standard ENVI-met library options were utilized. The predominant soil type in Ahmedabad is Loamy, characterized by zero reflectance and 0.9 emissivity, with a non-irrigated surface. The road surface is Asphalt, featuring a reflectance of 0.15 and emissivity of 0.9.

4.3 Limitations

The research methodology reveals limitations in urban thermal performance analysis. By relying exclusively on BCR and neglecting building height considerations, the study potentially oversimplifies thermal dynamics. The restricted dataset, comprising only three sets of BCRs and SRI values, constrains the comprehensiveness of findings. Computational efficiency drove the deliberate exclusion of terrain complexities, with wind parameters standardized at 2m/sec and 270° across simulations. The use of Level of Detail-1 (LOD-1) modelling further restricted granularity, focusing solely on building form while excluding intricate architectural details like fenestration. Additionally, the uniform residential building typology disregards thermal performance variations across different building use categories, potentially limiting the study's broader applicability and insights.

5. RESULTS AND CONCLUSION

All the site scenarios were simulated for the peak day, i.e., May 20th. The air temperatures were extracted for pedestrian level i.e., at 1.5m above ground level. The air temperature values were averaged out for the whole site to analyse the effect of each hour. Sinsel's 2021 study investigated the impact of super CRs on pedestrian-level air temperatures across different urban environments. Current study followed the same framework to extract air temperature data at 1.5m height, which was averaged for further analysis.

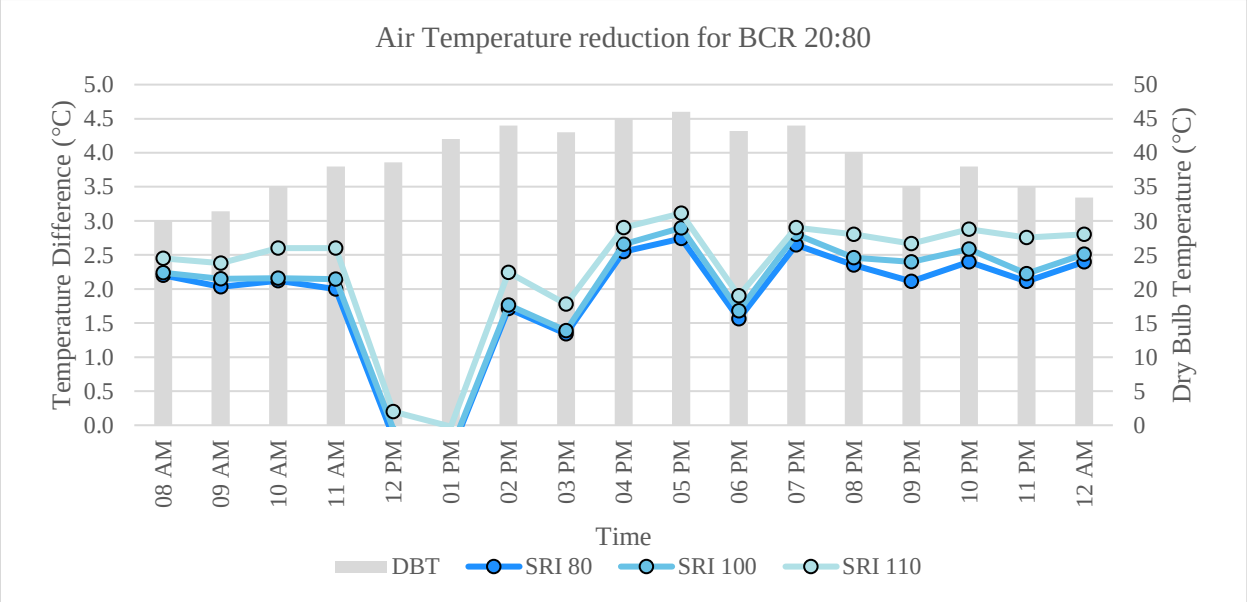

Figure 2. Air temperature reduction for BCR 20:80 and SRI 80,100 and 110

The investigation of air temperature reduction across different BCR scenarios reveals nuanced thermal dynamics influenced by SRI variations. In the BCR 20:80 configuration (Figure 2), the peak DBT hour demonstrated the most modest temperature reduction with SRI 110, achieving a 3.11°C decrease, followed by SRI 100 and SRI 80. Notably, the average air temperatures exhibited negative reductions, indicating temperatures higher than the .epw DBT values during peak solar radiation periods.

Similar thermal behavior was observed in the BCR 35:65 scenario (Figure 3) where the air temperature reduction at peak DBT hour was marginally lower at 2.87°C with SRI 110, again followed by SRI 100 and SRI 80. Unlike the previous case, these reductions remained positive, though diminished around 3 PM near the peak solar radiation timeframe.

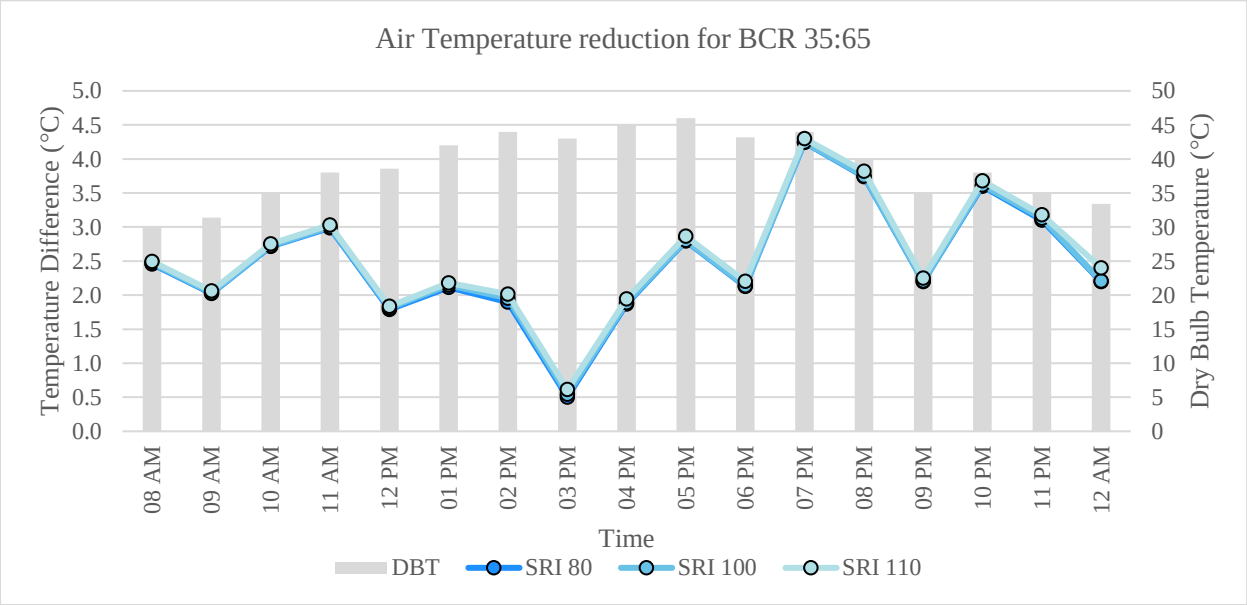

Figure 3. Air temperature reduction for BCR 35:65 and SRI 80,100 and 110

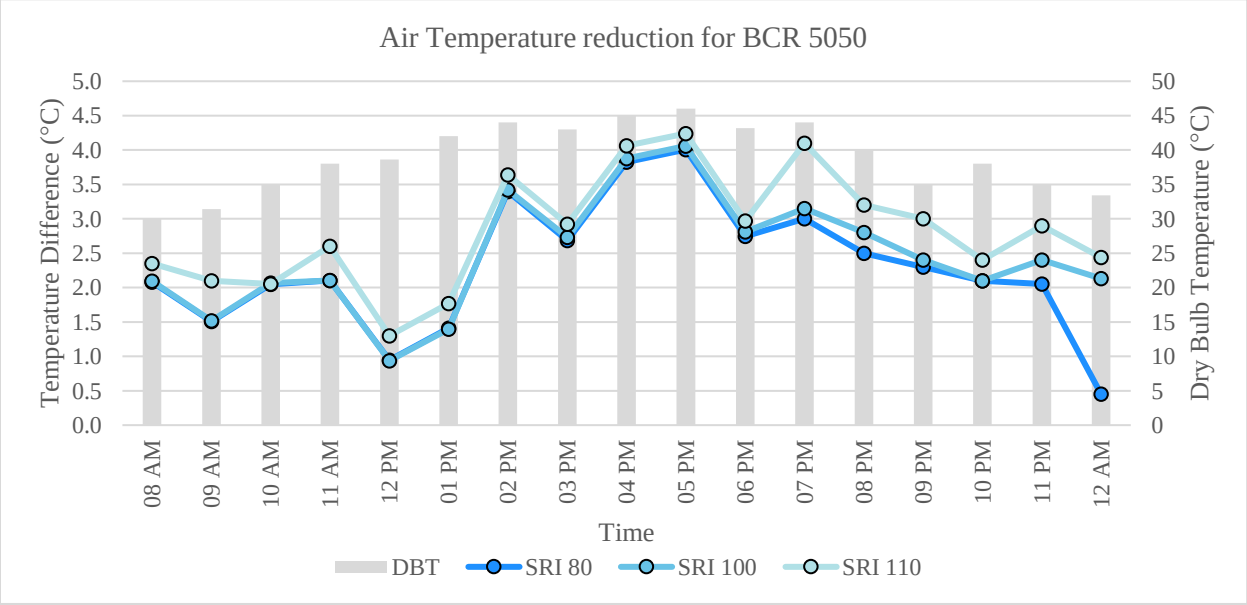

Figure 4. Air temperature reduction for BCR 50:50 and SRI 80,100 and 110

The BCR 50:50 configuration presented comparable thermal characteristics (Figure 4), with the lowest air temperature reduction of 4.24°C occurring with SRI 110. There is a heating effect near peak solar radiation hours, with a discernible temporal lag. Temperature analysis between 8 AM and 12 AM revealed distinct patterns (Figure 5). Minimum temperatures consistently occurred at 8 AM, while maximum temperatures peaked at 5 PM, aligning with the EPW file's peak DBT.

Of particular interest was the observation that the BCR 50:50 scenario exhibited the highest average minimum air temperatures, attributable to its more substantial urban geometric configuration. The finding highlights how urban geometry, solar reflectance, and material choices influence heat dynamics, emphasizing their role in mitigating heat island effects.

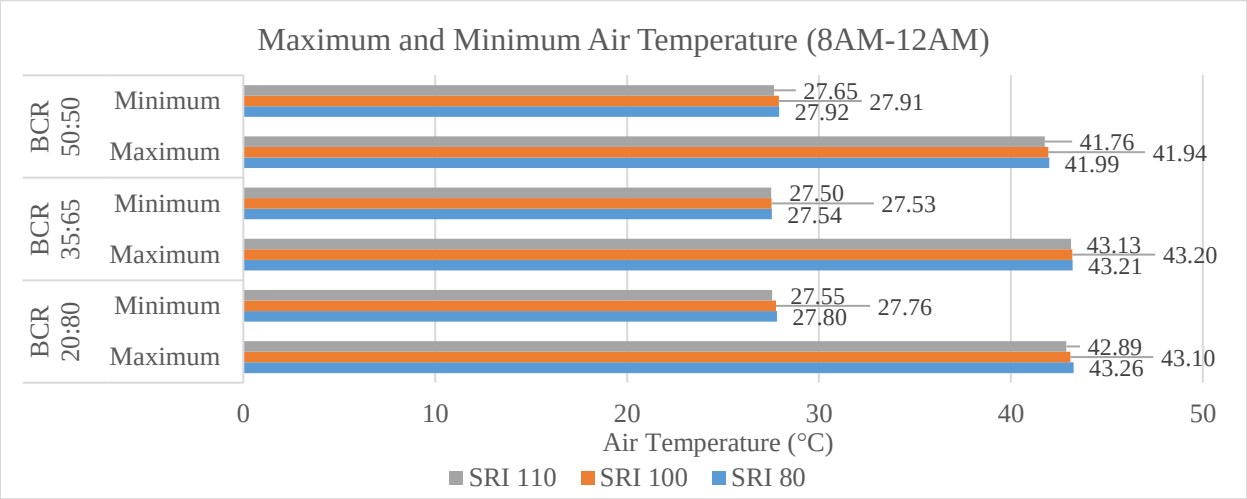

Figure 5. Maximum and minimum Air temperature for different BCR and SRI

The 50:50 BCR with SRI 110 emerges as the optimal case amongst all of the above as this configuration ensures that 50% of the horizontal built surface is covered with high-performance, heat-reflective material. Consider the thermal dynamics: in the 50:50 scenario, half of the horizontal urban surface (roof) becomes a reflective shield against solar radiation. In contrast, the 35:65 ratio limits high-SRI coverage to 35% of horizontal surfaces, while the 20:80 configuration reduces this to 20% horizontal reflective area.

Additionally, the indirect impact of cooler temperatures on cooling loads is noteworthy. An average reduction of 4.5% was considered, leading to a maximum reduction of 19.08% with a BCR of 50:50. Similarly, reductions of 14% and 12.9% were observed for ratios of 20:80 and 35:65, respectively (Figure 5).

6. DISCUSSION

The study provides critical insights into UHI mitigation through innovative material and geometric configurations. By examining the interplay between building coverage ratios and solar reflectance indices, the research reveals nuanced strategies for temperature reduction. The 50:50 BCR and SRI 110 emerged as a promising approach, demonstrating temperature reductions of 2.87°C to 4.24°C and potential cooling energy savings up to 19% in heat-intensive urban environments. The observed temporal lag in heat absorption highlights the complex thermal dynamics of urban surfaces, underscoring the importance of strategic material selection and urban design interventions. Future research should focus on exploring diverse urban contexts, advanced material technologies, and comprehensive green strategies to further enhance urban microclimate management and energy efficiency.

SUMMARY
This study focuses on the Huzhu Beishan High-Altitude Long Tunnel and leverages CFD simulations to evaluate the velocity field and CO concentration field under jet fan spacings of 150 m, 200 m, 250 m, and 300 m. Incorporating vehicle types and traffic volume data obtained through field surveys, along with the traffic three-phase flow theory, various vehicle distributions were designed to reflect different speeds. The momentum source method was employed to simulate the piston effect of vehicles on the tunnel airflow. Furthermore, vehicle CO emissions were adjusted to account for high-altitude environmental conditions. To validate the simulation results, experimental data from the Yingtian Street Yangtze River Tunnel in Nanjing was used as a benchmark. Through an analysis of the CO concentration distribution, it was determined that a 150m longitudinal spacing for jet fans satisfies the tunnel's air quality requirements.

Keywords: High-Altitude Long Tunnel, Jet Fan, Longitudinal Spacing.

1. INTRODUCTION

Under China's Belt and Road Initiative, the Qinghai-Tibet Plateau region, as a key trade and transportation hub, has experienced significant growth in its road network, accompanied by a notable increase in both vehicular and freight traffic (MOT China, 2022). Considering the unique geological conditions of mountainous regions, long tunnels have progressively become a critical component of modern transportation. Due to the enclosed structure, long tunnels are more prone to accumulating harmful gases, such as vehicle exhaust emissions. Therefore, ventilation systems are essential for diluting pollutant concentrations and ensuring the safe operation of the tunnels. Currently, longitudinal ventilation systems are the preferred solution for ventilation in many ultra-long highway tunnels (PIARC. 2016).

However, in high-altitude regions such as the Qinghai-Tibet Plateau, the reduced air pressure and oxygen concentration can significantly affect engine load and combustion characteristics, thereby influencing vehicle emissions (Wang et al., 2018). Furthermore, the ventilation efficiency of longitudinal ventilation systems depends on the induction and pressurization effects produced by the jet fans. In low-pressure environments, the thrust of jet fan blades is reduced, resulting in a diminished effective working range. Therefore, to ensure optimal performance of the ventilation system, it is essential to investigate the appropriate longitudinal spacing of jet fans. This study focuses on the high-altitude, ultra-long tunnel at Huzhu North Mountain, utilizing field survey data on vehicle types and traffic volumes. Using CFD numerical simulations, the CO concentration

distribution under varying longitudinal spacings of jet fans was assessed. The findings of this study offer valuable insights into the design of jet fan arrangements in high-altitude tunnels.

2. METHODOLOGY

2.1. Model Description

The Huzhu Beishan Extra-Long Tunnel, located on the Jiaxi Highway in Qinghai Province, is a Grade I highway tunnel featuring twin bores and four lanes. The average length of the left and right bores is 11.15 km, and the tunnel is equipped with two ventilation shafts measuring 1.1 km and 1.4 km, respectively. With an altitude of approximately 3 km at both the entrance and exit, it is the second extra-long tunnel in China constructed in a cold, high-altitude region. This tunnel surpasses the previous record held by the Laqi Mountain Tunnel in Qinghai Province (total length of 5.55 km) and is now the longest tunnel in Qinghai Province. The schematic plan of the ventilation design is shown in Fig. 1. To evaluate the ventilation effect of jet fans, the working area of the jet fan closest to the exhaust port of Ventilation Shaft 1 in the left bore was selected for simulation. The area is about 5.92 km away from the tunnel entrance, and the CFD model is shown in Fig. 2.

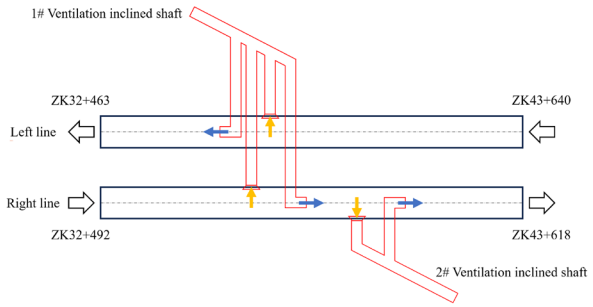

Figure 1. Ventilation Design for the Huzhu Beishan Long Tunnel.

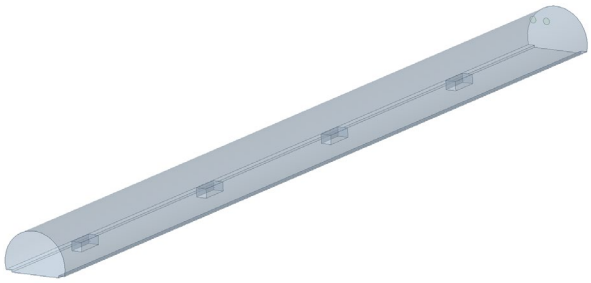

Figure 2. CFD Model.

Based on the traffic volume survey of the road section where the tunnel is located, the equivalent traffic volume, adjusted for the proportion of different vehicle types, is 6,416 PCU/day for the near-term scenario and 17,081 PCU/day for the long-term scenario. The peak-hour traffic volume is estimated to account for 12.5% of the daily traffic volume. According to the three-phase traffic flow theory, four representative vehicle speeds—80 km/h, 60 km/h, 40 km/h, and 20 km/h—are selected to represent distinct traffic conditions. Referencing to the summary of the pollutants emitted by vehicles and their corresponding amounts in China in 2021, carbon monoxide (CO) and

nitrogen oxides (NOx) account for 49.3% and 37.4% of the total emissions, respectively (Zhao et al., 2023). Considering that standard passenger cars are predominantly gasoline-powered, CO is selected as the target pollutant for this study.

2.2. Turbulence Model and Boundary Conditions

This study utilizes the Realizable k-epsilon turbulence model (Shih et al., 1995), which provides notable advancements in the analysis of circular jets and has been validated as an effective approach for simulating tunnel ventilation (Xu et al., 2021).

2.3.1. Environmental characteristics at high altitudes

Air parameters such as atmospheric pressure, temperature, and gas density are changed when the altitude rises. The effects of altitude changes need to be fully considered when designing the simulation of high-altitude tunnels to ensure the credibility of the simulation results. The equation for the variation of atmospheric pressure with altitude can be deduced by considering the temperature variation in the troposphere at altitudes from 0 to 11 km (Jiang et al., 2021):

$$P = P_0 \cdot \left(\frac{T - k\mu gH}{T}\right)^{\frac{1}{kR}} \tag{1}$$

Where P_0 is the standard atmospheric pressure, 101325Pa; μ is the molar mass of air, 29 kg/mol; g is the acceleration of gravity, 9.8 m/s^2; R is the universal gas constant, 8.314 kJ/(kmol·K); T is the temperature, K; H is the altitude, km; $k = \gamma - 1/\gamma R = 0.02268$, where γ is the molar heat capacity ratio.

According to the ideal gas equation of state $PV = mRT/M$, the air density at different air temperatures and pressures can be deduced:

$$\frac{\rho}{\rho_0} = \frac{P}{P_0} \cdot \frac{T_0}{T} \tag{2}$$

Where ρ_0 is the density of air at standard conditions, 1.293 kg/m3.

2.3.2. CO emissions at various vehicle speeds in high-altitude areas

A comprehensive experimental study on vehicle carbon emissions in high-altitude regions was conducted to investigate the CO_2 emission factors of vehicles across different altitudes (2.0–4.5 km), as well as the emission ratios of other gases, including CO and NOx, relative to CO_2 (Jiang et al., 2024).

VSP (Vehicle Specific Power) provides a comprehensive measure of the actual engine load and CO_2 emissions from the motor vehicle. It is the ratio of engine power to vehicle mass, simplified as Eq. (3),

$$VSP = \frac{[A \cdot v + B \cdot v^2 + C \cdot v^3 + (a + g \cdot grade) \cdot v \cdot m]}{m} \tag{3}$$

Where VSP is the instantaneous vehicle specific power (kW/t); v is the instantaneous speed (m/s); a is the instantaneous acceleration rate (m/s^2); $grade$ is the road grade; m is the total vehicle mass (t); A is the rolling resistance coefficient (kW·s/km); B is the friction

coefficient (kW·s^2/km^2); C is the aerodynamic resistance coefficient (kW·s^3/km^3).

At an altitude of 2.5–3.0 km in the Huzhu Beishan Tunnel, the CO_2 emission factor is determined to be 167 g/km. By assuming a standard passenger vehicle mass of 1,500 kg, the VSP values were calculated for four representative vehicle speeds—80 km/h, 60 km/h, 40 km/h, and 20 km/h—along with the corresponding CO emissions. The results are summarized in the Table 1.

Table 1. CO emissions at various vehicle speeds.

Velocity (km/h)	20	40	60	80
VSP (kW/t)	-0.957	-1.914	-2.87	-3.827
CO emission (g/h)	13.74	27.39	45.09	60.12

2.3.3. Vehicle motion model

Vehicles are the primary source of air pollution in tunnels, and their movement exerts a notable influence on tunnel air, commonly referred to as the piston effect. Strictly speaking, vehicle movement is a transient phenomenon. However, under stable traffic conditions, the interaction between vehicles and tunnel air can be approximated as steady-state. The force exerted by an individual vehicle on tunnel air is defined as follows (Lin et al., 2018):

$$F = \frac{\rho}{2} \cdot C_d \cdot (U_{car} - U_t) \cdot |U_{car} - U_t| \cdot A_{car_front} \tag{4}$$

Where C_d is the vehicle drag coefficient, Dimensionless; U_{car} is the vehicle speed, m/s; U_t is the longitudinal average wind speed of tunnel section, m/s; A_{car_front} is the vehicle frontal projected area, m2.

Let N_{real} represent the equivalent number of vehicles (in terms of standard passenger cars) under actual traffic conditions, and N_{geo} denote the number of vehicle geometric models used in the CFD simulation. A vehicle correction factor, f, is introduced, defined as $f = N_{real}/N_{geo}$. Assuming vehicles are uniformly distributed within the tunnel and travel at a constant speed, the influence of an individual vehicle on the tunnel air is expressed in Eq. (5) to Eq. (7).

$$S_{m,x} = \frac{F \cdot f}{V_{car}} \cdot \cos\theta \cdot \cos\varphi \tag{5}$$

$$S_{m,y} = \frac{F \cdot f}{V_{car}} \cdot \cos\theta \cdot \sin\varphi \tag{6}$$

$$S_{m,z} = \frac{F \cdot f}{V_{car}} \cdot \sin\theta \tag{7}$$

Where $S_{m,x}, S_{m,y}, S_{m,z}$ are the momentum source terms of the vehicle in three directions (x, y, z) in the Cartesian Coordinate System; θ and φ are the angles between the vehicle's motion direction and the global coordinate system axes.

The specific boundary conditions are as shown in Table 2. To meet the requirements of simulation accuracy, the first layer of the mesh in the boundary layer was set to 0.01 m to ensure that the y parameter fell between 30 and 300. And coarse, medium, and refined meshes were tested to ensure that the simulation results were independent of the mesh. Ultimately, the maximum size of

the tunnel space is 0.4m, the maximum size of the jet fan surface is 0.05m, and the total number of grids is approximately 5.6 million.

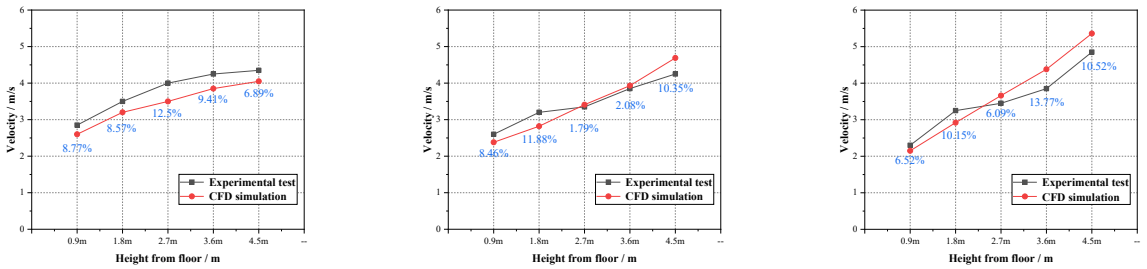
Table 2. The simulation conditions.

Project	Name	Settings
General	Gravity	9.81 m/s^2
	Pressure	70340Pa
	Ambient temperature	293.15K
Materials	Air density	0.834 kg/m3
	CO density	0.809 kg/m3
Boundary Conditions	Tunnel inlet	Velocity-inlet, 3m/s Temperature = 293.15K
	Tunnel outlet	Pressure-outlet
	Tunnel surface	Wall; Temperature=274.5K Roughness heights: 0.008m Roughness constant: 0.02
	Jet fans	Fan; Jet velocity: 35.6m/s
	Vehicle surface	Wall; Insulation Roughness heights: 0.01m Roughness constant: 0.02
	Exhaust tailpipe	Velocity-inlet Temperature = 350K (Song et al., 2019)

3. RESULTS

3.1. Model Validation

To ensure the accuracy of the numerical simulation results, the numerical model was validated through field tests conducted in the Yingtian Street Yangtze River Tunnel. For further details, please consult Reference (Zhao et al., 2022). The validation results as shown in Fig. 3, which indicate that the simulation values exhibit less fluctuation compared to the test values, with the relative error consistently remaining within 15%.



(a) (b) (c)

Figure 3. Vertical velocities at various distances downstream of jet fans: (a) 20 m; (b) 60 m; (c) 100 m.

3.2. CO Concentration Distribution

Initially, the distribution of CO within the tunnel was calculated for different longitudinal spacings of jet fans (150m, 200m, 250m, and 300m) with vehicles traveling at varying speeds. A monitoring plane at a height of 1.2m was selected, and the CO concentration results are presented in Fig. 4. According to tunnel health standards, under normal operating conditions (>20 km/h), the CO

concentration within the tunnel should not exceed 100 cm^3/m^3; during traffic congestion (≤20 km/h), the CO concentration should not exceed 150 cm^3/m^3. Consequently, the maximum value of the following CO distribution contours are based on the design concentration limits specified by the health standards.

The figure illustrates that: (1) In the initial stage of the jet, the convolution range is limited, and the CO concentration near the vehicle exhaust tailpipe is relatively high; (2) As the jet interacts with the surrounding air, the CO dilution effect increases, leading to a reduction in CO concentration; (3) As the jet further develops, its effectiveness diminishes, resulting in a weaker CO dilution effect and the spread of CO around the vehicles; (4) As the longitudinal spacing of the jet fans increases, CO accumulation in the far field intensifies, and the area exceeding health standards expands. Therefore, it is recommended that the longitudinal spacing of jet fans be maintained at 150m.

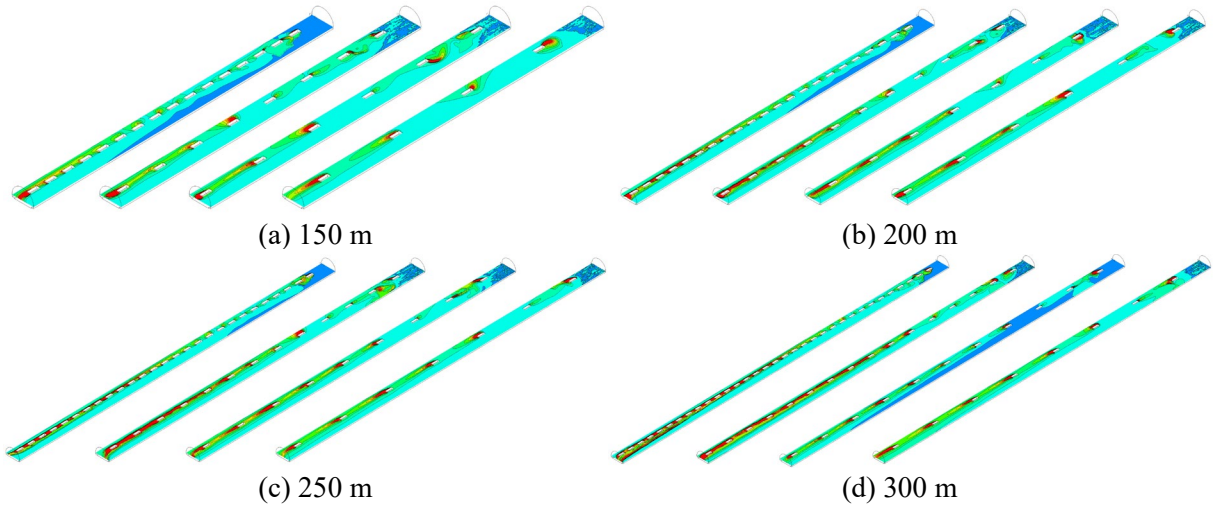


Figure 4. CO Concentration Distribution at Y=1.2m Section at Different Vehicle Speed: (a) 150 m; (b) 200 m; (c) 250 m; (d) 300 m.

3.3. Axial Velocity and Turbulence Intensity of Jet Fan

The fully development of the jet is a crucial condition for ensuring the efficient operation of jet fans. If the longitudinal spacing between fans is insufficient, a uniform flow may not be established within the tunnel, which could adversely affect the performance of subsequent jet fans. Typically, the end of the working section of the jet fan with fully developed has characteristics such as "uniform distribution of cross-sectional velocity and stable turbulence intensity". Fig. 5 and Fig. 6 present the variations in velocity and turbulence intensity along the central axis of the jet fan at a vehicle speed of 20 km/h, under different longitudinal spacings between the jet fans. It can be seen that a longitudinal spacing of 150m is appropriate, enabling the jet to fully develop.

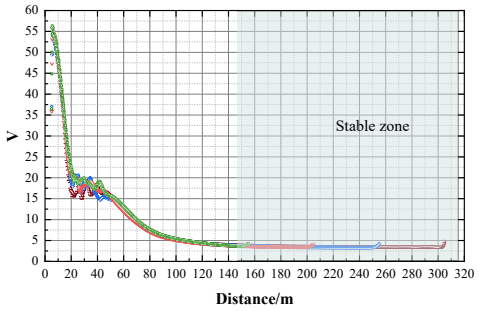

Figure 5. Axial Velocity of Jet Fans at Different Longitudinal Spacing

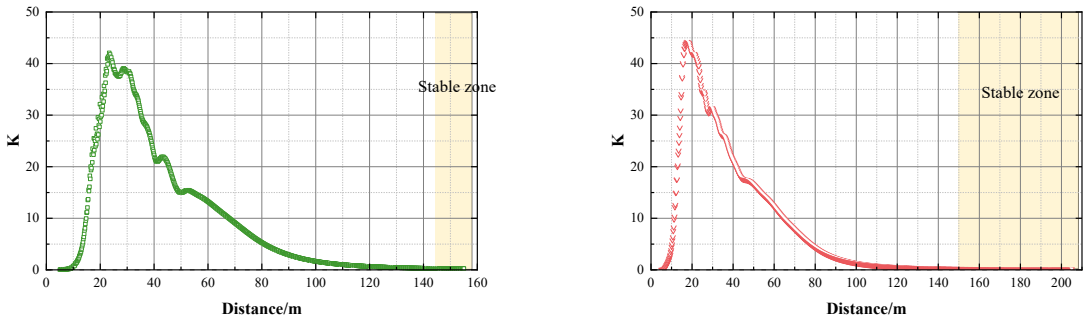
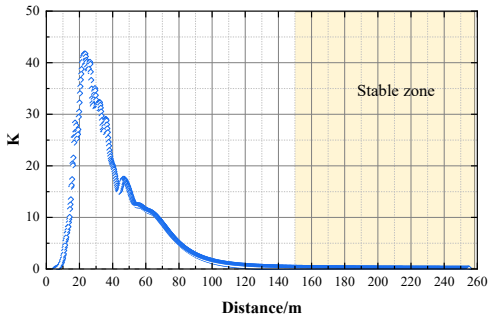
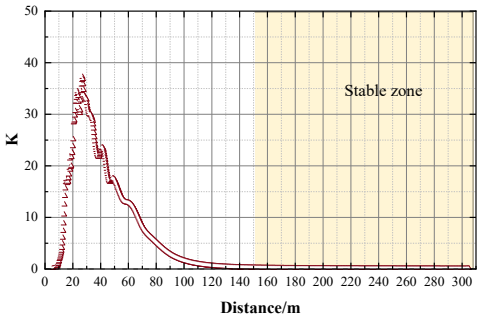


(a) 150 m

(b) 200 m



(c) 250 m



(d) 300 m

Figure 6. Jet Turbulence Kinetic Energy at Different Longitudinal Spacing.

4. CONCLUSIONS

This study calculated the CO concentration distribution within the tunnel under different longitudinal spacings of jet fans and vehicle speeds. By assessing the CO dilution effect, airflow uniformity, and turbulence intensity stability, it is recommended that the fan spacing be set at 150m. This spacing not only meets the health requirements within the tunnel but also ensures the optimal performance of the jet fans.

SUMMARY
The distribution of physical parameters within and around buildings have a significant impact on human health and comfort, highlighting the importance of rapid and accurate prediction of building physical fields. This review focuses on recent advancements in utilizing machine learning (ML) as a surrogate model for computational fluid dynamics (CFD) to predict these fields. First, the study outlines methods for acquiring datasets, discusses the influence of dataset scale on the performance of surrogate model, and presents commonly used techniques for data preprocessing. Next, the review summarizes four types of input features and explores strategies for feature selection. It also reviews the mainstream surrogate models currently employed in research, along with some innovative approaches to modelling. Finally, two major approaches for optimizing built environment based on surrogate models are discussed. This review emphasizes the practical value of ML and provides guidance for its applications in the built environment.

Keywords: Building physical field, Machine learning, Surrogate model

1. INTRODUCTION

The distribution of physical parameters both inside and outside buildings (e.g., air velocity, air temperature, and pollutant concentration) profoundly impacts human health and comfort. Therefore, rapid and accurate prediction of building physical fields is essential for effectively regulating ventilation systems and optimizing building layouts. Computational fluid dynamics (CFD) has become a key tool for simulating complex physical phenomena, such as airflow distribution and thermal transfer. However, CFD simulations require numerous iterative steps to achieve computational convergence, which can be time-consuming.

In recent years, machine learning (ML), a crucial branch of artificial intelligence (AI), has shown potential for achieving rapid and accurate predictions of building physical fields. Current research approaches using ML to accelerate these predictions are mainly divided into two categories: first, as a surrogate model, ML completely replaces traditional numerical simulation methods by constructing a mapping relationship between inputs and outputs, enabling the rapid prediction of environmental parameters (Calzolari & Liu, 2021). Second, ML can enhance numerical simulations by replacing or optimizing specific components, such as improving turbulence modelling (Vinuesa & Brunton, 2022). Compared to surrogate models, auxiliary numerical simulations require more time to compute building physical fields.

The review will focus on strategies for improving the performance of surrogate models, addressing aspects such as dataset acquisition and processing, feature selection, and model innovation. Additionally, this review systematically outlines the practical implementation pathways for

surrogate models in real-world applications.

2. PERFORMANCE IMPROVEMENT OF SURROGATE MODELS

2.1. Dataset

Accurate and comprehensive datasets are fundamental for training ML models. Currently, IoT-based platforms, when equipped with well-calibrated sensors, provide a valuable source for dataset collection (Qu et al., 2023). However, most research still relies on data collected through numerical simulations, and some studies even use data generated by combining multiple software or models (Xu et al., 2023). Additionally, emerging technologies such as computer vision (CV) have proven to significantly enhance data dimensionality and resolution, making them effective tools for gathering information about the built environment (Wang et al., 2024).

Research within specific computational domains has shown that as the number of training samples increases, the prediction error of model gradually decreases. However, when the number of samples reaches a certain critical threshold, further reductions in prediction error become negligible; this threshold can be considered the optimal size (Athavale et al., 2019). Moreover, this review found that in over 80% of studies, the proportion of the training set is not less than 70%, with the 7:3 or 8:2 ratio of training set to test set being commonly used.

Compared to general data, building physical field data typically have larger sizes and higher dimensions. Data preprocessing helps improve the training efficiency of models and can be classified into three types based on their purpose: Firstly, considering the diversity of data distribution in this field, data structure and type conversion, such as normalization, should be performed to make the data more suitable for subsequent analysis. Secondly, raw data often contain outliers and noise, making data cleaning a crucial step in ensuring data quality. Lastly, given that these datasets generally include a vast amount of high-dimensional data, dimensionality reduction techniques can be applied to simplify the dataset. Among these techniques, downsampling is the most used method for data dimensionality reduction. It reduces data complexity by dividing high-resolution grid data obtained from CFD simulations into blocks and calculating the average value of all grid points within each block (Jing et al., 2024).

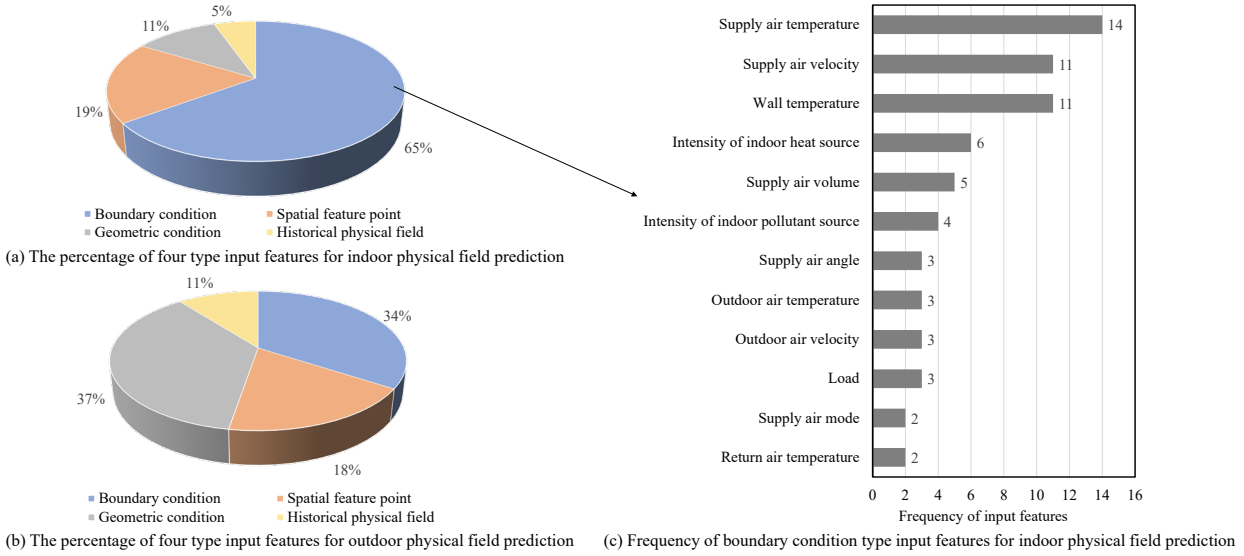
2.2. Input feature

In the process of constructing ML models, selecting appropriate input features play a pivotal role, as it directly impacts the efficiency of the models. Based on actual needs, the input features used in relevant research can be broadly classified into four categories: boundary conditions, spatial feature points, geometric conditions, and historical physical fields.

When ML is applied to building physical field prediction, the use of boundary conditions as input features has become a widely adopted strategy. Particularly in the context of indoor physical fields, the proportion of boundary conditions exceeds 60%. As shown in Fig. 1(c), common boundary conditions, such as supply air temperature, supply air velocity, and wall temperature. These features reflect the significant impact of indoor environmental control systems and external environmental factors on indoor physical fields. In the case of outdoor physical fields, boundary conditions still play a crucial role, with a usage proportion of 34%. Given that some boundary condition data can be difficult to obtain in real-world situations, the development of sensors offers

a promising direction for ML to reconstruct physical fields in real-time. Sparse physical parameters, monitored by a limited number of sensors, can reflect the state of physical parameters at specific spatial locations. By learning the spatial correlations of the data, ML can predict the entire physical field based on the sparse data measured by fewer sensors. Geometric conditions, which are core elements in building structure and layout, significantly influence the distribution of building physical parameters. While factors like building shape and size have some impact on indoor physical fields, the utilization of building geometric information in indoor physical field prediction remains relatively low. In contrast, for outdoor physical field prediction, the usage percentage of building geometric information reaches 37%, making it the most frequently used type of input features.

Non-time-series models typically rely on the first three types of input features, while time-series models mainly use historical data of physical fields as input. Although this type of data is crucial for prediction, current research employing it for physical field prediction remains relatively scarce. This reflects the limitations of actual related demands and underscores the challenges time-series models face in terms of training difficulty and accuracy.



(a) The percentage of four type input features for indoor physical field prediction

(b) The percentage of four type input features for outdoor physical field prediction

(c) Frequency of boundary condition type input features for indoor physical field prediction

Figure 1. The percentage of four type input features and the frequency of boundary condition type input features for indoor physical field prediction.

For selected input features, the key is to ensure their sufficient statistical correlation with the output variables, while avoiding unnecessary features that could increase computational burden. Recursive feature elimination (RFE) and principal component analysis (PCA) are two widely used techniques for feature data processing and analysis, playing important roles in the field of ML. Furthermore, understanding of the importance of individual features and their impact on model predictions is vital for guiding the selection of input features. Correlation analysis is a key method to achieve this goal, focusing on the degree and direction of the relationship between variables. Correlation coefficients, such as Spearman, are commonly used to quantify the strength of association between variables. Additionally, regression analysis is an effective method for revealing interrelationships between variables. Zhang et al. (Zhang et al., 2020) used multivariate regression analysis (MRA) to compare the significance of different variables, successfully

identifying key factors related to the indoor environment and reducing the variable space by 50%.

2.3. Model

From the perspective of the "No Free Lunch" theorem, the average expected performance of various models is equivalent, and no single model can achieve accurate predictions in all scenarios. In the research area of using ML to predict building physical fields, numerous scholars have focused on model comparison and selection tasks.

Due to their exceptional nonlinear processing capabilities and high flexibility in model conversion, artificial neural networks (ANNs) dominate the field of building physical field prediction. Deep learning (DL) models, as an extension of ANNs, achieve efficient processing and learning of complex datasets by constructing deeper neural networks. Among these, models like multilayer perceptron (MLP) and convolutional neural networks (CNNs) are particularly widely used. MLP is illustrated in Fig. 2 with its basic architecture diagram, which consists of input, hidden and output layers, all of which are fully connected. The neurons in each layer are connected to all neurons in the previous layer, with connections between neurons being weighted. Each connection corresponds to a weight value, which represents the signal strength. CNNs are further evolved from MLPs with the help of structures such as convolutional layers, pooling layers and fully connected layers in order to efficiently extract local and global features in images, which is particularly suitable for learning and prediction of physical field data under regular grids.

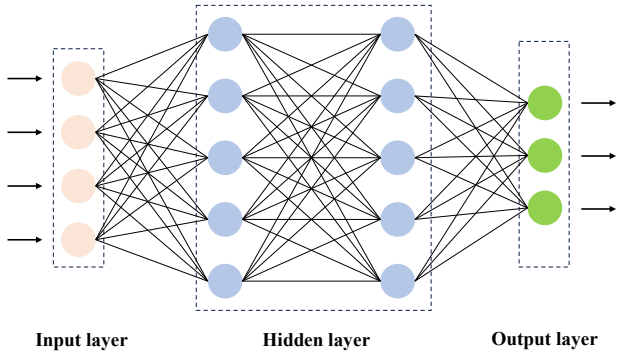


Figure 2. Architecture diagram of MLP with three layers.

Table 1. Advantages, disadvantages, and typical applications of models for building physical field prediction.

Model	Advantages	Disadvantages	Typical applications
MLP	Universal approximation capability for continuous functions via fully-connected layers, suitable for structured data	Parameter count escalates exponentially with input dimensions, struggles with high-dimensional spatial fields	Mapping low-dimensional parameters to scalar physical field outputs
CNN	Spatial feature extraction through local receptive fields and weight sharing, optimal for gridded data	Requires fixed-size inputs, limited adaptability to irregular geometries	Steady-state physical field prediction on regular grids
GAN	High-resolution field generation through adversarial training, complex distribution modeling	Training instability risks, potential physical law violations in generated fields	High-fidelity physical field synthesis
FNO	Spectral-domain global pattern learning with resolution-invariant architecture	Data-intensive operator training requirements, spectral bias towards low-frequency components	Generalizable physical field prediction across complex geometries

With technological advancements, cutting-edge DL models such as generative adversarial networks (GANs) and fourier neural operators (FNOs) have gradually infiltrated the field of built environment. GANs learn and generate samples that approximate the real data distribution through adversarial optimization between a generator and a discriminator. FNOs use Fourier transform to map the data to the frequency domain space, capture the frequency domain features with neural networks, and then invert them back to the time domain to complete the prediction, which is capable of handling input data of different resolutions, and can realise the generalised prediction of the physical field in complex geometries. The advantages, disadvantages and typical application scenarios of each of the above models are shown in Table 1.

After comparation and analysis, innovation at the structural level of the selected models can further enhance their performance in prediction of building physical field. By incorporating attention mechanisms, models can significantly improve their ability to analyse and process key information in input data, thereby enhancing prediction accuracy (Yasuda et al., 2022). Additionally, the concept of hybrid models is increasingly gaining attention in the trend of model development (Prince & Hati, 2021). These models focus on combining the characteristics of multiple models to overcome challenges that a single model cannot address.

3. APPLICATION OF SURROGATE MODLES IN THE FIELD OF BUILT ENVIRONMENT

Fully trained ML models, in addition to demonstrating exceptional performance, enable ultra-fast predictions of physical fields with time resolutions as low as seconds or even milliseconds. This prediction speed represents a significant improvement of three to five orders of magnitude compared to traditional CFD methods (Gao et al., 2024; Zheng & Xu, 2024). With this advantage, ML models can provide strong support for real-time optimization of the built environment.

Two main approaches in current research on built environment optimization based on surrogate models are summarized in Fig. 3. The first approach involves constructing a sufficient dataset to train a surrogate model. Based on this model, a wide range of input parameter combinations are explored under established constraints, and selections are made based on the evaluation values of the objective function. Finally, the rationality of the optimal input parameters is assessed through numerical analysis or experiment. Notably, this approach not only relies on human expertise to intuitively select input features but also incorporates advanced techniques such as optimization algorithms. Essentially, this approach shares roots with the trial-and-error method, but thanks to the efficient prediction capabilities of ML models, the computation time for physical field samples under different input parameters is greatly reduced. Additionally, optimization algorithms replace traditional manual judgment processes, ensuring the accuracy of the final input parameters and enhancing the efficiency of the overall optimization workflow.

The core advantage of the second approach lies in its ability to directly predict optimal parameters without the need for intermediate judgment and adjustment processes. Gao et al. (Gao et al., 2023) utilized their proposed sparse sampling perception network (SSPN) to predict concentration distributions. Subsequently, using these predictions as input, they efficiently derived suitable decontamination strategies through MLP. The latter part of this approach establishes a nonlinear mapping relationship between environmental parameters and design parameters. By accelerating

the prediction of optimal design parameters, this approach effectively shortens the time span of the optimization workflow. However, due to the lack of iterative comparison and adjustment of parameters, as well as strict necessity constraints, its accuracy may be slightly inferior to the first approach (Li et al., 2024). Furthermore, the implementation of this approach depends on a dual-model architecture: one surrogate model for building physical field prediction and another prediction model for optimal design parameter prediction. This means that the cost of collecting and preparing datasets is quite high in the early stages. In contrast, the first approach only requires constructing a dataset for a single model, which can quickly provide necessary samples for the optimization algorithm.

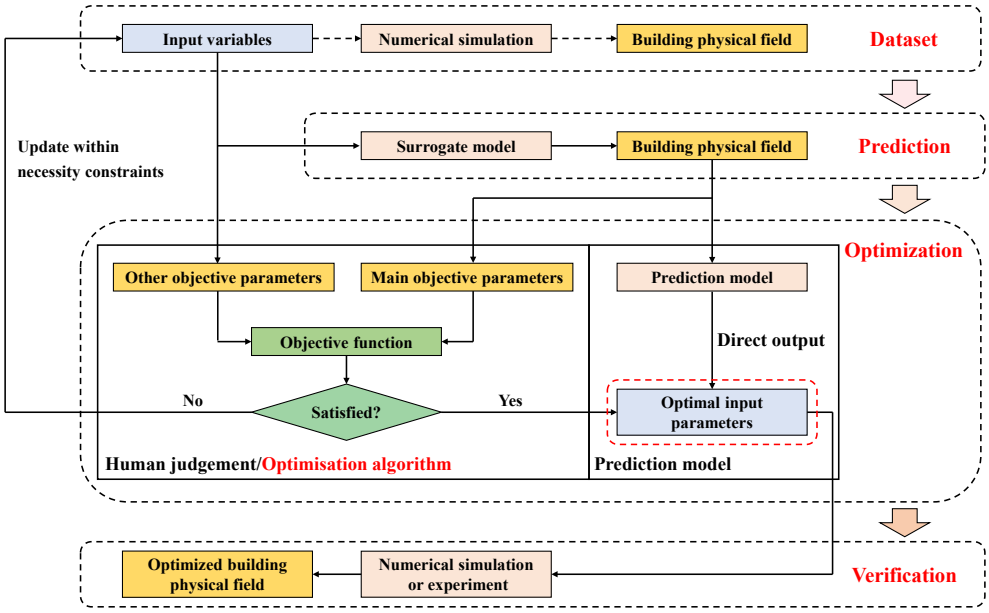

Figure 3. Two major approaches for optimizing built environment based on surrogate models.

As shown in Fig. 4, it is evident that the first approach is currently adopted in most research. Compared to human judgment, more studies combine optimization algorithms and other methods to select the optimal input parameters. In contrast, the second approach has not yet become widespread, with only a few studies attempting to optimize air supply strategies. In terms of surrogate models, ANNs are the preferred choice, although models such as GANs and XGBoost are also used. These surrogate models demonstrate powerful capabilities in simulating building physical fields, providing a foundation for subsequent optimization work. In terms of optimization algorithms, Genetic Algorithms (GAs) are widely used due to their strong global search capabilities and robustness. To further enhance the ability to solve multi-objective optimization problems, the Non-dominated Sorting Genetic Algorithm II (NSGA-II) is used to replace GAs. Additionally, Particle Swarm Optimization (PSO) has also been applied to a certain extent because of its fewer parameters and relatively faster convergence speed. Li et al. (Li et al., 2023) combined the global search capability of PSO with the local fine-tuning ability of the Grey Wolf Optimizer's (GWO), adopting a hybrid PSO-GWO optimization algorithm. This hybrid method exhibits higher optimization performance and a lower computational burden. Besides the optimization algorithms, Reinforcement Learning (RL), which learns optimal strategies through the interaction between agents and the environment, has also attracted attention.

Furthermore, the Sankey diagram reveals that the design parameters of the built environment can be categorized into three types: supply air parameters, layout parameters, and morphological parameters. This indicates that the environment is primarily optimized through three means: control of ventilation system, optimization of building layout, and design of building form.

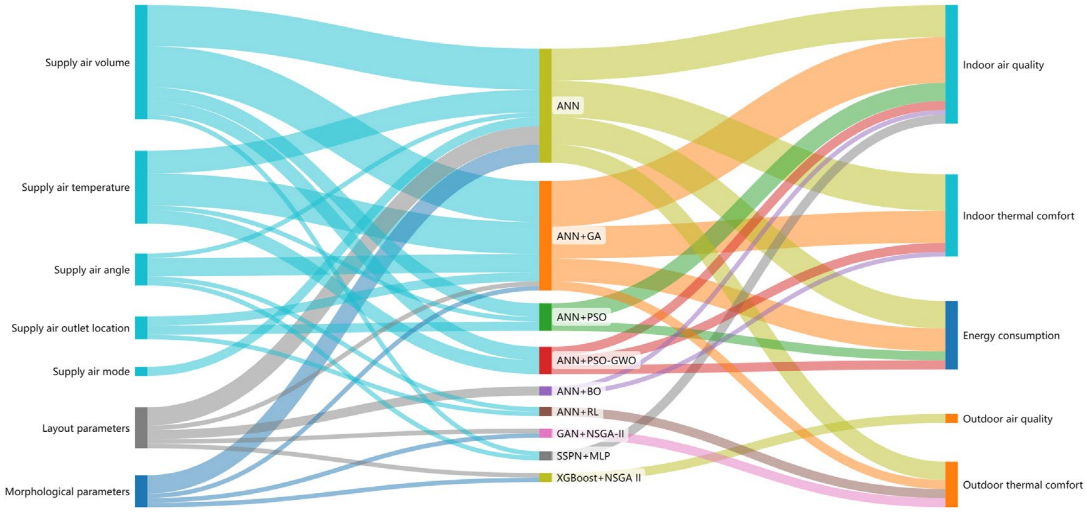

Figure 4. Sankey diagram to show the relationship between different design variables, models and design objectives.

4. DISCUSSION AND FUTURE PERSPECTIVES

ML models with superior performance can serve as an efficient means to rapidly and accurately predict building physical fields, thereby providing a powerful reference for the optimization of built environment. However, the dependence of ML models on large-scale datasets and their generalization ability in practical applications remain significant challenges. In recent years, the rapid development of few-shot learning has offered potential solutions to these problems, primarily through methods such as data augmentation and transfer learning. Data augmentation generates new virtual data from limited real samples to ensure model performance, while transfer learning focuses on leveraging similarities between data, tasks, or models to fine-tune model parameters with a small dataset after training in an existing domain, thereby enabling the application of the model to a new domain. This method allows for the transfer of surrogate models across different building geometric conditions to predict physical fields.

Furthermore, most current ML models make predictions without incorporating any physical prior knowledge, learning solely the mapping relationship between input and output through the training set. Although this approach can effectively avoid the time-consuming process of extracting physical attributes, it may not necessarily adhere to physical laws during computation and sometimes fails to meet the convergence constraints of traditional physical algorithms. Physical Informed Neural Networks (PINNs), as a cutting-edge approach, incorporate key physical characteristics and information into deep learning models. This represents a potential step toward higher-quality predictions and enhances model interpretability.

5. CONCLUSION

This study reviews the research progress on using ML as surrogate models for predicting building physical fields. It analyses key strategies for improving the performance of surrogate models from three perspectives: dataset, input feature, and model. Additionally, the review discusses two major implementation pathways for applying high-performance ML models in practical built environment optimization. However, due to the inherent complexity of building physical fields, surrogate models still face challenges such as high dependence on datasets, insufficient generalization ability, and lack of model interpretability. This review aims to provide guidance for the predictive applications of ML in the field of built environment.

SUMMARY
This paper investigates the optimal combination of thermal insulation and phase change materials (PCMs) to retrofit the inside of external walls. Multiple variants of office and residential buildings located in Brussels are analysed by means of dynamic building performance simulations. Findings reveal that, for external wall retrofitting, the building's insulation performance has the greatest impact on energy savings, with PCMs having a more significant effect in lightweight structures. The results substantiate the utility of PCMs as a retrofit measure, particularly in well-insulated office buildings, outperforming adding thermal insulation due to the high internal loads. For interior retrofitting with a maximum thickness of 5 cm, the combination of PCMs and thermal insulation is more effective than insulation alone in most scenarios. This combination effectively balances heating and cooling energy savings, reducing overall energy demand up to 4.8% in the office building and up to 26.7% in the residential building.

Keywords: Phase Change Materials, Retrofit, Energy Efficiency, Dynamic Building Performance Simulations

1. INTRODUCTION

In light of the contemporary challenges of climate change and the energy crisis, Europe strives for a climate-neutral economy with net-zero greenhouse gas emissions by 2050. According to the Energy Performance of Buildings directive, 85% of buildings were built before 2000 and among those, 75% have poor energy performance, highlighting the pressing need for targeted interventions in the building sector (EU 2024/1275, 2024). In response to this challenge, the renovation wave is a key policy initiative to drive the energy efficiency of the building stock to reach the EU targets (Çıldır et al., 2020). This initiative involves the implementation of passive and active retrofit strategies to reduce year-round operating costs and energy use of buildings. Among these strategies, passive solutions enhance the thermal resistance of the building envelope, reducing heat loss to the outside environment and thereby reducing the energy required for cooling and heating (Ibrahim et al., 2024). These strategies - such as incorporating thermal insulation, replacing exterior windows and improving airtightness - are widely adopted practices in the building sector. However, such highly-insulated, airtight buildings can lead to a series of unintended consequences, such as overheating and increased energy demand for cooling during the summer due to heat trapped in the sealed building envelope (Sage-Lauck & Sailor, 2014). In this context, phase change materials (PCMs) have received considerable attention as a promising passive retrofit strategy for buildings. By phase transitioning - typically from solid to liquid in building integrated applications - these

materials can store and release a large amount of latent heat under nearly constant temperatures (i.e. the phase change temperature). Their integration increases the building's thermal storage capacity and stabilizes temperature fluctuations, with the potential to improve thermal comfort and reduce energy demand. In addition, their high energy storage density makes them suitable for reducing construction materials while preserving maximal indoor space, particularly in retrofit scenarios (Al-Absi et al., 2022; Khan et al., 2022). Recent studies using dynamic building performance simulations have demonstrated their influence on the indoor thermal environment of existing buildings. Li et al. reported that depending on the PCMs' location and climate conditions, uncomfortable degree hours were reduced by 24% to 40% (Li et al., 2023). As evidenced by total energy demand reductions of -1.7% to 32.2% reported by various researchers, the effect of PCMs is intrinsically dependent on the boundary conditions of the case study, like building characteristics, climate conditions, PCM characteristics, and location within the building (Abilkhassenova et al., 2023; Mohseni & Tang, 2021; Zhussupbekov et al., 2023).

However, there is a lack of studies investigating PCMs as a complementary retrofit strategy in combination with conventional measures, such as upgrading the thermal envelope. Additionally, current literature on PCMs as retrofitting strategy has primarily focused on analysing their integration in specific individual buildings in the context of their respective climate conditions. This paper goes beyond the state-of-the-art by exploring the potential of PCMs as a complementary retrofit strategy across diverse building contexts, assessing their impact on energy efficiency over a range of building characteristics.

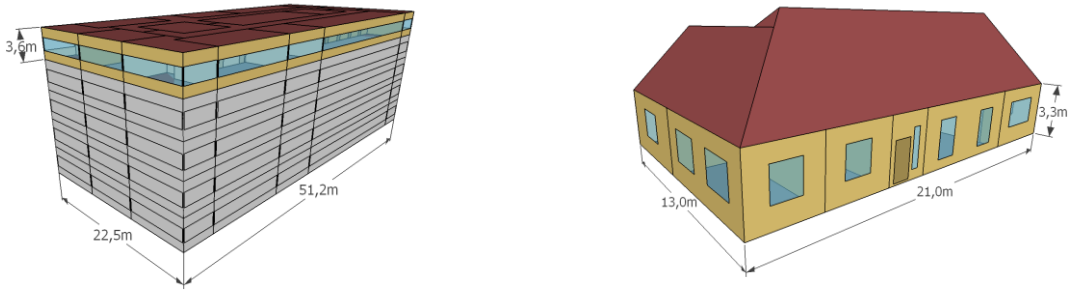
2. RESEARCH METHODOLOGY

A simulation-based approach is designed to evaluate the impact of passive retrofit strategies on the energy performance of two building typologies, including an office building and a detached residential building. The proposed solutions feature a combination of both conventional retrofit strategies, such as enhancing the building envelope by adding thermal insulation, and novel ones by integrating PCMs. The simulation models used in this study are not validated against empirical data; instead, this study adopts a simulation-based comparative analysis to assess the relative impacts of different retrofit interventions on building energy performance. To ensure the accuracy of the results, the assessment is conducted using multi-zone dynamic building performance simulations with EnergyPlus v9.6, a simulation engine validated by the BESTEST evaluation protocol. These models simulate the thermal flows and the resulting energy demand for both cooling and heating. Additionally, the validated "conduction finite difference" (CondFD) and "phase change" models are deployed to simulate the thermal behaviour of PCMs in the building envelope (Tabares-Velasco et al., 2012).

2.1 Description of numeric model

Two reference building models are considered: the top floor of a five-storey office building and a detached residential building, both located in the Belgian city of Brussels. The building models are parametric, allowing for variation in building characteristics and retrofit strategy. This approach makes it possible to investigate the effectiveness of the retrofit strategies across multiple contexts. Figure 1.a illustrates the office building. The top floor, with an area of 1153 m², is divided into 17 different thermal zones by means of internal partitioning. The external walls and roof are subjected to exterior boundary conditions, while the interior floor is subjected to adiabatic conditions as it is

adjacent to the storey below. The detached residential building, illustrated in Figure 1.b, has a floor area of 211 m² and is divided into eight different thermal zones, separated by internal walls. The window-to-wall (WTW) ratio is 40% in all orientations for the office building and 20% for the residential building.



(a) (b)

Figure 1. Buildings examined in the simulation study (a) Office building (b) Residential building

The internal gains of the buildings are considered using the objects "People", "Lights" and "ElectricEquipment" with assumptions based on international standards (ASHRAE 90.1, 2022). Ventilation and infiltration are incorporated with the "Design flow rate" models to comply with the standard for office buildings (ASHRAE 62.1, 2022) and the Belgian residential standard (NBN D 50-001, 1991). Additionally, the "ZoneMixing" object is used to model air mixing occurring between the thermal zones. The HVAC system is modelled using the input object "Ideal Loads Air System", which models the heating or cooling demand as if it were supplied by an ideal system without thermal inertia or efficiency losses. The applied thermostat set-points comply with the thermal comfort category II for air-conditioned zones, as recommended in the relevant standard (NBN EN 16798-1, 2019). The input parameters for the models are summarized in Table 1.

Table 1. Input parameters for numerical model

Parameter	Value for office building	Value for residential building
People	18.58 m²/person	4 occupants
Lights	7.86 W/m²	25 W
Electric equipment	8.07 W/m²	1000 W
Ventilation flow rate	0.0085 m³/s*person	0.001 m³/s*m² (floor area)
Infiltration flow rate	0.0005 m³/s*m² (exterior surface area)	0.0005 m³/s*m² (exterior surface area)
Heating set-point (occupied/unoccupied)	20°C/16°C	20°C/16°C
Cooling set-point (occupied/unoccupied)	26°C/32°C	26°C/32°C

2.2 Input variables of parametric model

Building upon the reference buildings, a parametric model is developed to explore the performance of PCMs as a complementary retrofit strategy across multiple building contexts. This parametric model comprises variations in the original building envelope construction, including a heavyweight structure and a lightweight variant, and 4 variations in thermal performance. The heavyweight structure details a cavity wall, and the lightweight structure features a lightweight steel-framed construction for the office building and a timber-framed structure for the residential building. Table 2 outlines the variation in external wall and roof configurations with different thermal inertia.

Table 2. External wall and roof configuration for heavyweight and lightweight variants (outside to inside layer)

Exterior wall			Exterior roof		
Heavyweight	**Lightweight Steel**	**Lightweight Timber**	**Heavyweight**	**Lightweight Steel**	**Lightweight Timber**
Facade brick 9 cm	Cement render	Wood cladding	Bitumen roofing	Bitumen roofing	Wood cladding roof
Air gap	Rigid thermal insulation	Thermal insulation between timber rafters	Screed 6 cm	Thermal insulation	Thermal insulation between timber rafters
Thermal insulation	Plywood 18 mm	Plaster 10 mm	Thermal insulation	Thermal insulation in steel frame	Plaster 10mm
Hollow brick 13.8 cm	Thermal insulation in steel frame		Concrete slab 15 cm	Plywood 18mm	
Plaster 10 mm	Plaster 10 mm		Plaster 10 mm	Air gap	
				Plaster 10 mm	

For the opaque external constructions, four variations of thermal performance are defined. The constructions are identical, except for the thickness of the thermal insulation layers, which varied to achieve a thermal transmittance (U-value) equal to 1 W/m²K (type: U1), 0.6 W/m²K (type: U0.6), 0.24 W/m²K (type: U0.24) and 0.1 W/m²K (type: U0.1). For each of these variants, distinct window assemblies with varying U-values and solar heat gain coefficient (SHGC) are considered, respectively: single-glazed windows (U = 5 W/m² K, SHGC = 0.8); double-glazed windows (U = 3 W/m² K, SHGC = 0.8); double-glazed window with low-e (U = 1.5 W/m² K, SHGC = 0.5); triple-glazed windows with low-e (U = 1 W/m² K, SHGC = 0.5). These variations cover the range from poorly insulated buildings to those meeting the insulation values suggested for Passive House standards.

2.3 Retrofit measures

In this paper, two different passive retrofit strategies are examined separately and in combination to investigate the impact on the thermal behaviour of the building. For each of the 24 building variants, six combinations of retrofit measures are simulated. The conventional retrofit solution includes enhancing the thermal resistance of the external wall assemblies applying rigid polyurethane foam (PUR) with a thermal conductivity of 0.025 W/mK on the interior part of the external wall, covered with a finishing layer. To complement this conventional strategy, this study investigates the integration of PCMs on the inside of the external walls, also covered with a plaster finishing layer. The PCM selected for this study is the Rubitherm© organic macro-encapsulated PCM, which is commercially available with different melting temperatures and has been widely researched (Al-Absi et al., 2022; Prabhakar et al., 2020). With the aim of reducing cooling loads, the melting temperature of the PCM is selected to be 25°C, closely aligning to the cooling set-point of the building. The thermal conductivity of the PCM is 0.2 W/mK, the specific heat capacity is 2000 J/kgK and the latent heat of fusion is 230 kJ/kg. The thermal behaviour of the PCM is simulated in EnergyPlus with the CondFD solution algorithm. This algorithm follows the temperature-enthalpy function of the material during each iteration of the calculation, and accurately considers the phase change enthalpy and specific heat. The study investigates scenarios where only PUR (5 cm) or PCM (5 cm) is applied, as well as cases where both are combined with a total thickness of 5 cm, complementing each other. These configurations lead to six distinct retrofit combinations, which are simulated for each building variant. In these combined

configurations, the PCM is placed closer to the interior to maximize its heat transfer with the indoor environment. Table 3 gives an overview of the different baseline and retrofitted scenarios, including variable parameters, retrofit options and total number of cases.

Table 3: Overview of baseline and retrofitted scenarios

Scenario	Building typology	Thermal inertia	Thermal performance level	Retrofit options [Insulation-PCM cm]	Number of cases
Baseline	Residential; Office	Lightweight; Heavyweight	U0.1; U0.24; U0.6; U1	None	16
Retrofitted	Idem baseline	Idem baseline	Idem baseline	5-0 ; 4-1 ; 3-2 ; 2-3 ; 1-4 ; 0-5	96

3. RESULTS

The parametric model developed in this study is used to evaluate the performance of various retrofit measures in reducing energy demand and improving thermal conditions across different building contexts. The simulations are conducted for a year, calculating the energy use for heating and cooling. To convert this to electricity demands, the heating energy demand is divided by 3.00 and the cooling demand by 4.10, corresponding to the respective seasonal coefficients of performance (SCOP) for room heating and cooling of an air-to-air heat pump system.

3.1 Retrofitting of building with different construction configurations

In the initial set of simulations, both the office and residential buildings were modelled with heavyweight and lightweight structures, each with four different levels of initial thermal performance, representing 16 variations of business-as-usual cases. These 16 models are the baseline scenarios used as a reference to assess the relative impact of retrofit interventions on the building's energy performance. Subsequently, each building variant is retrofitted through the addition of PCM, PUR or a combination of both at the inner surface of the external walls. This resulted in a total of 112 EnergyPlus simulations conducted (16 baseline scenarios and 96 retrofitted scenarios) of which the energy demand and the indoor thermal environment were analysed. Figure 2 illustrates the reduction in total energy demand after applying the six retrofit measures, compared to the baseline scenarios for each modelled variant of (a) the office and (b) the residential building.

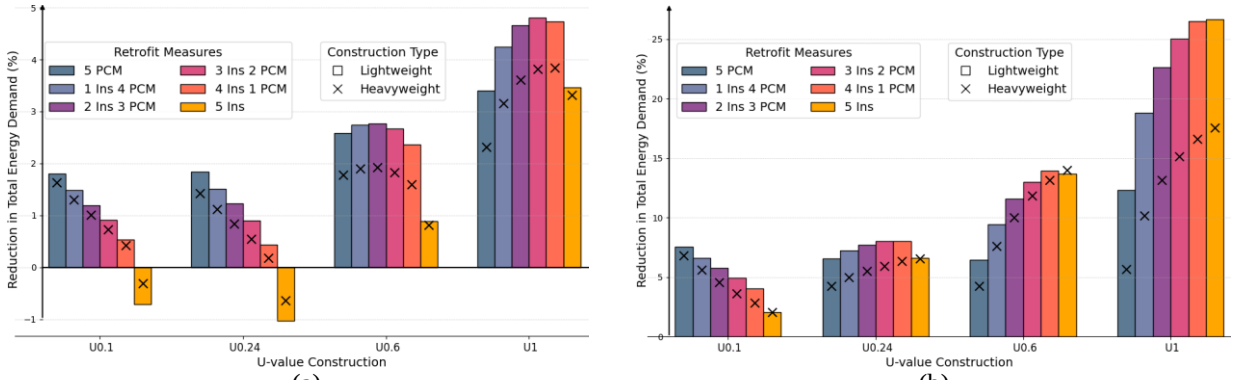


Figure 2. Relative reduction in total energy demand per retrofit measure in (a) Office building (b) Residential building located in Brussels. Bar plots represent results for lightweight buildings, whereas crosses on the graph indicate corresponding results for heavyweight buildings

The results from both graphs reveal that the reduction in total energy demand is significantly dependent on the building characteristics. Notably, the level of initial thermal performance demonstrates the most significant impact on the achieved energy savings, with a similar trend observed in both office and residential buildings. The findings indicate that, in the most effective retrofit configuration, the thickness of the PCM layer increases as the thermal performance of the building improves, while it decreases for lower thermal performance. In poorly insulated buildings, higher energy savings can be achieved by adding insulation, as it is an effective method to lower heating energy demand, which accounts for the largest share of energy demand in such buildings. However, in highly insulated buildings (U0.1) the best retrofit solution features adding 5 cm of PCMs, which contributes to energy savings by reducing the cooling loads. This strategy achieved overall energy savings of 1.4% to 12.3%. Conversely, the addition of insulation in these cases can increase cooling loads due to heat trapped within the building envelope, outweighing the reduction in heating loads. This effect is more pronounced in the office building because of the higher internal loads. In several scenarios, the most effective retrofit solution combines both thermal insulation and PCM, providing a balance in heating and cooling energy savings. This results in total energy savings ranging from 1.4% to 4.8% in the office building and 6.6% to 26.7% in the residential building, demonstrating the potential of PCMs as a complementary retrofit strategy.

Additionally, the findings demonstrate that the impact of adding PCMs is generally greater in lightweight structures than in heavyweight ones, regardless of the initial thermal performance. This can be attributed to the fact that lightweight structures face higher indoor temperature peaks and fluctuations, which can be stabilized through the implementation of PCMs. Figure 3 displays the indoor operative temperature trend of a specific zone of the residential building (U0.24) for 10 summer days. This figure shows the effectiveness of integrating PCMs to reduce indoor temperature peaks in lightweight structures, compared to heavyweight ones.

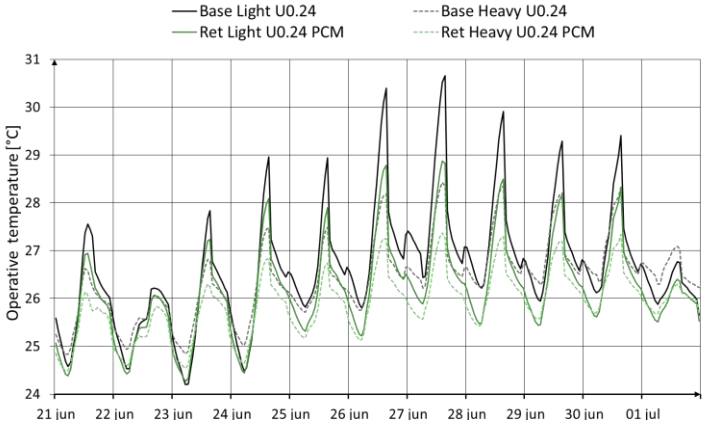

Figure 3. Impact of PCM integration on indoor operative temperature in lightweight and heavyweight building variants (U0.24) of residential building located in Brussels

Overall, the results reveal that energy savings from retrofitting solely with PCMs are relatively low, ranging from 1.4% to 3.4% for the office building and 4.2% to 12.3% in the residential building. These values are consistent with reported energy savings from the literature, ranging from 4.7% to 25.2% (Zhussupbekov et al., 2023), and highlight the need for additional strategies to improve the PCM efficiency, and quantify benefits, such as improvement in thermal comfort.

3.2 Sensitivity to climate conditions

The performance of PCMs is sensitive to the climate where the building is situated. In order to explore the site-specific influence on the retrofit measures, 4 different cities were selected to

represent the most prevailing climates in Europe, according to the Köppen-Geiger classification: Stockholm (cold climate without dry season and warm summer), Brussels (temperate climate without dry season and warm summer), Vienna (temperate climate without dry season and hot summer), and Madrid (temperate climate with dry season, hot summer and cold semi-arid climate). For this analysis, the simulations were restricted to the variants characterized by a lightweight structure and a building envelope U-value of 0.24 W/m² K. The different retrofit measures were evaluated for both buildings across the four cities. The most effective retrofit solution and the associated absolute and relative reductions in total energy demand are outlined in Table 4.

Table 4. Reduction in total energy demand across 4 cities

	Office			**Residential**		
Location	Optimal retrofit solution	Δ [kWh/m²]	Relative [%]	Optimal Retrofit solution	Δ [kWh/m²]	Relative [%]
Stockholm	4 Ins – 1 PCM	0.38	1.63	4 Ins – 1 PCM	1.57	6.44
Brussels	3 Ins – 2 PCM	0.23	1.78	4 Ins – 1 PCM	1.11	8.03
Vienna	3 Ins – 2 PCM	0.27	1.42	3 Ins – 2 PCM	1.16	6.17
Madrid	5 PCM	0.15	0.95	5 PCM	0.89	7.5

The energy savings from retrofitting these buildings are similar in each city, ranging from 1.0% to 1.8% for the office building and 6.2% to 8.0% for the residential building. However, the obtained results reveal a shift in the best retrofit strategy - combination of PCM and insulation - depending on the climate conditions in which the building is simulated. In cooling-dominated cities, such as Madrid, PCMs offer the most effective retrofit solution, while in heating-dominated cities, such as Stockholm, it is preferable to add more insulation and limit the thickness of PCMs to reduce the heating demand. This sensitivity analysis highlights the importance of considering climate conditions when making decisions to retrofit buildings with PCMs and thermal insulation.

4. CONCLUSION

This paper investigates the application of PCMs as complementary retrofit strategy to conventional approaches, specifically the enhancement of external walls through the addition of thermal insulation. To evaluate the performance of the retrofitting measures across different building contexts, a parametric model is developed that includes variations in thermal inertia and thermal performance of the structure, for both an office and a residential building. Dynamic building performance simulations are used to analyse the impact of the different retrofit strategies - adding PCMs and/or thermal insulation to the internal part of the external walls - on energy demand and the indoor thermal environment. The results of this research demonstrate the impact of the building characteristics on the energy savings potential of the retrofit strategies, with the thermal performance having the most significant impact. A similar trend is observed for both residential and office buildings, where higher amounts of PCM are more effective in well-insulated buildings, reducing cooling loads, while thermal insulation performs better in poorly insulated buildings, lowering heating demand. Additionally, the results indicate that the impact of adding PCMs is generally greater in lightweight structures than heavyweight, as they are more effective in mitigating indoor temperature peaks and fluctuations. The results demonstrate the potential of PCMs for building retrofitting, specifically in well-insulated office buildings with high internal loads, where they outperformed adding thermal insulation. When retrofitting the inside of exterior walls with a given maximal thickness of 5 cm, the combination of both thermal insulation and

PCMs consistently reduced energy demand more effectively than thermal insulation in most scenarios. The combination effectively balances heating and cooling energy savings, leading to overall energy savings of up to 4.8% in the office building and up to 26.7% in the residential building. Moreover, the results of the sensitivity analysis highlight the importance of considering boundary conditions, such as climate conditions, when selecting the appropriate retrofit strategy. Future research will extend the analysis including other retrofit strategies, such as shading controls and night ventilation, to assess their synergy with PCM retrofitting and explore additional benefits that PCM can provide in buildings, in particular improving thermal comfort. Moreover, the sensitivity analysis will be expanded to evaluate the performance of the retrofit strategies under future weather scenarios in the context of expected climate change impacts, contributing to the development of more energy-efficient and climate resilient buildings.

SUMMARY
Solar radiation plays a crucial role in integrated photovoltaic-green roof (PVGR) systems, but research on the distribution characteristics of solar radiation and photosynthetically active radiation (PAR) or daily light integral (DLI) of vegetation surface under PV shading is limited. To address this gap, a field experiment was conducted in Singapore. The results revealed that on a clear day, the maximum incident solar radiation and PAR on vegetation surface between PV arrays were up to 1136 W/m^2 and 1876.6 μmol/m^2/s, respectively, whereas they were significantly lower below PV panels. Regression analysis demonstrated a highly linear relationship between DLI and solar radiation with an average ratio of 1.799. A numerical model for DLI of vegetations for PVGR was developed, and the effect of PVGR design parameters on the average annual DLI of vegetations was clarified. The findings drawn herein contribute to optimizing PVGR design in terms of selection of plant species.

Keywords: Photovoltaic-green roof, Daily light integral, Solar radiation, Sky view factor

1. INTRODUCTION

In urban areas with limited land, green roofs (Shafique et al., 2020) and photovoltaic (PV) roofs (Ghosh, 2020) are becoming common solutions to meet growing energy demands and address climate change. Green roofs reduce air conditioning energy use through evapotranspiration, shading, and insulation (He et al., 2017), while also mitigating urban heat islands. PV roofs provide shading and have the potential to cover significant energy consumption in certain regions. However, space constraints create competition between these technologies. In recent years, a novel type of roof called PVGR has emerged, which combines both types of roofs together, as shown in Fig. 1. This configuration maximizes roof space, creates synergistic effects, and provides ecological benefits (Talwar et al., 2023). However, poor vegetation design can reduce PV efficiency by obstructing airflow or causing shading (Ogaili and Sailor, 2016). Solar radiation, critical for both PV and green roofs, affects energy balance, photosynthesis, and vegetation growth (Lamnatou and Chemisana, 2013). Accurate solar radiation prediction is essential for optimizing PVGR performance and guiding vegetation selection.

Several methods have been developed to predict solar radiation distribution in PV roofs or PVGR. Fathi and Samer. (2016) introduced a model for multi-row solar fields that accounts for the influence of all rows on the view factors of PV panels, highlighting how design parameters affect radiation distribution. Jahanfar et al. (2020) considered both direct and diffuse solar radiation beneath PV arrays, estimating the sky view factor (SVF) based on a simplified two-dimensional PV panel layout. However, this SVF model only considered the impact of three PV panels on the central point of the vegetated surface below, performing adequately only after calibration for

diffuse solar radiation, which limits its applicability across various weather conditions and PV array configurations.

Figure 1. A example of Photovoltaic-green roof (Ramshani et al., 2020).

Therefore, accurate calculation of SVF serves as a fundamental basis for predicting energy balance in photovoltaic green roofs. The calculation of view factors may be based on (Gupta et al., 2017). Considering the large number of PV arrays and the scalability requirement of the calculation process, this study adopts ray tracing method to reveal the variation pattern of view factors for vegetation surfaces under PV arrays. Photosynthetically active radiation (PAR, 400–700 nm) is essential for plant growth, driving key processes like photosynthesis and transpiration, and influencing urban energy, water, and carbon balance (Wane et al., 2022). Different plant species require varying levels of daily light integral (DLI), such as lettuce (DLI =14.5±4.16 mol/m^2/day) and Kailan (DLI = 47.22 ± 3.48 mol/m^2/day). Therefore, accurate estimation of PAR or DLI is imperative for selecting suitable plant species in PVGR. However, PAR measurements are not commonly available in most weather stations and are rarely conducted within urban built environments. The heterogeneous light environment created by PV arrays above the vegetation surface further poses challenges in selecting suitable plant species. Various methods have been proposed to estimate DLI. One widely used method is based on linear regression between DLI and global solar radiation at different locations (García-Rodríguez et al., 2020). However, this regression model is only applicable for unshaded conditions. For shaded area, considering the varying shading effects of PV arrays across different areas of the vegetation surface and the dynamic characteristics of radiation beneath PV arrays, further validation is required to ensure the accuracy in predicting DLI by SVF.

This paper aims to calculate the SVF of vegetation surface in PVGR and analyze how design factors affect these view factors. Based on the obtained view factors, a solar radiation transfer model for PVGR was developed. Field experiments were conducted to validate the model, and an analysis was performed on the distribution characteristics of solar radiation and DLI with different configurations. The results of this study are expected to provide valuable insights for the advancement of hygrothermal transfer models for PVGR and guide the optimal selection of plant species.

2. METHOD AND MATERIALS

2.1. Solar radiation transfer model of PVGR

Significant heterogeneity of solar radiation has been observed on the vegetation surface of PVGR (Schindler et al., 2016). To facilitate the analysis of distribution, a representative unit of PVGR was selected, as shown in the dotted box in Fig. 2. The PV arrays are assumed to be long enough , so that the solar radiation of the PVGR can be approximated as a two-dimensional distribution. Based on the projection position of the PV array, the vegetation surface is divided into three sub-surfaces: S1, S2 and S3. Additionally, the front and back surfaces of the PV panel are referred to as S4 and S5, respectively. Exposed to solar radiation from the sky, the multiple reflections among S1~S5 need to be taken into account.

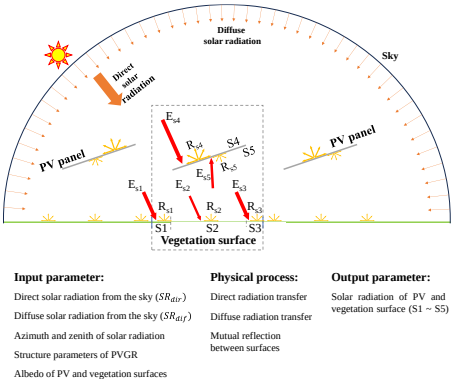

Figure 2. Schematic diagram of solar radiation transfer of PVGR.

In this unit, all the PVGR surfaces are discretized into meshes, and the radiation balance for all the meshes is represented from Eq. (1) to Eq. (5). Incident solar radiation $E_{n,i}$ consists of direct radiation ($D_{n,i}$), diffuse solar radiation from the sky ($R1_{n,i}$) and diffuse solar radiation from other surfaces ($R2_{n,i}$). The Liu and Jordan model (Liu and Jordan, 1960), which assumes isotropic sky diffuse radiation, was used to calculate $R1_{n,i}$. Reflected radiation ($R2_{n,i}$) is determined by the view factor ($VF_{n,i,j}$) and albedo of surfaces, as shown in Eq. (4). The shading factor ($F_{shading,n,i}$) for direct solar radiation is calculated by tracing rays emitted from the mesh center to detect obstructions. By solving Eqs. (1)-(5) simultaneously, the solar radiation for all surfaces can be obtained.

$$E_{n,i} = D_{n,i} + R1_{n,i} + R2_{n,i} \tag{1}$$

$$D_{n,i} = Vec_n \cdot Vec_{solar} \cdot SR_{dir} \cdot F_{shading,n,i} \tag{2}$$

$$R1_{n,i} = VF_{sky,n,i} \cdot SR_{dif} \tag{3}$$

$$R2_{n,i} = \sum_{j=s1}^{s5} E_j \cdot alb_j \cdot VF_{n,i,j} \tag{4}$$

$$E_j = \frac{1}{m}\sum_{k=1}^{k=m} E_{j,k} \tag{5}$$

Where, SR_{dir} and SR_{dif} are measured direct and diffuse radiation, while $F_{shading,n,i} = 1$ is determined based on whether rays intersect PV surfaces. $E_{j,k}$ is the incident solar radiation on mesh k of surface j.

2.2. Field experiment of solar radiation and PAR distribution of PVGR

To investigate the distribution pattern of solar radiation and PAR under PV array and validate the model described in Section 2.1, a field experiment was carried out in Kent Vale, Singapore. As shown in Fig. 3, three arrays of PV panels were installed on the grassland. Each row of PV panels measured 34 cm × 232 cm in size, with a height of 30 cm for the PV array and a gap of 30 cm between each array. The tilt angle of the PV panels was set at 10°, facing southwards. Pyranometers were positioned on both the front and back surface of the PV panel, as well as on the vegetation surface beneath the PV arrays to measure global solar radiation, while PAR sensors were only positioned at vegetation surfaces for measuring photosynthetic light intensity. Additionally, direct and scattered radiation on the horizontal plane were measured using an SPN1 pyranometer from T2 lab at Kent Vale. The field experiment was conducted from 25th Feb. 2022 to 27th Mar. 2022, with a data collection interval of one minute. The detailed specifications of the sensors utilized in this experiment are presented in Table 1.

（1） （2）

Figure 3. Photo of field experiment in Kent vale of Singapore: 1) Solar radiation and DLI measurement of vegetation and PV surfaces; 2) Global solar radiation and diffuse solar radiation measurement at T2 lab of Kent vale.

Table 1 Specifications of sensors used in field experiment.

Parameter	Sensor	Spectral response	Measurement range	Accuracy
Global solar radiation	Onset S-LIB-M003	300-1100nm	0-1280 W/m^2	±5%
PAR	Onset S-LIA-M003	400-700nm	0-2500 umol/m^2/sec	±5%
Diffuse solar radiation	SPN1	400-2700nm	0-2000 W/m^2	±5% for daily integral and ±8 % for hourly averages

3. RESULTS AND ANALYSIS

3.1. Solar radiation and PAR distribution

The measured global solar radiation and diffuse solar radiation on the horizontal plane outside the PV array during seven consecutive non-rainy days from 1st March to 7th March is presented in Fig. 4. And the solar radiation and PAR distribution of PVGR surfaces are presented in Fig. 5, with the annual solar trajectories illustrated in Fig. 5(3). It is evident that the solar radiation received by the back surface of the PV panel and the vegetation surface beneath the PV array was significantly lower compared to that received by the front surface of the PV panel and the vegetation surface between PV arrays, particularly at noon when direct solar radiation was intense. The PAR distribution exhibited a similar pattern. The maximum PAR on the vegetation surface between PV array was approximately 5.2 times higher than the maximum PAR below PV panels, indicating a significant shading effect caused by the PV panels. To examine the correlation between global solar radiation and PAR, a scatter plot of PAR versus solar radiation for all measured points is presented in Fig. 8. It is obvious that both daily averages and hourly averages

show strong and significant linear relationships. And hourly data displays greater variability around the mean compared to daily data, consistent with the findings reported by Tan and Ismail (2016).

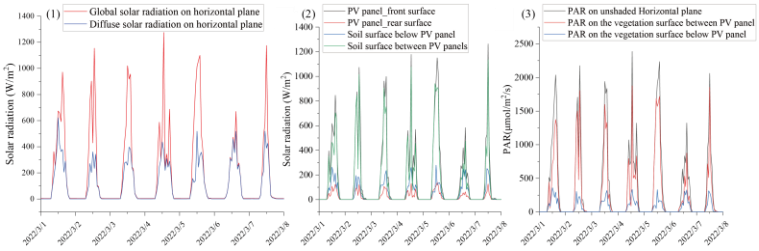

Figure 4. Solar radiation and PAR distribution: 1) Global and diffuse solar radiation on unshaded horizontal plane; 2) Distribution of Solar radiation for PVGR surfaces; 3) PAR of vegetation surface below PV array and unshaded horizontal plane.

To facilitate comparison with previous studies, a linear regression analysis with an intercept of zero is performed on the entire daily dataset collected during experiment, enabling determination of the ratio (R_{PAR}) between daily PAR value (namely DLI) and global solar radiation. The results show that the R_{PAR} value in this study is 1.799, lightly lower than the recommended value of 1.867 by Tan and Ismail (2016). One reason for this discrepancy is that Tan et al. only considered unshaded conditions, where direct solar radiation contributes a large proportion compared to this study. It has been observed that a higher diffuse radiation component leads to a reduction in R_{PAR}, as scattering affects the PAR spectrum more significantly than longer wavelengths.

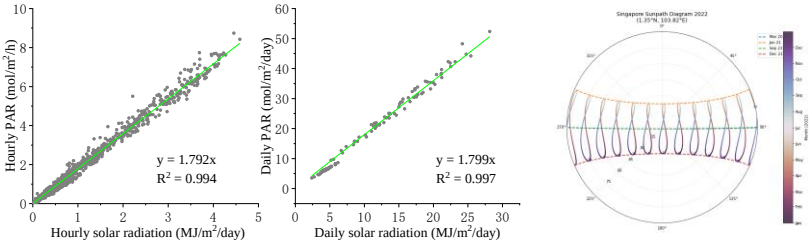

Figure 5. Scatter plot between PAR against solar radiation: 1) Scatter plot of hourly average values; 2) Scatter plot of daily average values; 3) Singapore solar trajectories

3.2. Validation of solar radiation transfer model of PVGR

After inputting the albedos of PV panel and vegetation surface, along with the radiation data (Fig. 4), the solar radiation for different surfaces in PVGR can be simulated based on the model proposed in section 2.1. The albedo values, measured during the field experiment, were 0.1 for the front surface of PV panels, 0.7 for the back surface of PV panels, and 0.24 for the vegetation surface. The comparison between measured and simulated solar radiation (Fig. 6) shows that the model effectively reproduces observed variations. The corresponding RMSE and R^2 are presented in Table 2, demonstrating a high level of efficiency and reliability of the model.

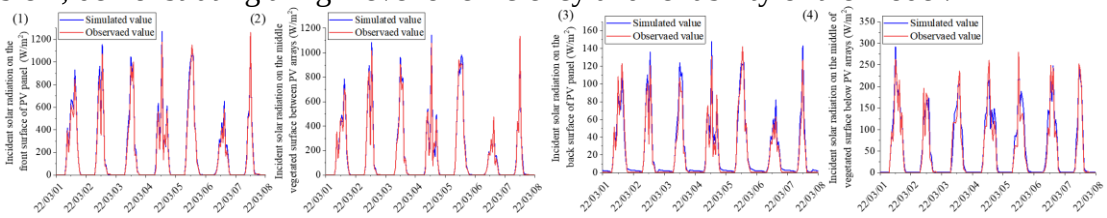

Figure 6. A comparison between measured solar radiation and simulated values on PVGR surfaces: 1) The front surface of PV panel; 2) Vegetated surface between PV arrays; 3) The back surface of PV panel; 4) Vegetated surface below PV panel.

Table 2 RMSE and R^2 for solar radiation simulation of PVGR.

	PV_front	PV_back	Soil_below_PV	Soil_between_PV
RMSE (W/m^2)	51.29	10.36	25.50	37.1
R^2	0.975	0.928	0.895	0.985

3.3. Solar radiation and DLI distribution of vegetation surface

Global and diffuse solar radiation on a horizontal plane were collected at Kent vale in 2021 by T2 lab in Singapore. The measured radiation data were used as input for the solar radiation transfer model in order to analyze the distribution of solar radiation and DLI on vegetation surfaces throughout the entire year. Based on simulation results, the average hourly and total solar radiation is presented in Fig. 7 (1) and Fig. 7 (2), respectively. It is evident that the front surface of PV panels receives the highest solar radiation, while the back surface experiences the lowest levels. As for vegetated surfaces, S1 and S3 exhibit similar levels of solar radiation, with approximately 1.5 times higher than that of S2. Fig. 7 (3) and Fig. 7 (4) illustrates monthly and annual DLI values based on the regression model in section 3.1. During March and September, the solar position is directly above the PV panel, causing significant shading effect that results in low levels of solar radiation for S2. From April to August when the solar position tilts towards to the north hemisphere, S3 receives more direct solar radiation than S1; similarly, when it tilts towards the south hemisphere in other months, S1 receives more direct solar radiation. Throughout the year, DLI of S1~S3 ranges from 10 to 20 $mol/m^2/day$, suitable for crops like *Latuca sativa L.* and *Capsicum annum L.* (Song et al., 2018).

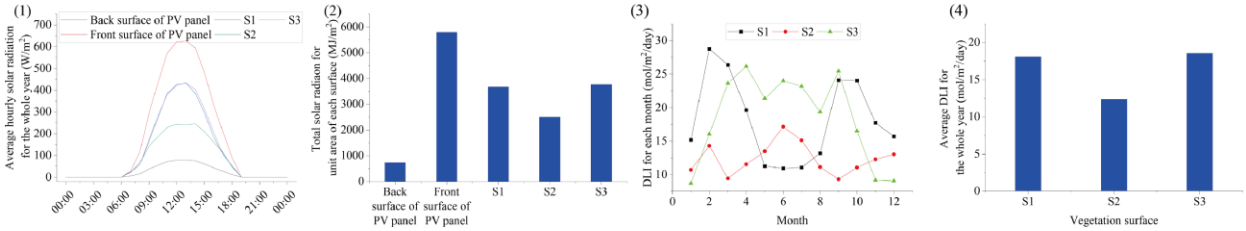

Figure 7. Solar radiation and DLI of PVGR surfaces:1) Average hourly solar radiation of PVGR surfaces for the whole year; 2) Total solar radiation of PVGR surfaces for the whole year; 3) Average DLI of vegetation surfaces for each month; 4) Average DLI of vegetation surfaces for the whole year.

Fig. 8 shows how design parameters of PVGR affect DLI on vegetated surfaces. A higher PV does not impact total incident daylight on vegetated surfaces but can reduce DLI inhomogeneity. The spacing between PV arrays and the width of PV panels primarily influence the DLI of vegetated surfaces by adjusting the coverage ratio of PV panels. Increasing the row space or reducing the width of PV panels can enhance the DLI of vegetated surfaces, but it may also decrease power generation per unit area from PV panels. The impact of tilt angle for PV panels and roof deck on DLI varies for different vegetated surfaces. A larger tilt angle results in a higher DLI for S2, while for S1 and S3, this relationship is non-monotonic due to the combined effect of shading and sky view factors. Given the complex nonlinear relationship between DLI and design parameters of PVGR, specific analyses should be conducted for different configurations to accurately determine the optimal plant species.

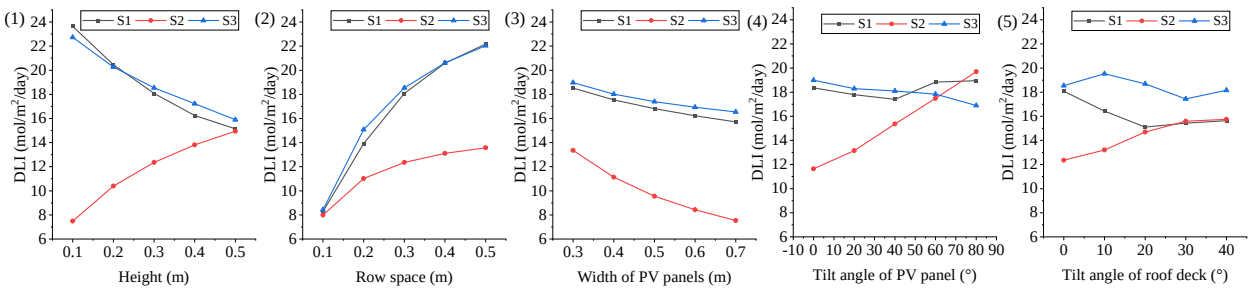

Figure 8. The effect of PVGR parameters on average DLI of vegetations for the whole year: 1) Installation height of PV panel; 2) Row space between PV panels; 3) Width of PV panel; 4) Tilt angle of PV panel; 5) Tilt angle of roof deck.

4. DISCUSSIONS

Accurate prediction of solar radiation distribution lies in the premise of PVGR optimization design. Previous studies usually oversimplified the effect of PV arrays on the SVF of vegetation surface, which weakens the simulation accuracy. While DLI is widely used to select plant species, its prediction under PV shading using the linear relation with SVF has limitations and lacks verification in PVGR scenarios.

To address these gaps, this study proposed a novel solar radiation transfer model for PVGR, incorporating SVF calculated via ray tracing and accounting for multiple radiation reflections. Field experiments revealed a strong linear relationship between DLI and solar radiation under PV arrays, enabling accurate DLI prediction using the regression model developed in this study. A comparison with Tan's DLI model (Tan and Ismail, 2016) for shaded conditions Eq. (6) in Singapore is presented in Table 6. The results show that DLI predicted by Tan's model is higher than that by this study. This discrepancy can be attributed to two key factors: 1) the constrained scenarios and durations of the field experiment by Tan et al., and 2) the inability of the SVF to comprehensively capture the shading impact of PV panels. It is worth noting that, the relationship between DLI and daily solar radiation may vary across different climates and geographical conditions, necessitating the modification of the empirical DLI model when applied in diverse areas.

$$DLI = 31.52 \cdot SVF + 2.9099 \quad (6)$$

Table 6 Comparison of DLI prediction between Tan's model and this study.

	DLI of S1 (mol/m²/day)	DLI of S2 (mol/m²/day)	DLI of S3(mol/m²/day)	Average DLI (mol/m²/day)
Tan's model	19.199	16.690	19.185	18.358
This study	18.079	12.357	18.542	16.326
Error	1.120	4.333	0.643	2.032

5. CONCLUSIONS

This paper focuses on Singapore as the research area, conducting a field experiment and numerical simulation to examine the solar radiation distribution characteristics of PVGR. The following conclusions were drawn:1) The SVF of the vegetation surface is primarily influenced by the installation height of PV panels, row spacing, and the width of PV panels. 2) Under the shading effect of PV panels, a strong linear relationship was observed between solar radiation and DLI of

vegetated surfaces, with a DLI-to-solar-radiation ratio of 1.799. 3) The solar radiation transfer model developed in this study accurately reproduces radiation variations on PVGR surfaces. Notably, a significant difference was found between the DLI between PV arrays and the DLI under PV panels, with the former's average DLI for the entire year being approximately 1.5 times higher than the latter's. 4) DLI on vegetated surfaces is significantly influenced by the design parameters of PVGR, and this effect varies across different configurations.

While this study represents a preliminary exploration, more extensive field measurements and theoretical studies are essential in the future. For instance, optical properties variations of PV and vegetation surfaces in different spectra range should be taken into account, which benefits to improve the simulation accuracy of solar radiation. Besides, the vegetation growth model of different species under PV array should be further explored, which aims to provide accurate structure parameter for PVGR in long-term simulations. Moreover, the optimal layout algorithm of PV array under the constraint of vegetation lighting requirement need to be developed, so that the maximum power generation and vegetation survival can be realized at the same time.

SUMMARY

It is important to incorporate fluid flow early in the design process, it may be difficult to use CFD due to its high computational cost. A way around this is to create a machine learning (ML)-based surrogate model. Once this model has been trained, the surrogate can generate new flow fields for unseen boundary conditions in seconds. ML and reduced order models (ROMs) are coupled to produce these surrogates. Specifically, functional principal component analysis (FPCA) is compared against proper orthogonal decomposition (POD). The results show that flow fields can be predicted for new boundary conditions but there is room for improvement.

Keywords: Built Environment, Reduced Order Modelling, Machine Learning, Indoor Air Quality

1. INTRODUCTION

Understanding the effect of airflow in enclosed/indoor environments is of great interest due to its close relationship to occupant safety, thermal comfort, and energy efficiency. Optimally placed air conditioning could increase the comfort of the inhabitants (Chow, 2022). When this temperature deviates too far from the norm, there can be negative effects such as a decrease in mental performance (Mendell and Heath, 2005). Insufficient ventilation can also cause pollutants to build up such as CO_2 known as stale air, some of the side effects of stale air include nausea, headaches, fatigue and skin/eye irritation (Jansz, 2017). Showing the importance of incorporating fluid flow early into the design process, however, this is impractical with the traditional CFD process as iterating through multiple designs is computationally expensive and takes a significant amount of time. However, creating an ML surrogate is a potential solution. CFD produces a large amount of data that can be used for training. Generating the flow fields for new boundary conditions much faster.

2. GAP IN THE LITERATURE

Although CFD produces a large amount of data that can be leveraged with different ML models, it is not feasible to train a new model for each new case with various geometries and boundary condi-

tions. The goal is to create a more generalisable model using a limited dataset and provide results for multiple geometries/boundary conditions. ROMs have previously been used in many different ML models, including the built environment. Some benefits include decreasing the training time of the model while using less data, however, there is a negative in that accuracy is lost. This is because ROMs extract dominant flow features while losing information on the smaller structures, examples of ROM include POD and FPCA. POD is done by the method of snapshots, where snapshots of a flow-field are used to find the corresponding eigenvectors and the coefficients of the corresponding flow (Sirovich, 1987). These eigenvectors which are known as the principal components are ranked based on most dominant to least dominant. The coefficients then contain the score which are eigenvalues in a diagonal matrix which determine the strength of each component in the reconstruction. Using more components captures a larger range in variation and increases accuracy while decreasing has the opposite effect (Ooi et al., 2021). FPCA is a development of PCA/POD the key difference is the data is treated as a function, the principal components are now eigenfunctions significantly changing the outputs (Shang, 2014). Some of the differences can be seen in table 1, this helps visualise the differences between the two different ROM (Sari et al., 2017) such as the covariance matrix which is now a covariance function that describes the changes between the different eigenfunctions. Past work focuses on using different ML methods to predict the coefficients instead of the components, this allows for some prediction within a set of bounds. An example of this is in Lumet et al., 2025, where POD is used in conjunction with GPR to predict pollutant dispersal, using the GPR to interpolate the coefficients while keeping the original components. However, to produce more generalisable results these components must also be learned by the model,this work focuses on predicting these components with these coefficients.

Table 1. Sample table with shaded background

Element	POD	FPCA
Covariance Matrix	$\mathrm{Cov}(X) = \Sigma_{p\times p}$	$\mathrm{Cov}(X(s),X(t)) = G(s,t)$
Eigen-structures	$v_1, v_2, ..., v_p$	$\varphi_1(t), \varphi_2(t), ...$
Principal Components	$z = (X-\mu, v_k), k = 1,2,...,p$	$\zeta_k = (X-\mu, \varphi_k), k = 1,2,...$

Minimal work has been done on applying FPCA to the built environment. For different cases such as in MRI data, FPCA can recover data more effectively than traditional POD (Viviani et al., 2005). There is a need to test this method for different types of data.

3. METHODOLOGY

The first step was to use Ansys Fluent to generate the data for the model, this is done by creating a script to automate the data generation process. A 2D slice of a room was taken with inlet/outlet conditions being moved through the y-axis. This can be seen in the following figure 1, the reference for the geometry and the boundary conditions are from Hoque and Omar, 2019. Following the data generation different ROMs were applied both POD and FPCA. A GPR using the radial basis function (RBF) kernel was then used to create a model that would predict the components and coefficients for both POD and FPCA. A total of 484 different simulations were used each a different combination of inlet/outlet locations. Experiments were done to determine the best kernel. Once these have been predicted independently, the flow data can be reconstructed to produce a predicted flow field of velocity magnitude for unknown inlet/outlet positions.

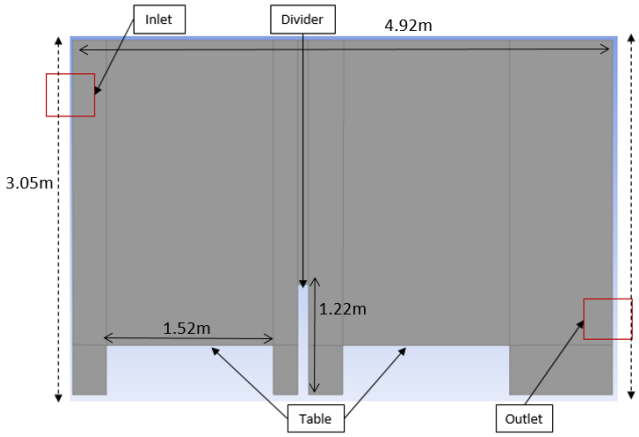

Figure 1. The geometry of the CFD model can be seen which includes the locations of inlet/outlet locations, it is important to note that the dashed lines represent how the inlet/outlet locations move to generate the training data. The inlet and outlet size is This geometry is based on a similar 2D model created by Hoque and Omar, 2019.

4. RESULTS

As previously mentioned, FPCA has been shown to capture a greater range of variations in the data, this can be seen in figure 2 where the first components capture 60% of the variation in the data when compared to POD at only 30%.

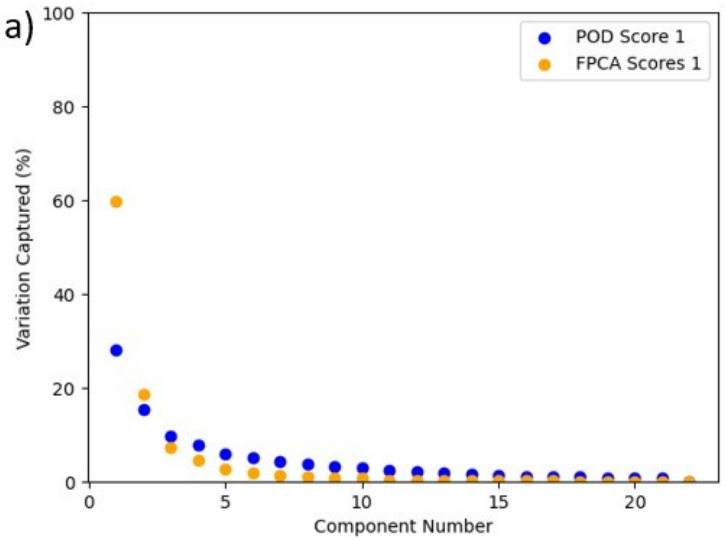

Figure 2. Scatter graphs showing the percentage each mode captures for an inlet location, showing that FPCA captures a larger range of variation with fewer modes.

The results show that it is possible to predict the coefficient and the components for these flow fields using GPR. Once these have been reconstructed, the flow field starts off strong but struggles to develop the flow towards the outlet. This could be due to the fact that the model struggles to predict the later components of FPCA, producing this incorrect flow field. The results show the difference in the flow field prediction when compared to traditional POD as the downwards curve of the flow can be more accurately visualised shown in figure 3. These results use a different number of components but capture a similar amount of variation; this is to directly compare the effectiveness of both models and to determine how they affect the reconstruction.

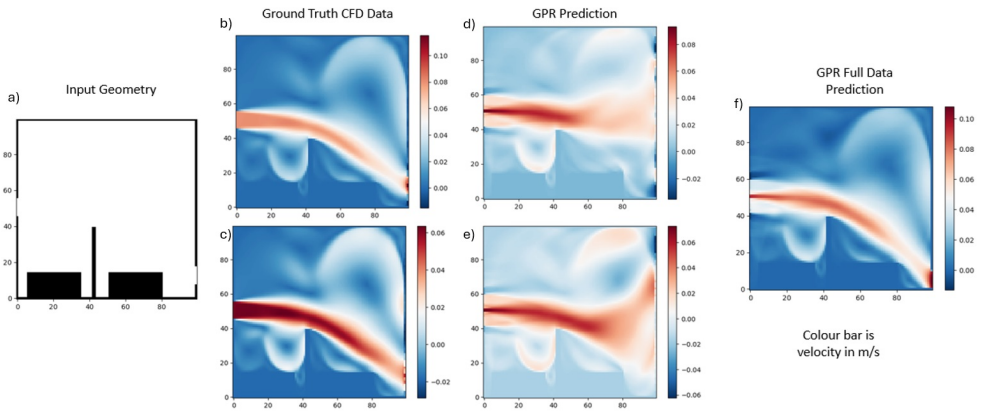

Figure 3. Contour plots comparing the flow field for an inlet position showing a) Inlet position, b) ground truth CFD data after POD reconstruction, c) ground truth CFD data after FPCA reconstruction, d) the GPR prediction using POD data, e) the GPR prediction using FPCA data and f) the GPR prediction for the full data set.

5. CONCLUSION

FPCA can be used to project the flow field in the reduced space captures 87% of the variation using 2 FPCA components compared to POD needing 11 components to reach 86%. 2 POD components only captures 47% of the variation showing the significant change in using FPCA. It also shows that it is more accurate when reconstructing the velocity field, as the distinct flow pattern can be seen, but there is room for improvement as the model struggles towards the outlet.

SUMMARY
This work introduces a project currently underway at RIVM that aims to develop a risk assessment methodology for combined exposure to indoor pollutants following energy retrofits.

In the near future, many homes will be retrofitted to meet the targets on the use of fossil fuels set out by the Dutch Climate Agreement. To assess the impact on indoor air quality and health, we initiated a partnership with housing associations to conduct a measurement campaign, monitoring air quality and occupant behavior before and after renovations. In parallel, we plan to develop quantitative models to estimate the changes in exposure to chemical, microbiological, and radiological agents resulting from these retrofits. Finally, we are exploring methods for integrating the individual health risks associated with exposure to indoor pollutants into a single risk assessment framework.

This work presents the preliminary steps of our study, including a detailed description of our measurement campaign. In addition, we are establishing a network for effective sharing of knowledge with industry and municipal stakeholders.

Keywords: Indoor Air, Retrofitting, Risk assessment, Behavior

1. INTRODUCTION

In 2021, the Dutch government introduced the National Insulation Program (NIP) as part of the Dutch Climate Agreement ('Klimaatakkoord') to make homes more energy efficient. The program aims to provide new insulation to 2.5 million homes - approximately 30% of the total Dutch housing stock - by 2030. Many homes are therefore expected to be retrofitted within the next 5

years, and while reducing housing stock energy demands is critical for sustainability, the large scope of this retrofitting operation has raised questions about its impact indoor air quality. Naively implemented measures may unintentionally worsen indoor air quality (IAQ) (Wang et al., 2022).

Evaluating the potential impacts of energy retrofitting measures (ERM) on indoor air quality is relevant both for public health and public acceptance of these measures. Considerable expertise on the topic exists in relevant domains. However, knowledge gaps remain, making it currently unclear whether robust estimates of net retrofitting effects on IAQ can be achieved. At the Dutch National Institute for Public Health and the Environment (RIVM), the project 'ENABLE' (Energy Transition and Indoor Climate: Towards a risk assessment framework for combined and aggregate exposure.) aims to improve understanding of these effects.

In partnering with housing associations, we are conducting a measurement campaign. During the winters of 2025, indoor environmental factors and airborne chemical, microbiological, and radiological (CBR) pollutants will be monitored in 24 domestic homes, before and after energy retrofits. Multiple efforts have already been made to measure the effects of energy retrofit measures on both sources of and exposure to airborne agents. However, results are difficult to compare due to differences in retrofit measures, measurement equipment, sampling methods, sampling times, building types and occupant behavior (Fisk et al., 2020). To improve comparability and strengthen conclusions, additional research and data collection remain essential. Additionally, we track occupant behavior and perceived indoor air quality, as studies indicate that the user perception of retrofit technologies impact user's implementation (Ortiz et al., 2020).

In addition to measurements, exposure can be estimated with physics-based source-to-dose models. Existing models assess human exposure to chemical substances, biological agents, and radiation in various settings. However, due to the numerous confounding factors that influence indoor pollutant dynamics and exposure, most available models consider highly specified environments. While these detailed models provide valuable insights, they may not always be suitable for determining overall risk. Building on previous research, this study will identify suitable models to estimate occupant exposure before and after retrofitting.

Finally, air quality is often assessed based on the deviation of pollutant concentrations from benchmark values. Instead, we aim to determine air quality from the cumulative health risk of exposure to several indoor pollutants. Such integrated risk estimates are rare, as CBR risk assessments differ significantly in health endpoints and metrics. For example, chemical risk assessments follow the EFSA guidelines on grouping approaches, radon risks are based on a combination of biokinetic models for airways and epidemiological studies, and microbiological hazards use quantitative microbial risk assessment (QMRA) (Committee et al., 2019; ICRP, 2017; UN, 2020). In our proposed case study, we provide an overview of these methodological differences and explore the feasibility of combining them in a single framework. The results of our exposure analyzes, both from the measurement campaign and from our quantitative model, serve as input for this case study.

2. METHODOLOGY

2.1. Recruitment of participating homes

We partnered with housing associations to find 24 domestic homes undergoing substantial energy retrofits. The houses were built around 50-60 years ago, share similar layouts with 90 to 110 m^2 floor area, and sit on sand soil without crawl spaces. Retrofit measures include the following:

- Adding blown-in mineral wool cavity insulation to existing glass wool insulation and repair mortar joints.
- Replacement of windows with HR++ glass and new wooden frames.
- Installing a new 55mm PIR-insulated roof with new tiling.
- The predominantly naturally controlled ventilation system is replaced with a central heat recovery system and sensor or manually controlled mixing fans in each room. The mixing fan moves air from rooms with high CO_2 concentrations to the hallway, relying on the raised pressure gradient to draw in fresh air.
- Maintaining existing gas stoves.

2.2. Monitoring of indoor air

A summary of the indoor environmental factors and pollutants monitored is presented in Table 1. Before starting the measurement, all participants complete surveys on the perceived state of the home environment and their habits. In addition, participants will be asked about occupancy, activity levels, notable indoor activities and perceived indoor air quality levels three times a day.

Table 1. Summary of monitored indoor air parameters, and sampling methodology employed.

Parameter	Sampling method	Sampling location	Sampling time
Active, Continuous Measurements			
Temperature	MF52A NTC Thermistor	L, K, MB, B	2 Weeks (1 min intervals)
Humidity	Sensirion SHT4x	L, K, MB, B	2 Weeks (1 min intervals)
CO_2	SenseAir S88	L, K, MB, B	2 Weeks (1 min intervals)
TVOC, NO_X	Sensirion SGP41	L, K, MB, B	2 Weeks (1 min intervals)
PM 1.0, 2.5, 10	Cubic PM2012B	L, K, MB, B	2 Weeks (1 min intervals)
Noise	ACOEM CUBE, Classe 1	Indoor (L)	2 Weeks
	Munisense NP9, Classe 2	Outdoor	2 Weeks
	Unclassified[a]	Outdoor	2 Weeks
Integrated-Time Measurements

General VOC (incl. BTEX)	VOC Chek 575 Passive Sampler	L	2 Weeks (passive)
General VOC (TO-15 screening)	Silonite Canisters	L	2 Weeks (active)
Formaldehyde	UME[x] 100 Passive Samplers	L	2 Weeks (passive)
Aspergillus Fumigatus	Polystyrene petri dish[b]; qPCR	MB, B	3 Weeks (passive)

[a] DIY noise sensor, design by sensor.community, [b] growth-medium-free,
L = Living room, K = Kitchen, MB = Master Bedroom, B = Bathroom

2.3. Review of source-to-dose models

To control the influence of confounding factors, such as occupant behavior, we propose evaluating exposure in pairs of pre- & post-retrofit homes. This approach helps isolate the effects of energy retrofits on indoor air quality. We will review the available physics-based source-to-dose models and determine, through a multitude of selection criteria, which are the best suited to estimate indoor exposure variations due to energy retrofitting interventions.

2.4. Risk Assessment

In our proposed case study, for each of the respective CBR fields, we characterize the health risk from exposure to an illustrative common indoor pollutant to highlight contrasts and commonalities. These will be; Formaldehyde, commonly found in building materials and household products, is classified as a human carcinogen and can cause irritation of the eyes, nose, and throat; Aspergillus fumigatus, a well-known biological hazard, releases airborne conidia (spores) that can lead to severe lung infections; And Radon (Rn-222), a radioactive noble gas naturally occurring in soil and certain building materials, which is also classified as a carcinogen.

3. DISCUSSION

As part of the ENABLE project, we measured indoor environmental factors and airborne pollutants of 24 domestic homes. This measurement campaign is the first in a series of two, with the next round scheduled for the winter of 2025/2026.

The planned measurement campaign includes a relatively small number of homes, which may limit statistical significance. However, it is expected to provide valuable information on the measurability of different agents in the indoor environment, as well as the significance of observed differences before and after retrofitting interventions. Through this campaign, we aim to assess the feasibility and identify key focus areas for future larger-scale studies.

Furthermore, this project explores the feasibility of integrating risk estimates of exposure to CBR agents. However, combined exposure to stressors from different CBR agents could lead to health effects that are not simply the aggregate risk of individual agents. Such interactions between stressors could introduce errors in our risk assessment. Future work of the ENABLE project will include *in vitro* experiments to investigate these interactions.

Although in its early stages, the project has established a network of researchers, industry partners, and municipal stakeholders. Researchers and stakeholders interested in contributing to the ENABLE project are encouraged to contact us.

SUMMARY
Climate change and carbon emissions have emerged as critical environmental issues worldwide, with the building sector being a major source of carbon emissions. Therefore, it is necessary to predict and benchmark energy consumption considering climatic factors and building elements to achieve energy savings. However, existing methods for analyzing energy consumption factors focus only on the primary influence between input and output variables, highlighting the need for additional approaches to analyze relationships among variables. This study explores the application of causal discovery methods to analyze relationships between climatic factors and building elements. Using synthetic data, the performance of the Peter-Clark (PC) and Fast Causal Inference (FCI) algorithms was compared. The results indicate that while the PC algorithm identifies simple associations, it struggles with hidden confounders. In contrast, the FCI algorithm effectively detects both associations and hidden confounding effects. The study highlights the importance of domain knowledge and suggests future work on diverse data scenarios and algorithm comparisons.

Keywords: Causal discovery, Peter-Clark algorithm, Fast causal inference algorithm, synthetic data

1. INTRODUCION

Climate change and carbon emissions have emerged as critical environmental issues worldwide, with the building sector being a major source of carbon emissions. Consequently, research is being conducted to develop and predict energy usage models that consider various design elements of buildings and climatic conditions. In particular, South Korea is collecting building and energy data for energy benchmarking and analyzing the impact of climate and building factors on the Energy Use Intensity (EUI) (Kim et al., 2019). However, existing data-driven modeling and analysis approaches heavily depend on the expertise of professionals in model construction, and primarily focus on one-dimensional sensitivity analyses between input and output variables. As a result, it is challenging to include and analyze factors related to the interdependencies among variables or hard-to-predict elements, such as occupant behavior, within these models.

Causal discovery is an approach used to identify and understand the causal relationships among variables based on a dataset (Spirtes et al., 2000). By discovering these causal structures, it enables to move beyond simple correlations, providing evidence into the data's inherent dependencies and improving the accuracy of predictive models and decision-making processes (Eberhardt, 2017). Therefore, in this paper, the relationship between solar radiation and building cooling energy consumption was analyzed and compared using the widely used causal discovery methods, the

Peter-Clark (PC) and Fast Causal Inference (FCI) algorithms, on synthetic data. The experiment consists of the following three steps: 1) synthetic data generation. 2) causal discovery using PC and FCI algorithm. 3) compare result and analysis.

2. METHOD

Causal discovery algorithms can be classified into two types: constraint-based and score-based. The constraint-based approach verifies the independence between variables through conditional independence constraints and constructs the graph accordingly. The score-based approach generates a number of candidate causal graphs and selects the graphs with the highest scores. In this study, we conducted research using the PC and FCI algorithms, which are part of the constraint-based methods.

The PC algorithm (Spirtes et al., 2001) is an approach that discovers causal structures under the assumption that no unobserved confounders exist. The process consists of the following steps: 1) It starts by assuming that all variables are connected with edges. 2) It then tests for independence between each pair of variables, removing edges where independence is confirmed to complete the structure. 3) Finally, it determines the direction of influence for the remaining edges to finalize the causal graph. Since the algorithm assumes no unobserved confounders, it may face difficulties in accurately identifying relationships between variables when hidden confounding factors are present. Additionally, as the algorithm focuses primarily on detecting conditional independence, the direction of causal influence may not always be clearly established. The FCI algorithm (Spirtes et al., 2001) is similar to the PC algorithm but operates under the assumption of unobserved confounders, making it applicable when some or all confounding variables are not observed. The procedure of edge removal and initial structure formation is similar to that of the PC algorithm. However, unlike the PC algorithm, the FCI algorithm further incorporates potential hidden confounders when orienting the edges.

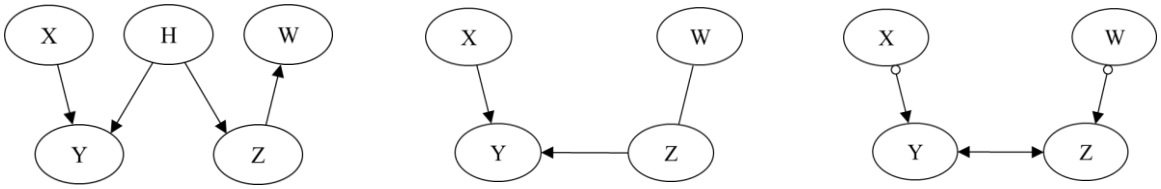
As an example of causal discovery with two algorithms, an analysis and comparison were conducted on 1,000 sample data generated based on Eq. (1)–(5). To compare the differences between the two algorithms, a confound factor H was introduced, which can represent factors such as occupants in the building sector. X, Y, Z, and W are observable factors, which may correspond to variables like outdoor temperature and wall insulation. The confound factor H was designed to influence Y together with X, while also affecting Z, which in turn influences W. Subsequently, causal discovery was performed on the data for X, Y, Z, and W, excluding H. The PC and FCI algorithms were implemented using the Python causal-learn package (Zheng et al., 2024). For the independence verification method, the default Fisher's Z conditional independence test was applied, and the significance level of individual partial correlation tests (alpha) was set to the default value of 0.05.

$$H = uniform[0, 2] \quad (1)$$
$$X = uniform[0, 1] \quad (2)$$
$$Y = 0.4 \times X + H + normal[0, 0.8] \quad (3)$$
$$Z = 0.5 \times H + normal[0, 0.6] \quad (4)$$
$$W = 0.2 \times Z + normal[0, 0.9] \quad (5)$$

Fig 1 shows the analysis results of the sample data using the PC and FCI algorithms. Fig 1(a)

represents the ground truth structure designed for the test, illustrating the causal relationships when the confound factor H is observed. In the case of the PC algorithm, it successfully identified the causal influence of X on Y, but failed to account for the confound factor, leading to the incorrect inference that Z has a direct influence on Y (Fig 1(b)). Additionally, the algorithm detected an association between Z and W, but was unable to determine the direction of the relationship.

In contrast, the FCI algorithm identified the influence of X on Y while also suggesting the presence of a hidden confounding factor (Fig 1(c)). Additionally, the relationship between Z and W indicates weak causal evidence; however, unlike the ground truth, it is inferred that the influence flows from W to Z. In such cases, the graph estimation process can be improved by incorporating domain knowledge (Shen et al., 2020).



(a) ground truth (b) PC (c) FCI

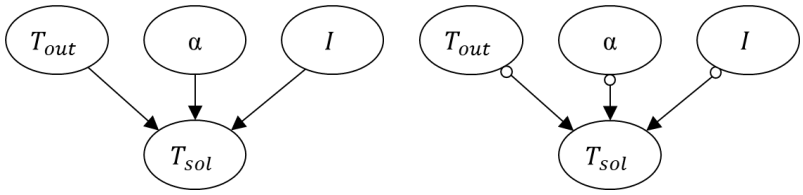
Figure 1. Compare of PC and FCI algorithms

3. RESULTS

In this study, causal discovery was conducted to analyze the relationships between climatic and building factors. Since real-world data contains many uncertainties, a simplified and interpretable structure was designed to generate and utilize synthetic data. The synthetic dataset consists of the sol-air temperature (T_{sol}), the relevant climatic factors (outdoor temperature T_{out}, global solar irradiance I, and extra infrared radiation Q_{ir}), and a building-related factor, solar radiation absorptivity α. The sampling ranges for each variable are presented in Eq. (6)–(9) in the form of [mean, standard deviation], and the sol-air temperature was calculated using Eq. (10). Using these variables, 1,000 samples of synthetic data were generated. To illustrate the difference in interpretation between the PC and FCI algorithms, extra infrared radiation was treated as a hidden confounder, and causal discovery was applied to a dataset in which this variable was excluded.

$$T_{out} = normal[26, 3] \quad (6)$$
$$\alpha = normal[0.5, 0.2] \quad (7)$$
$$I = normal[100, 10] \quad (8)$$
$$Q_{ir} = normal[10, 2] \quad (9)$$
$$T_{sol} = T_{out} + (\alpha \times I - Q_{ir}) \div 4 + uniform[0, 1] \quad (10)$$

Fig 2 shows the results of causal discovery performed using the PC and FCI algorithms, assuming extra infrared radiation (Q_{ir}) as a hidden confounder in the synthetic data. The independence verification method and the significance level of individual partial correlation tests are the same as those described in Section 2. The results indicate that both the PC and FCI algorithms consistently identified T_{out}, α, and I as variables influencing T_{sol}. However, since the FCI algorithm accounts for hidden confounders, the results also imply the presence of an unobserved confounding factor, even though these variables are shown to affect T_{sol} (Fig 2(b)).



(a) PC (b) FCI

Figure 2. Compare of PC and FCI algorithms with synthetic data

4. CONCLUSION

In this paper, a pilot study was conducted on the causal discovery approach to identify the relationships between climatic factors and building elements. Synthetic data were generated, and analyses were performed using the PC and FCI algorithms, with the results compared. The findings revealed that in the presence of hidden confounding variables, the PC algorithm provides information on simple associations, whereas the FCI algorithm offers insights into both associations and the presence of hidden confounding factors.

However, the PC algorithm is advantageous when the relationships between input variables are clear, suggesting the need to analyze various scenarios beyond the one assumed in this study. Additionally, incorporating domain knowledge can enhance causal discovery compared to relying solely on data.

For future work, we plan to compare the performance of the PC, FCI, and other algorithms across more diverse data scenarios, as well as analyze the impact of integrating domain knowledge on causal discovery outcomes.

ACKNOWLEDGEMENTS

SUMMERY
Continuous energy monitoring is essential for identifying potential savings and predicting the energy requirements of buildings. Energy meters are often located in underground spaces that are difficult to reach with wireless technology. This paper presents an experimental study comparing different Low Power Wide Area Networks (LPWAN) technologies in terms of building penetration and radio coverage. The technologies Low Power Long Range Wide Area Networks (LoRaWAN®), Narrow Band Internet of Things (NB-IoT), Sigfox 0G and Wireless Smart Ubiquitous Networks (Wi-SUN®) are evaluated experimentally.

It also proposes a distributed hybrid IoT architecture that combines multiple LPWAN technologies using an abstraction layer to optimize cost and coverage. Communication is message-based using the publish-subscribe messaging pattern. It is implemented using the MQTT protocol. The abstraction layer decodes the proprietary binary data and converts it to a normalized JSON format.

Keywords: energy monitoring, smart buildings, smart metering, LPWAN

1. INTRODUCTION

The Dortmund University of Applied Sciences and Arts operates more than a dozen university buildings spread across the city of Dortmund. These buildings are heated and air conditioned using various forms of energy: District heating and cooling networks, gas and electricity. The energy meters are located in underground rooms and energy supply tunnels that are difficult to reach with wireless technology. Continuous energy monitoring is essential for identifying potential savings and for adaptive model predictive heating control of buildings (Wan et al., 2023). The paper presents an experimental study that compares different LPWAN (Low Power Wide Area Networks) technologies in terms of building penetration and radio coverage. These LPWAN technologies differ in terms of topology (star, mesh), power consumption, link budget, radio coverage and radio range. The experiments will be carried out in various university buildings and in a district heating and cooling tunnel linking several buildings on the campus (see Fig 1 (a)).

Furthermore, the paper proposes a distributed hybrid IoT architecture that combines different LPWAN technologies to optimize cost and coverage. The architecture connects existing energy

meters and sub-meters with different interfaces (M-Bus, Pulse, SML) via multiple LPWAN radio technologies to the IoT middleware.

2. PROBLEM DEFINITION AND METHODICAL APPROACH

This research compares four LPWAN radio technologies for smart metering applications in deep indoor and underground environments. The aim of the research is to investigate the building penetration loss (BPL) of different radio technologies in real-life scenarios. An empirical evaluation is chosen using a pre-installed radio infrastructure. The measurements are performed with inexpensive off-the-shelf equipment. We focus on measuring the BPL without considering the power consumption of the equipment.

We consider two scenarios: In the first scenario, the radio infrastructure, such as gateways (GWs) and base stations (BSs), is installed inside the building. Radio waves propagate through walls and ceilings. It is assumed that the energy meters are located in the basement of the buildings. In the second scenario, the wireless infrastructure is installed outdoors. The radio waves propagate through the windows or the exterior wall into the building (Outdoor to Indoor, O2I). Theoretical path loss models for indoor environments and O2I penetration can be found in (ITU-R, 2015) and (3GPP, 2024) respectively. It is very difficult to calculate the BPL based only on theoretical models because radio waves propagate in different ways in the building due to reflections and diffraction. Especially in deep indoor and underground scenarios such as basements and tunnels, the real signal path and thus the entire link budget is too complex to be accurately represented by a linear model (Malarski et al., 2019).

Therefore, we chose an empirical experimental evaluation where the received signal strength indicator (RSSI) is measured at outdoor measurement points (MPs) at ground level and then compared with the RSSI measured at indoor MPs on the first floor and underground MPs in basements and a tunnel (see Fig. 1 (a)). The BPL is calculated from these measurements and compared between the different radio technologies.

3. RELATED WORK

LPWAN technologies have received increased attention in recent years. They are characterized by their long range and low power consumption. LPWAN technologies known for their good building penetration include LoRaWAN®, NB-IoT, Sigfox 0G and Wi-SUN®. Kadusic et al. (2022) provides an overview of LoRaWAN®, NB-IoT and Sigfox and the characteristics of these radio technologies. Hoo et al. (2023) compares Wi-SUN® with LoRaWAN® and NB-IoT. The main application is a building management system. Naumann and Oelers (2021) compares the energy consumption and the link budget of NB-IoT, LoRaWAN® and Sigfox based on theoretical models.

Roosipuu et al. (2023) investigates the use of NB-IoT for monitoring and control of smart urban drainage systems. Different depths of devices in manholes are investigated. Persia et al. (2017) presents a connectivity analysis of NB-IoT and LoRaWAN® for smart grid applications in outdoor, indoor and deep indoor environments. Tangsunantham and Pirak (2022) presents an experimental evaluation of Wi-SUN® for advanced metering in smart grids. Thrane et al. (2020) presents an experimental evaluation of an NB-IoT propagation model for deep indoor scenarios. The measurement campaign was conducted in a system of long underground tunnels.

4. TECHNOLOGY OVERVIEW

LPWAN technologies known for good building penetration operate in the sub-GHz spectrum and include LoRaWAN®, NB-IoT, Sigfox 0G and Wi-SUN®. LoRaWAN®, Sigfox 0G and Wi-SUN®operate in the unlicensed spectrum of 868 MHz in Europe, while NB-IoT operates in the licensed spectrum of 800 MHz (band 20) or 900 MHz (band 8) in Europe. To ensure fair use of the unlicensed spectrum, each device is limited in transmit power and duty cycle (DC). In the 868 MHz band, the transmit power is normally limited to 14 dBm (25 mW) and a DC of 0.1%, except in the G1 band (868.0 - 868.6 MHz) where a DC of 1% is allowed and the G3 band (869.4 - 869.65 MHz) where a transmit power of 27 dBm (500 mW) and a DC of 10% is allowed. The G3 band is typically used for downlink (DL) messages where a BS is connected to many devices and transmits at high power. In contrast, quality of service can be guaranteed in the licensed spectrum, where the mobile network operator (MNO) controls the use of the spectrum an the DC is not limited.

The proprietary Sigfox 0G radio technology was developed by the French company Sigfox S.A. (now owned by UnaBiz). It uses Ultra Narrow-band (UNB), achieves long range and requires low power. The Sigfox 0G network is based on a star topology and requires a local 0G network operator to carry the traffic generated. In Europe, Sigfox 0G is using the G1 band for the UL and the G3 band for the DL. Sigfox supports up to 140 uplink (UL, from device to BS) and 4 DL messages per day, each carrying a payload of 12 bytes and 8 bytes respectively, at a data rate of 0.1 kbit⁄s. Sigfox 0G subscription cost is 10 € per year for one device and 140 UL, 4 DL messages per day (Heliot Europe).

LoRaWAN® is based on the proprietary LoRa radio technology developed by Scemtech. LoRaWAN® defines the communication protocol and system architecture and is managed by the open LoRa Alliance. It can achieve data rates between 0.25 kbit⁄s and 11 kbit⁄s in Europe. The payload of the messages can be from 51 to 222 bytes in Europe depending on the data rate. The number of messages is limited by the DC regulations in Europe and may be even lower due to restrictions by the LoRaWAN® network operator. The Things Network's (TTN) fair use policy limits a device's airtime to 30 s per day. LoRaWAN® networks can be operated by a network operator, a community such as TTN, or self-deployed. LoRaWAN® thus offers a high degree of flexibility for the end user.

Wi-SUN® is based on the open IEEE 802.15.4g/e standards. Unlike other LPWAN technologies, it offers mesh and multi-hop features for enhanced reliability and range. In addition to low power consumption and long range, it offers lower latency and higher data rate up to 300 kbit⁄s compared to the other LPWAN technologies. The downside of Wi-SUN® is the lower link budget and therefore lower range and building penetration, and the lack of off-the-shelf devices for the end user. The target applications of Wi-SUN® are in the field of building automation (Hoo et al., 2023).

NB-IoT operates in licensed spectrum and is standardized by the 3rd Generation Partnership Project (3GPP) as LTE Cat-NB1 and -NB2. It is only available through MNOs. Implementing NB-IoT is cost effective as it is based on existing cellular infrastructure. Compared to other LPWAN technologies that operate in unlicensed spectrum, the transmit power and DC are not limited by regulation. Therefore, the link budget is higher, resulting in better building penetration. The downside is higher power consumption. NB-IoT offers data rates of up to 62 kbit⁄s in Cat NB1 and up to 159 kbit⁄s in Cat NB2 in the UL and up to 26 kbit⁄s and 127 kbit⁄s respectively in the DL. Applications are typically low throughput, delay tolerant and low mobility. Examples are smart

meters and remote sensors. The cost of the subscription is 11 € for a SIM card, 500 MByte for 10 years (1NCE).

Table 1 compares the key parameters of the technologies. The link budget is the maximum possible path loss from transmitter to receiver. A high value is important for penetrating underground environments. The values are taken from (Naumann and Oelers, 2021) and the data sheets of the experimental equipment in Table 2.

Table 1. Comparison of different LPWAN technologies (Europe)

Technology	LoRaWAN®	Sigfox	NB-IoT	Wi-SUN®
Topology	star	star	star	mesh
Band in MHz	868	868	800 / 900	868
Tx power GW in dBm	14 / 27*	27	23	14
Tx power device in dBm	14	14	23	14

5. EXPERIMENTAL EVALUATION OF LPWAN TECHNOLOGIES

5.1. Experimental setup

An area of the campus consisting of several challenging buildings for building penetration was chosen as the experimental environment (see Fig 1 (a)). We use several off-the-shelf devices for the experiments (see Table 2). Since there are no end-user Wi-SUN® devices available, we use a development kit from Silicon Labs. This equipment does not provide an accurate measurement of RSSI, but is intended to provide an estimate of building penetration with real devices.

Table 2. Devices used in experiments

Device	LPS8	DLOS8	LoRa E5 mini	SIM7020E	MKR FOX	SLWSTK6007A
type	GW	GW	device	device	device	dev kit
manufacturer	Dragino	Dragino	Seeed	Simcom	Arduino	Silicon Labs
radio chip	SX1308	SX1301	STM32WLE	MT2625	ATAB8520E	EFR32MG12
technology	LoRa	LoRa	LoRa	NB-IoT	Sigfox	Wi-SUN®
band MHz	868	868	868	900 / 800	868	868
Tx pow. / dBm	14 / 20	14 / 27	14	23	13	14
Rx sen. / dBm	-140	-140	-136.5	-131	-132	-120

5.2. Indoor experimental evaluation of LoRaWAN® and Wi-SUN®

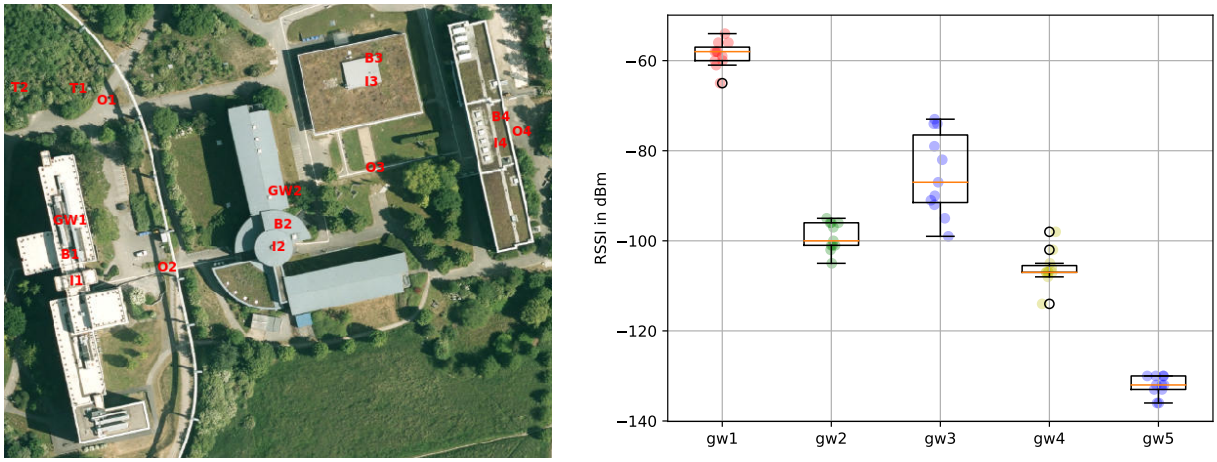
In the first measurement campaign, we compare LoRaWAN® with Wi-SUN®. The experiments are performed in building 2, where the LoRaWAN® gateway GW2 (LPS8) is placed on the first

floor near a window. Measurements are made on different floors and in the basement to measure the penetration loss of the ceilings. With LoRaWAN® it is possible to reach every floor of the building up to the 3rd floor and even the basement. Penetration loss is 10 dB for each ceiling upstairs and 55 dB to the basement.

With Wi-SUN® it was only possible to penetrate two ceilings. The basement could not be reached with this technology. In general, it was not possible to establish a stable connection when the RSSI was lower than -95 dBm. Due to the relatively low link budget, building penetration is not Wi-SUN®'s strength. Rather, its strengths lie in high data throughput and low latency.

5.3. O2I penetration of LoRaWAN®, Sigfox OG and NB-IoT

Fig. 1 (a) shows the experimental area at the campus Emil-Figge-Str. in Dortmund. The outdoor MPs are named O1, O2, O3 and are located between the buildings. The indoor MPs I1-I4 are located on the first floors in the entrance halls of the buildings. The MPs in the basements of the buildings are labeled B1-B4. There are two MPs in the energy supply tunnel, T1 and T2. T1 is placed under an emergency manhole of the tunnel, T2 is placed directly at the heat meters. Two LoRaWAN® gateways are placed in the area. The outdoor gateway GW1 (DLOS8) is placed on the roof of building 1, while the indoor gateway GW2 (LPS8) is placed inside on the first floor near a window. Both gateways are preinstalled and not placed for this work.



(a) (b)

Figure 1. (a) Experimental area at campus Emil-Figge-Str. with measurement points marked in red (b) LoRaWAN®RSSI values of Gateways at measurement point O2

At each MP, several measurements are made for each radio technology except Wi-SUN®. The results are shown in Table 3. For LoRaWAN®, the reported RSSI fluctuates a lot. Fig. 1 (b) shows the fluctuation of the RSSI reported by the gateways. The values are not normally distributed and have outliers. The RSSI values in the figure are reported by four gateways receiving the messages from a device at O2. The RSSI values in the Table 3 are the medians of the measurements at the indicated MP. In this challenging environment, Sigfox 0G was unable to reach the basements of the buildings (except B2 and B4) and the energy supply tunnel. LoRaWAN® can reach the basements and the tunnel except for MP T2, which has a greater distance to the emergency manhole than T1. Two MNOs with different frequency bands are evaluated. Vodafone (NB Vo) uses band 20 (800 MHz) for NB-IoT, while Deutsche Telekom (NB DT) uses band 8 (900 MHz). The RSSI values for NB-IoT are measured DL and are obtained directly from the NB-IoT

modem using AT commands. The UL RSSI values for LoRaWAN® are obtained from the TTN back-end. The DL RSSI is obtained from the device using AT commands. The Sigfox 0G RSSI values are measures UL at the BS and reported by the Sigfox back-end system.

Table 3. RSSI values in dBm for LoRaWAN® (LW), NB-IoT (NB) and Sigfox

MP	LW UL	LW DL	NB DT	NB Vo	Sigfox
O1	-72	-68.5	-66	-77	-96.5
O2	-58	-61	-66	-74	-94
O3	-57	-55	-63	-73	-101
O4	-83.5	-84	-64	-74	-100
I1	-81	-78.5	-74	-84.5	-111
I2	-87	-90	-85	-90	-116.5
I3	-102	-102.5	-90	-99	-127
I4	-93	-94	-77	-81	-114
B1	-101	-106	-95	-116	-
B2	-111	-110	-97	-112	-137
B3	-114	-115	-110	-111	-
B4	-111	-106	-85	-94	-124
T1	-116	-112	-107	-114	-
T2	-	-	-112	-118	-

To compare the BPL of different LPWAN technologies, the RSSI of the indoor MPs is subtracted from the RSSI of the nearest outdoor MP. Table 4 compares the BPL for each indoor MP.

Table 4. Calculated O2I BPL from nearest outdoor MP to indoor MP in dB

	I1	B1	I2	B2	I3	B3	I4	B4	T1	T2
LoRaWAN® UL	23	43	29	54	45	57	9.5	27.5	44	-
LoRaWAN® DL	17.5	45	29	55	47.5	60	10	22	43.5	-
Sigfox 0G	14.5	-	22.5	43	26	-	13	23	-	-
NB-IoT DT B8	8	29	22	34	27	47	13	21	41	48
NB-IoT Vo B20	10.5	42	17	39	26	38	7	20	39	45

Due to measurement inaccuracies, these values are not exact and it is not possible to rank the performance of the technologies in terms of BPL. In addition, the LoRaWAN® GWs adjust the transmit power depending on the RSSI, so the BPL in the DL may be too low.

The BPL depends more on the signal path than on the LPWAN technology used. The LoRaWAN® GW1 is placed on top of building 1, the signal has to travel through all ceilings to reach the first floor and the basement. Therefore the BPL of I1 and B1 is much higher for LoRaWAN®compared to NB-IoT and Sigfox 0G. The basement of building 4 is underground on the west side and above ground on the east side. The signal of LoRaWAN® comes from the west, that of NB-IoT and Sigfox 0G come from the east, so the BPL of LoRaWAN® is much larger than that of NB-IoT and Sigfox 0G. The Sigfox 0G BS is much further away than the LoRaWAN® GWs. The angle of entry into the buildings is therefore significantly flatter compared to LoRaWAN® and the BPL is in a similar range to NB-IoT.

From the measured values it can be concluded that the angle at which the signal enters the building, and therefore the position of the GW and BS, has a greater influence on BPL than the technology used. This means that if the LPWAN infrastructure is unknown, the suitability of a LPWAN technology must be determined by measurements. However, the measured values can be used to determine the order of magnitude of BPL to be expected. It is clear to see that the MPs in the basements have a very high BPL of up to 60 dB for LoRaWAN®, which means that the signal is attenuated by a factor of 10^6.

6. LPWAN ARCHITECTURE

There are many reasons to choose a LPWAN technology. In addition to range and building penetration, cost, availability of devices and infrastructure play a major role. In addition, technologies are constantly evolving. Technologies such as Wi-SUN®, which are not widely used today, may become more prevalent in the future, while other technologies such as Sigfox may become less important. In particular, the market for LPWAN energy monitoring devices is changing rapidly. Even if a separate LoRaWAN® infrastructure is operated, it is usually cheaper to use an NB-IoT device than to install a separate LoRaWAN® gateway for a single device if there is no LoRaWAN® coverage at the device's location. For this reason, a hybrid and modular

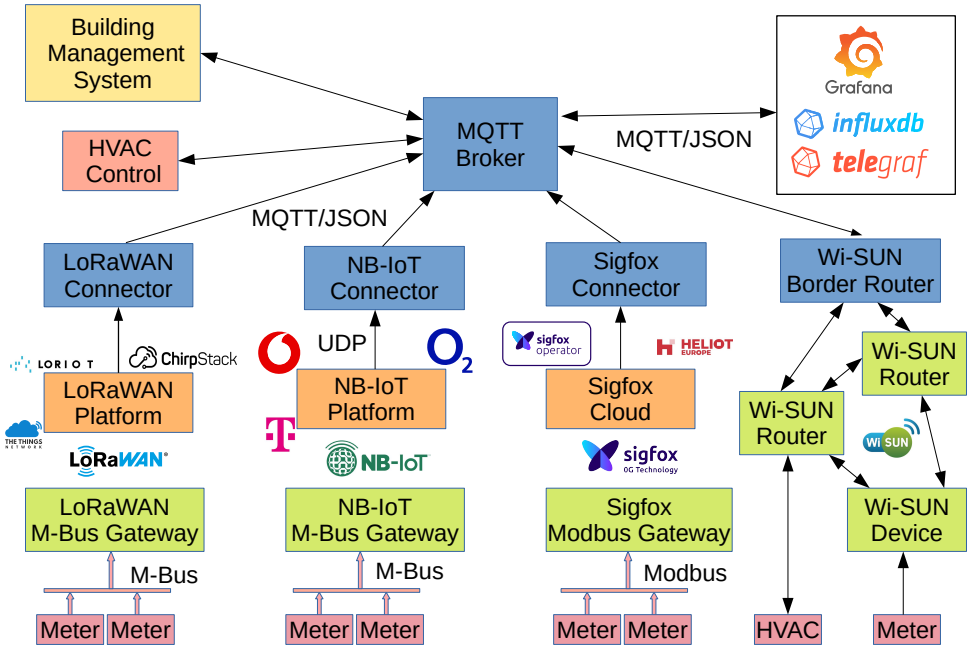


Figure 2. Proposed architecture for energy monitoring and control

architecture is proposed in which multiple LPWAN technologies can be integrated (see Fig. 2). The communication is message based and uses the publish-subscribe messaging pattern. It is implemented using the MQTT protocol. Multiple devices such as meters are connected to a MQTT broker via software connectors. The software connectors provide an abstraction layer for LPWAN technologies with a common interface based on MQTT and JSON.

The architecture connects existing energy meters and sub-meters with different interfaces to the IoT middleware via multiple LPWAN radio technologies. The district heating and cooling meters provide an M-Bus interface, while the gas meters provide only pulses to be counted. Energy data from different sources and technologies is transmitted over different wireless technologies. A connector for each technology receives the energy data over the Internet, decodes the binary

data, and converts it to a normalized JSON format. The energy data is then published to a MQTT broker, which acts as a central hub in the system. The data is stored in a time series database for later analysis and visualization in a web front-end.

7. CONCLUSIONS

The paper presents an experimental evaluation of four LPWAN technologies in deep indoor environments. LoRaWAN® and NB-IoT show better building penetration than Sigfox 0G and Wi-SUN®. By using licensed radio bands and automatic retransmission in case of packet loss, NB-IoT offers higher reliability compared to other LPWAN technologies. Compared to NB-IoT, LoRaWAN® has the advantage of lower power consumption, greater flexibility in the choice of infrastructure, and a wider range of devices available for energy monitoring. Wi-SUN® may become more important in the future due to its mesh topology. However, there are currently no energy monitoring devices available for use in Europe. Furthermore, Wi-SUN® has the lowest building penetration compared to the other LPWAN technologies considered. Sigfox 0G generally offers a high link budget and therefore the potential for high building penetration, but only two out of four basements are reached in the experimental evaluation. This is likely due to the low density of Sigfox BSs in the area studied.

A hybrid and modular architecture for energy monitoring has been proposed that can integrate multiple LPWAN technologies. The architecture has been implemented and tested for LoRaWAN® and NB-IoT. It is successfully used for energy monitoring in several buildings at the Dortmund University of Applied Sciences and Arts.

SUMMARY
Recently, several administrative registration datasets have become public or partially accessible, including building registries, monthly energy billing information, building footprint polygons, business registration data, ministry-maintained facilities data, and weather data. However, from a building analysis perspective, these datasets remain fragmented as they are by-products of administrative processes not originally designed for integration. This paper introduces the *DataNet* project, which aims to integrate multifaceted building energy datasets nationwide in South Korea. The main objectives are to establish a national data framework that accelerates the transition to carbon neutrality in the building sector, and to support more effective, evidence-based performance analysis. In this project, the building registry serves as a reference base, with other datasets linked through addresses and associated attributes, such as building or business names. To date, we have collected and linked 13 of the 19 targeted datasets. This paper presents the overall framework, data categories, spatial and temporal resolutions, and linkage approach.

Keywords: data framework, linked data, carbon neutrality, evidence-based, performance gap

1. INTRODUCTION

As a cornerstone initiative to support evidence-based decision making in Korea's decarbonization strategy, the *DataNet* project was launched in April 2023, with a four-year timeline extending through December 2026. This collaborative endeavor brings together approximately 130 researchers and experts from 16 institutions across the country. The project is structured into four distinct work packages: (1) development of multi-faceted data linkage technologies, (2) design of unstructured data informatization techniques, (3) establishment of building energy consumption performance evaluation methodologies, and (4) construction of an Integrated Building Energy Database (I-BED) system and preparation of a utilization framework. This paper focuses specifically on the first work package — the result of multi-faceted data linkage — which has been the primary focus during the initial two years (2023-2024) of the project. The paper explains the data identification, collection, and linking approaches at a nationwide scale, along with an overview of the constructed 13 datasets.

Carbon neutrality achievement in the building sector faces considerable complexity due to the scale of existing building stock, which numbers approximately 7 million buildings in South Korea.

While most policies and regulations focus on large buildings, new constructions, and energy-efficient buildings, small buildings (less than 1,000 ㎡), which account for more than 90% of existing building stock, remain overlooked in energy and GHG emissions management. Kim et al. (2019), Ahn et al. (2022), Kim et al. (2022) and Kim et al. (2024) highlighted this South Korean challenge and proposed a cost-effective approach to address it. The management of these buildings is particularly challenging due to limited data availability. Addressing these underserved areas is critical for achieving carbon neutrality in the building sector in an equitable manner. To support this goal, the *DataNet* project focuses on building-level benchmarking, aiming to establish appropriate baseline consumption patterns and identify inefficient buildings at a nationwide scale.

The IEA EBC Annex 53 framework identifies six primary factors: climate, building envelope, building services and energy systems, building operation and maintenance, occupants' activities and behavior, and indoor environmental quality (Yoshino et al. 2017). The *DataNet* project extends this framework by adding two additional factors and further subdividing total energy consumption by source and usage. These factors can be categorized into eight main groups: (1) weather factors (temperature, humidity, solar radiation), (2) building physical factors (form, shape, size, thermal properties, window-to-wall ratio), (3) system factors (system load, efficiency, specifications), (4) building type factors (primary space use categories), (5) operational and activity factors (number of workers, operating hours), (6) social factors (age, gender, behavior patterns), (7) demographic factors, and (8) neighboring factors (Figure 1). These various factors are essential for ensuring equitable energy benchmarking.

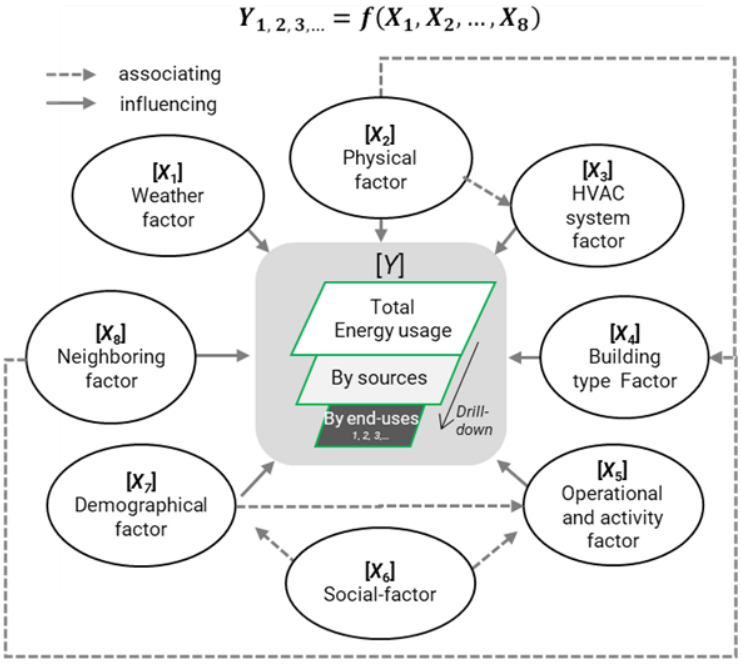

Figure 1. Conceptual diagram illustrating the association between multi-faceted factors and energy consumption.

2. DATASETS

Government-held (partially) open data serves as a critical foundation for such analysis, providing extensive coverage and meta-level insights that would be impossible to obtain through individual research efforts. However, these datasets have been independently developed by different

government departments for their specific administrative purposes. For instance, the Ministry of Land, Infrastructure and Transport (MOLIT), Ministry of Health and Welfare (MOHW), and Ministry of Education (MOE) maintain building registration, medical facility information, and educational facilities databases, respectively. This siloed approach to data collection and management has created disconnections that hinder the building-level integration necessary for comprehensive energy performance analysis.

The data identification and selection process consisted of several steps. First, the government-held open datasets were reviewed primarily through the Public Data Portal (www.data.go.kr), which serves as an integrated platform providing multiple datasets from various government departments and agencies. Second, the potential contribution to evidence-based energy benchmarking also was evaluated. Third, the building-level matching capability (data interconnectivity) between siloed instances was assessed using attributes such as building primary key, addresses, or business names. Finally, factors were allocated based on the expanded IEA EBC Annex 53 framework (Figure 1).

Table 1. Overview of identified and collected datasets for building energy benchmarking

	Data Name	Responsible Ministry	Working Progress	Key Information
X_1	Meteorological Observation data	KMA	Done	Regional weather data (temp., RH, solar radiation, etc.)
X_2	Building registry	MOLIT	Done	Address, name, register type, use purpose type, approval date, area, floor info., parking lot, etc.
	Energy Performance Certificates	MOLIT	TBD	Address, name, Grade, simulation info., etc.
	GIS Bldg. footprint data	MOIS	Done	Address, name, number of floors, 2D polygon (shape), etc.
X_3	Mech. equipment maintenance information	MOLIT	TBD	Address, name, field diagnostics for building mechanical equipment
X_4	Cultural facility information part A (Cultural Center, Literature Center)	MCST	Done	Address, name, facility use type, workforce composition information, no. of visitors, operating hours, etc.
	Cultural facility information part B (Libraries, Museums, and Art Galleries)	MCST	Done	*Same as above*
	Medical facility information.	MOHW	Done	Address, name, medical facility class, workforce composition info., no. of beds, operating hours, equipment, etc.
	Higher education facilities information	MOE	Done	University-related statistical information
	K-12 education facility information	MOE	On-going	Elementary/middle/high school-related statistical info.
	Childcare facility information	MOE	On-going	Basic information and current status of childcare centers
X_5	Local administrative business permit data	MOIS	On-going	Permit information for various industries
	Commercial small business information	MSS	TBD	Address and industry data for businesses nationwide
	Apartment management information	MOLIT	TBD	Apartment management fees, energy usage information
	Building historical permit data	MOLIT	TBD	Construction permits, demolition, loss-related information
X_{6-7}	Assessed land value info.	MOLIT	Done	Individual publicly announced land prices
	Resident registration data	MOIS	TBD	Household member information (no. of member, gender, age, etc.)
X_8	GIS Bldg. footprint data *Same as above X_2*	MOIS	Done	2D polygons (shapes) of nearby buildings in a 50-meter buffer around the buildings
	Land use plan info.	MOLIT	TBD	Land use planning information,
	Building 3D geometry data	MOLIT	TBD	3D building form, address, etc.
Y	Monthly energy billing registry	MOLIT	Done	Energy consumption by sources (electricity, gas, district heating)

2.1 National Building Energy Database as a reference base

The Korea Real Estate Agency has been constructing and maintaining the National Building Energy Integrated Database (NBEID) over the past decade by combining building registry information with building energy consumption billing data (Choi et al., 2017; Ji et al., 2020). The NBEID provides nationwide building-related energy consumption information by integrating two core databases: Building Registry DB, which contains essential building information, and Monthly Energy Billing DB, which records energy usage data (Figure 2). Using the Building Registry DB as a reference base, other datasets were linked according to three matching categories: 1:1 matched, 1:N matched, and unmatched. Figure 3 shows an example matching process from footprint polygon data to a building register (standalone type and complex type).

This database comprises approximately 6.25 billion electricity, gas, and district heating usage records collected from about 50 million individual meters connected to approximately 7.3 million buildings nationwide. This information enables the analysis of energy consumption patterns by meter type across national buildings, providing macro-level insights into energy usage patterns and trends. The *DataNe*t project aims to integrate and link recently released or partially released public data at the building level, utilizing the NBEID and its Building Registry DB as the foundation for data integration.

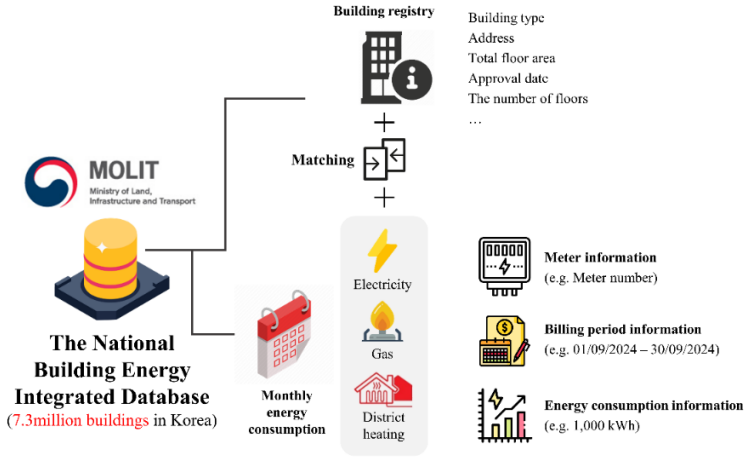

Figure 2. Overview of the National Building Energy Integrated Database

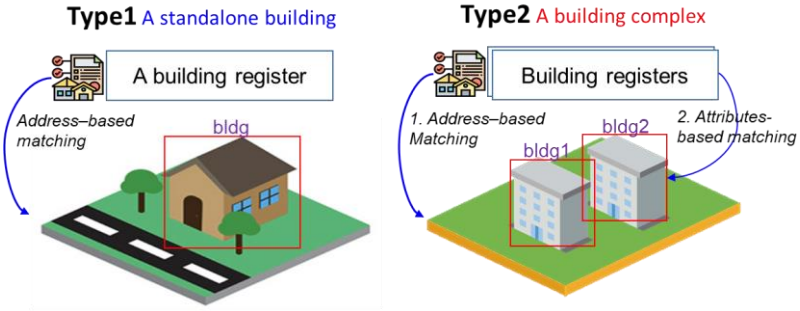

Matching Class	Matching Sub-class	Remark
1:1 Match	Address with bldg. name 1:1 matching	High reliability in matching
	Address only 1:1 matching	
1:N Match	Attribute cross-matching	Medium reliability in matching
	Address code matching	
Un-mappable	Unmappable	Unable to match

Figure 3. Building footprint polygon and registry matching examples for various building configurations within a single land plot

2.2 Data collection with influential factors

The NBEID has numerous applications, such as deriving national-level energy intensity statistics (Kim et al., 2019) and proposing benchmark values for energy benchmarking (MOLIT, 2020). However, from a 'ceteris paribus' perspective, more diverse information is required for energy benchmarking. Based on this perspective, international studies such as Total Energy Use in Buildings (IEA EBC Annex 53) and Building Energy Epidemiology (IEA EBC Annex 70) have been conducted to comprehensively understand building energy consumption patterns (Hamilton et al., 2013; Yoshino et al., 2017). Furthermore, major advanced countries are making efforts to connect building and energy information at the national level under government leadership. Notable examples include Standard Energy Efficiency Data Platform in the United States (Long et al., 2020), the National Energy Efficiency Data Framework in the United Kingdom (DESNZ, 2024), and the Digital Building Logbook (European Commission, 2023) and Building Stock Observatory (European Commission, 2024) in Europe.

From a building perspective, the datasets are completely fragmented, as they are by-products of administrative processes not designed for integration. The research team identified and collected 17 datasets representing fragmented energy consumption influencing factors, as shown in Figure 4. The datasets were classified into 'Common Base' and 'Use-Specific' categories, distinguishing between data that exists commonly across all building types and data that is disclosed specifically according to building use. The reference date for data collection is December 2022, and the energy consumption data spans five years from 2018 to 2022.

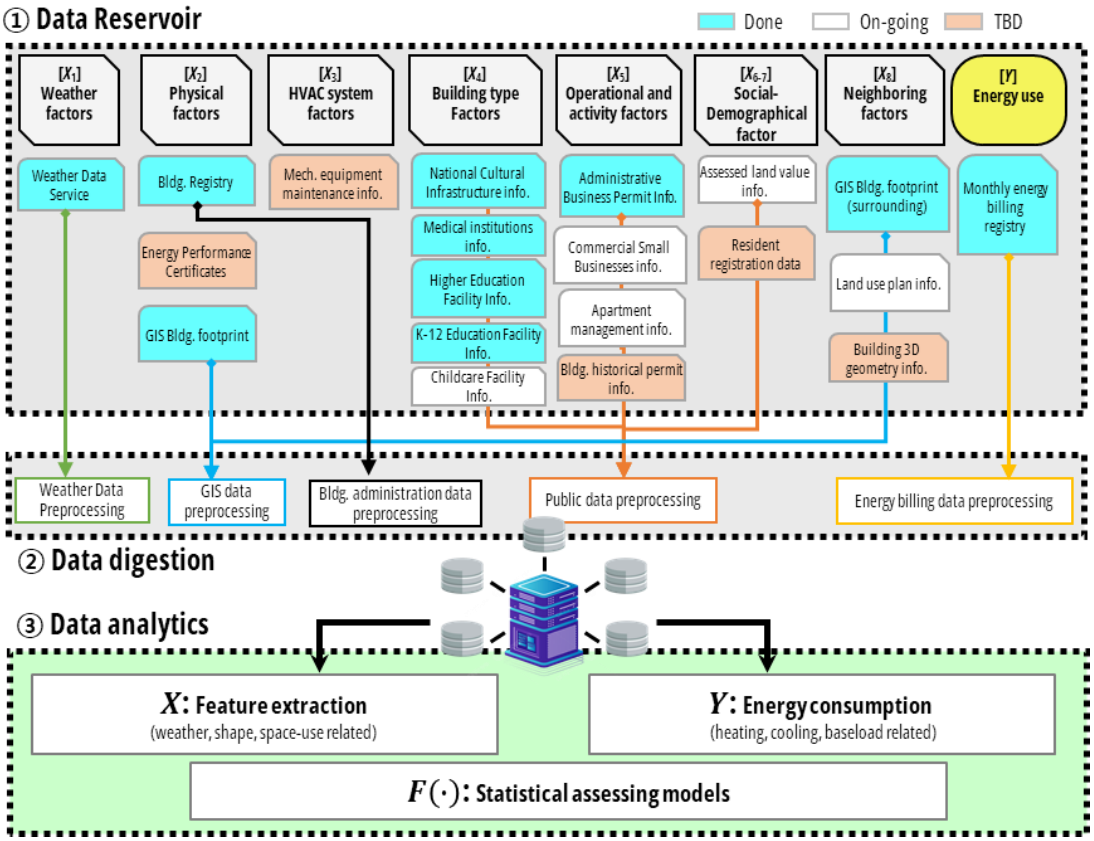

Figure 4. Data integration flowchart

3. SNAPSHOT OF DATASETS

From the established database, energy consumption data were extracted for approximately 590,000 buildings in Seoul, South Korea's capital city (total floor area: 369,027,000 m²). The total energy consumption of 60,459 MWh comprises: electricity: 28,305 MWh (83.0 kWh/m²), city gas: 31,135 MWh (92.6 kWh/m²), district heating: 1,018 MWh (60.7 kWh/m²), total energy intensity: 163.8 kWh/m². These energy flows are visualized in the Sankey diagram (Figure 5), which shows the overall energy distribution by source (left) and highlights cooling energy use (right).

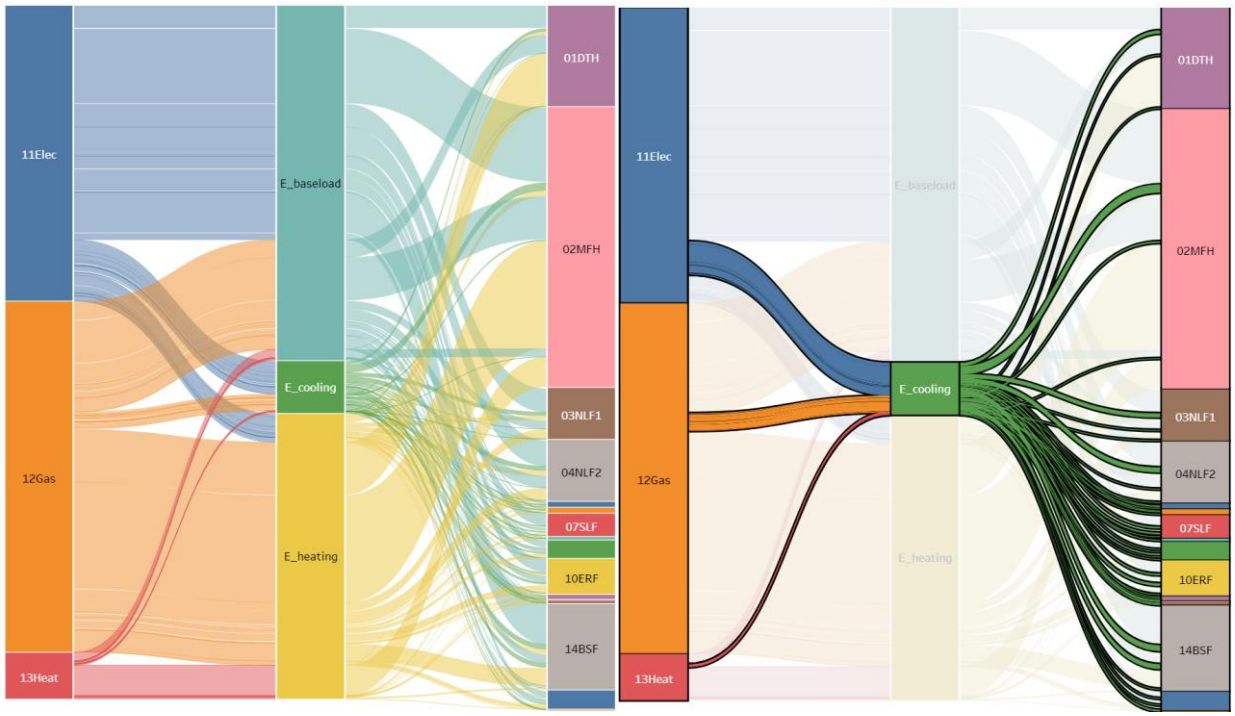

Figure 5. Sankey diagram illustrating energy flows from sources (left) and highlighting cooling energy use (right).

The diagram consists of three main sections: energy sources (left bar) displaying inputs 'Elec' (electricity), 'Gas' (city gas), and 'Heat' (district heating); energy use categories (middle bar) connecting sources to consumption types ('E_baseload', 'E_cooling', 'E_heating'), with flow line thickness indicating energy quantity; and final consumption (right bar) showing building type categories ('01DTH: detached house', '02MFH: multifamily housing', '07SLF: sales facility'). The color coding and flow lines illustrate energy distribution patterns, with 'Gas' primarily serving 'E_heating' (shown in yellow). For cooling energy specifically, electricity ('Elec', shown in blue) serves as the primary source, while gas ('Gas', shown in orange) and district heating ('Heat', shown in red) contribute minimally to cooling demands.

Figure 6 presents a prototype viewer developed for exploring building data status. The viewer comprises six main components: (1) an address search box for locating buildings, (2) building registration information displaying official building data, (3) building floor information with level-by-level usage details, (4) change-point regression analysis results revealing energy use patterns, (5) disaggregated heating and cooling EUI (Energy Use Intensity) data that show detailed energy consumption, and (6) monthly energy consumption by source, illustrating seasonal and temporal trends. In addition, the viewer provides shading information through two features: (7) an

interactive filter that allows users to select a season and cardinal direction to assess building shading performance, and (8) a GIS-based spatial map displaying shading index values for surrounding buildings. For a more detailed and exemplary application of the integrated datasets—particularly regarding the building footprint polygons—please refer to Choi et al. (2025).

Figure 6. Prototype Design of the Data Dashboard for individual buildings

4. DISCUSSION AND CONCLUSION

Regulating building energy performance during the operational phase must be based on data and evidence. Simply targeting high energy-consuming buildings for intensive management and penalties may be unreasonable, as energy consumption is influenced by various contextual factors. Similarly, buildings with large indoor parking areas receiving exclusions or incentives due to low energy use intensity warrants careful reconsideration. In this context, the present study aimed to establish a foundation for comprehensively linking and integrating data on buildings, energy consumption, and their influencing factors. To achieve this objective, 17 datasets were selected based on the building registry. Of these, 13 datasets—including the building registry, road name electronic map building polygons, and local government permit information—were successfully collected, linked, and integrated.

The data integration process presented several technical challenges, including differences in data formats and address systems across government agencies, as well as inconsistencies in data collection cycles and update timelines. To address these challenges, a combined approach using exact matching (1:1 between addresses and the building registry) and partial matching (1:N) techniques was implemented. Additionally, data refinement and processing methods were developed (Kim et al. 2024) to effectively analyze energy consumption characteristics. By linking fragmented datasets at the individual building level, this research aims to establish a methodology

that enables multifaceted assessment of energy consumption patterns, ultimately supporting more informed and accurate evaluations. As this data integration framework matures and becomes standardized, many of the current data linkage challenges are expected to be resolved. Furthermore, if this research contributes to the development of decision-support tools for policymakers, it could facilitate a significant paradigm shift in energy performance evaluation.

ACKNOWLEDGEMENTS

This work is supported by the Korea Agency for Infrastructure Technology Advancement(KAIA) grant funded by the Ministry of Land, Infrastructure and Transport (Grant RS-2023-00244769, Development of a data framework for integrating building energy datasets and applications to accelerate carbon neutrality in the building sector).

SUMMARY
Urban Building Energy Models (UBEM) rely on data-driven techniques and offer a structured approach and methods for making informed decisions to reduce the carbon footprint of buildings. Traditionally, UBEM focuses on modelling building structures and simplified representations of heating systems. However, a lack of knowledge about installed solar panels, electric vehicles (EVs), and heat pumps (HPs) can significantly impact the accuracy and effectiveness of these models. Understanding the presence of these assets is crucial for accurately estimating a building's energy use and its potential for decarbonization. This study applies a data-driven method to identify solar panels, EVs, and HPs from residential electricity consumption time-series data for use in UBEM. By analysing large datasets from buildings with varying levels of electricity usage, machine learning algorithms are applied to capture patterns in energy consumption over time. The proposed approach uses historical electricity consumption profiles to predict the presence of these assets, without depending on specific building characteristics. This allows for broader applicability across different building types and locations, even when detailed metadata is unavailable. Several machine learning techniques were compared, and thorough feature engineering was conducted to enhance the model's accuracy. The results demonstrate that the model can achieve an accuracy of over 90%, making it suitable to be sent for more optimization in production phase and prepare for real-world applications. However, future works will explore whether the model requires periodic retraining due to changes in weather conditions, although this effect varies across regions, highlighting the need for localized adjustments in future applications. Moreover, this approach can play a key role in supporting remote energy certification of buildings, making it a valuable tool for energy efficiency assessments.

Keywords: Machine-learning models, time series analysis, electricity smart meter, urban building energy modelling

1. INTRODUCTION

Traditional urban building stock models use urban building energy modelling (UBEM) principles which account for representative buildings (archetypes) to quantify the energy efficiency measures at the building stock level. These models address the heterogeneity in the building morphological characteristics, building age, insulation performance. Hence, these models cannot account for the complete variation in building operations which can cause inaccuracies and uncertainties in the outcomes [Guo et. al, 2025]. The models often lack information about installed photovoltaic (PV) panels and electric vehicles (EV). However, the energy intensive assets such as heat pumps (HP), photovoltaic panel (PV) and electric vehicles (EV) are usually either omitted from these models or studied in post-processing steps. Conventionally, these assets are not among the data available to the researchers conducting urban energy analysis.

The development of smart metering infrastructures has generated rich streams in time series format. Such time series contain hidden information on the type of installed building systems and play a huge role in assessment of operational energy conservation measures. One of the techniques

utilizing these streams is load profile characterization that can generate useful information to enhance building energy modelling and provide metrics to represent patterns and variability of load profiles (Kim et. al, 2023). Such characterizations can be used to identify the kind of electrical appliances and the electric-base heating systems. We utilize these time series and train machine learning models to predict what large consumer electrical assets are installed on a house associated to a time series of electricity consumption. The outcomes provide means for researchers to generate distributions of installed assets in the residential building stock by using large datasets of electricity smart meter.

1.1 State of the art

A variety of data-driven techniques have been adopted in building energy simulations for a variety of applications (Sharifi, 2023).When considering the use of time series of measured building energy use, numerous load profiling frameworks already exist in the literature mainly aimed to classify and identify homogeneous groups of daily load profiles with the aim of load forecasting. Wang et al. (2019) employed a deep learning predictive approach for district scale building energy modelling. The building network was constructed based on correlations between the energy use intensity of buildings, which significantly reduced the computational complexity of the deep learning models for energy dynamic prediction. This study estimated monthly aggregates as the final output and did not consider the time-series dynamics with limited information on installed heating, cooling and ventilation (HVAC) systems. Wei et al. (2021) predicted district heating load using shallow and deep machine learning algorithms that identified the effect of time horizon and historical time-series data on the prediction accuracy. Recent studies (e.g., Hafeez et al., 2020 and Kim et al., 2019) have demonstrated the effectiveness of machine learning techniques in energy including electricity and heating demand forecasting.

1.2 Research question

In this study, we will deploy ML techniques to train models that can predict installed assets such as HPs, EVs, and PVs on a house with given electricity consumption time series. Previous studies have deployed advanced ML techniques to directly forecast demand time series that are mostly used in operation phase. We, on the other hand, aim for using ML techniques to extract extra data from time series to feed into physics-based model in UBEM. As the implication of the work, distribution of installed HPs, EVs, and PVs can be eventually extracted from a large dataset of anonymous electricity demand time series for a region. As previous studies have been developed to serve a different purpose, we aim for extensive research on feature engineering, appropriate models, minimum and maximum required data availability, and check for possibility of model drift. We will also discuss the expected accuracy from the developed models and their possible implications for UBEM.

2. METHODLOGY

This study follows a common structured ML model training framework (Kim et al., 2023), starting with data collection. Labelled electricity consumption time series are imperative to train a model to predict installed EVs, PVs, and HPs from time series. We use a dataset provided by Fluvius which is the grid operator in Flemish region in Belgium (Fluvius, 2024). The time series are anonymous, but they have indication on which large electricity asset has been installed on the associated house. Once the raw data is gathered and cleaned up for analysis, exploratory data

analysis (EDA) is performed to understand distributions, detect anomalies, and identify potential relationships through statistical summaries and visualizations. Following EDA, data cleaning and preprocessing take place to handle missing values, correct inconsistencies, and remove outliers. This step ensures that the data is in a suitable format for modelling, including normalization or standardization if necessary. Once the data is cleaned, feature engineering and selection are applied to create new informative features while eliminating irrelevant or redundant ones that do not contribute to model performance. With the dataset prepared, it is then split into training, validation, and test sets to ensure proper model evaluation. Typically, a common split such as 80%-20% is used in this step, depending on dataset size. The next step involves initial modelling to establish a baseline, where simple models to serve as reference points for further improvement. In this step we use most common existing supervised algorithms for benchmarking. After establishing a baseline, more advanced ML models are trained, and hyperparameter tuning is conducted using grid search. Cross-validation, particularly k-fold cross-validation, is used to ensure generalizability. By that, we can show how much the model is trustable to be used in real applications. Model evaluation is conducted based on relevant performance metrics, such as accuracy in predicting labels, precision-recall, and F1-score as common metrics for classification tasks. Once models are trained and evaluated, model interpretation will be carried out using confusion matrix.

Our approach is generally called time series classification (TSC). Middlehurst et al. (2025) defines TSC as "fitting a model from a continuous, ordered sequence of real valued observations (a time series) to a discrete response variable" after their thorough review on an extensive list of applicable TSC algorithms. They listed and reviewed eight main algorithms that are tabulated in Table 1.

Table 1 Eight main algorithms for time series classification.

Method	Summary	Pros	Cons	Applications	Example Algorithm
Distance-Based	Measures similarity using distance metrics like DTW.	Simple, effective for small datasets.	Computationally expensive for large data.	Pattern recognition, anomaly detection.	KNN-DTW
Feature-Based	Extracts statistical features and applies ML models.	Interpretable, efficient for short series.	May lose temporal dependencies.	Medical signals, finance, monitoring.	Random Forest (RF), XGBoost
Interval-Based	Uses selected time intervals for classification.	Robust, handles long time series well.	Performance depends on interval choice.	Speech, financial forecasting.	Time Series Forest (TSF), RISE
Shapelet-Based	Identifies key patterns (shapelets) for classification.	Interpretable, phase-independent.	Computationally intensive, slow.	ECG analysis, gesture recognition.	Shapelet Transform Classifier (STC)
Dictionary-Based	Converts time series into symbolic representations.	Good for repetitive patterns, scalable.	Loses some temporal order info.	Text mining, speech, DNA analysis.	BOSS, WEASEL
Convolution-Based	Uses convolutional kernels to extract patterns.	Automates feature extraction, accurate.	Needs large data, computationally heavy.	Industry, activity recognition.	ROCKET
Deep Learning-Based	Uses neural networks (CNNs, RNNs, Transformers).	Scales well, learns complex patterns.	Requires large datasets.	Speech, biomedical diagnostics.	ResNet, InceptionTime, LSTMs
Hybrid Approaches	Combines multiple classification models.	High accuracy, leverages multiple methods.	Computationally complex, hard to interpret.	General-purpose, high accuracy TSC.	HIVE-COTE, Hybrid Ensembles

A common challenge to choose the best algorithm is to find the most important features to feed the ML algorithm. Features can be all single datapoints of the time series. This option results an exhaustive search for similarity between time series with the same label. However, this exhaustive search will also result in including datapoints that are not constructive or important in training models, also known as noises. Hence, finding the optimum interval will become another challenge. Advanced algorithms include feature engineering to avoid noise from the dataset. They only take the most important datapoints and their sequence, in case of time series analysis. According to Middlehurst et al. (2025), this step is called series-to vector transformations. In a next step, the transformed time series are ensembled to create a new dataset that only carries the most essential part of the initial dataset, also known as features dataset. The data of features explain the time series in a way that is better understandable for ML algorithms. This step can be a very labor-intensive manual or an automated step. The manual exercise requires a prior knowledge about the system that the data are derived from in addition to the ability to interpret the data itself. This can cause a robust and interpretable model. The automated approach requires less labor work, yet it can result in unstable models and uninterpretable models. Hence, it cannot help in upscaling the models in the given application of this study. Interpretation of the model will help other researchers to develop similar models for their datasets.

Given the computational limitation, high length of available time series, and familiarity with the physics behind the time series, we will use distance-based method. We generate the models using different algorithms for distance-based methods and make initial comparison. We explore the best features to feed to the models during our feature engineering step. The algorithm associated to the best model will be used for hyperparameter tuning using an exhaustive grid search. To provide a robust model to show applicability of the results, we then apply cross-validation by using a variety of different train and test sets to be able to show a realistic accuracy of the model. In cross-validation step, we make multiple folds of the data and each time train and test the model with different folds of the datasets. By that, the model is less prone to be biased by train and test set.

2.1. Dataset and EDA

The datasets used in this study contains 1300 sub-hourly electricity consumption time series (15 minutes time steps) from smart meters in Flemish region published by the grid operator, Fluvius, with open access to public (Fluvius, 2024). There are 300 case studies of each group named as HP+PV (buildings with heat pump and solar panels), EV_noPV (buildings with electric vehicles without heat pumps and without solar panels), EV+PV (buildings with electric vehicles without heat pumps and with solar panels), and Only_PV (buildings with only solar panels). There are also 100 cases without any of these devices installed. Figure 1 presents raw time series of average energy consumption in 15-minute intervals for different categories over the first five days of June 2023. Each line represents a different a building for the same label meaning a group with similar installed assets.

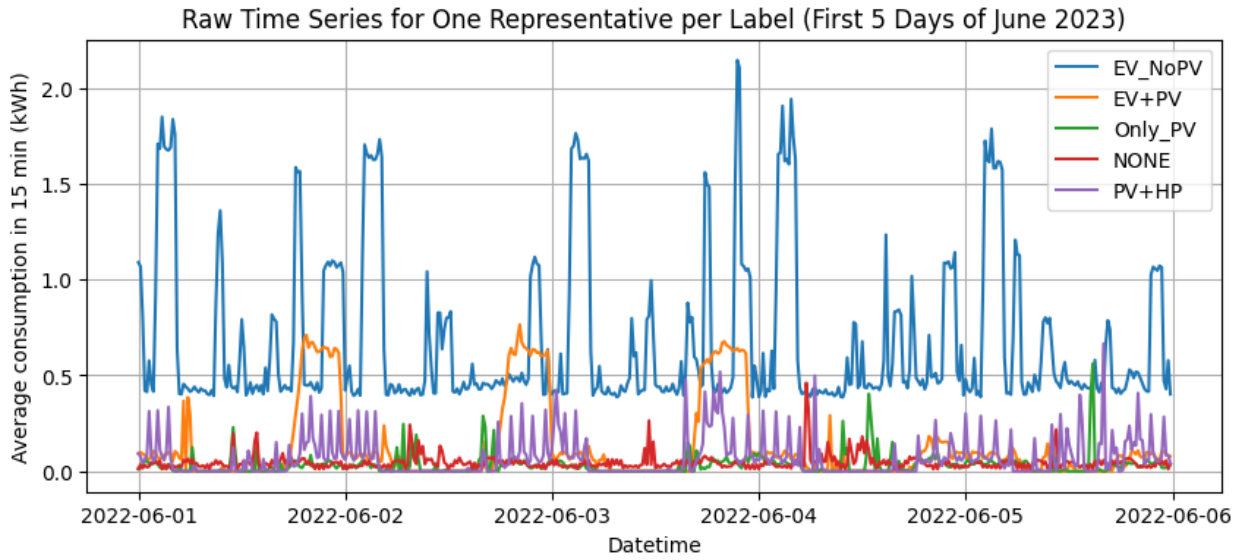

Figure 1 Time series of energy consumption for five different buildings with different labels

Figure 2 visualizes distributions of some initial statistical parameters that also reflect physics of the system and compare them between different groups. Boxplots provide valuable insights for feature engineering and classification. The peak energy consumption (left) and total annual demand (right) could serve as key predictive features for distinguishing between energy user categories. High peaks in EV_NoPV and EV+PV suggest these groups are more energy-intensive in comparions to other groups, making peak demand a strong indicator of EV ownership. The distribution of total energy demand further differentiates users, as Only_PV and NONE have consistently lower consumption.

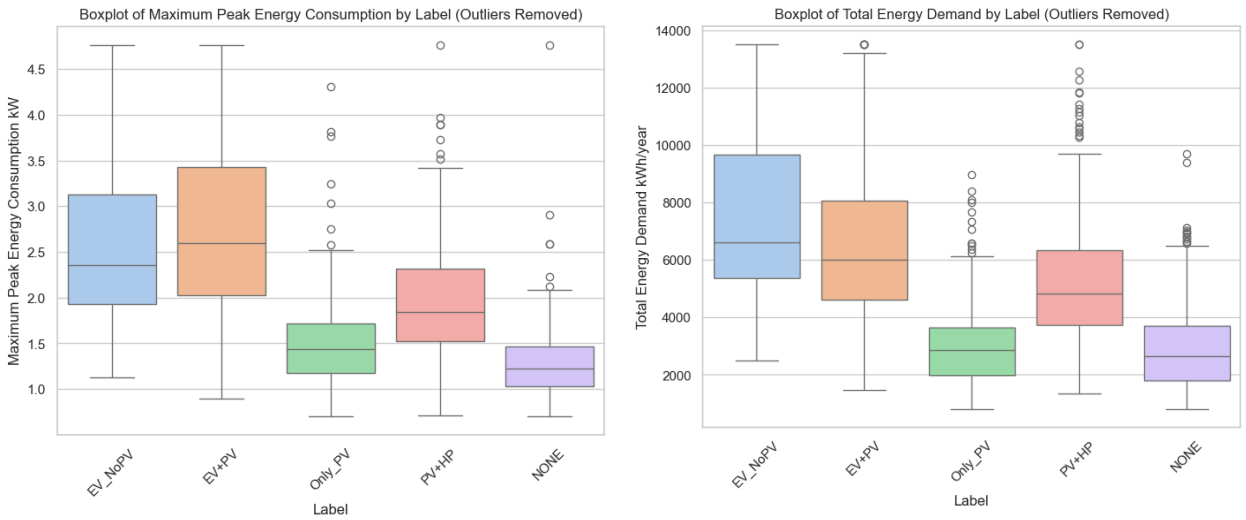

Figure 2 Boxplots depicting maximum peak energy consumption (left) and total yearly energy demand (right) for different labels

3. RESULTS

Searching for the most effective and efficient features is the first step. At this step, we only made

a preliminary comparison to find appropriate features that yield acceptable results with different algorithms. We used nine parameters for the time series in three groups being statistical features, frequency related features, and time series features. In this study, we extracted key statistical features from the electricity consumption time series. The mean that represents typical average energy usage for the building in a month or year. The standard deviation quantifies the variability, indicating fluctuations in consumption over time. The minimum and maximum values provide insight into peak and off-peak energy demand, crucial for detecting extreme usage behaviors. Additionally, skewness measures the asymmetry of the distribution, identifying whether consumption patterns are left- or right-skewed, which is important in distinguishing usage trends across different appliances. Finally, kurtosis assesses the presence of outliers by measuring the heaviness of the distribution tails, helping to detect unusual or extreme energy consumption events. A list of features with their abbreviations used in this study are listed in Table 2.

Table 2 A list of features with their abbreviations used in this

Feature Name	Abbreviation	Description
Mean	Mean	Average energy usage per month or year.
Standard Deviation	Std	Measures variability in energy consumption over time.
Minimum	Min	Lowest energy usage recorded in the time series.
Maximum	Max	Highest energy usage recorded in the time series.
Skewness	Skew	Indicates asymmetry in energy usage distribution.
Kurtosis	Kurtosis	Kurtosis
Summation	Sum	Summation of energy throughout the year

The features can be calculated on any given time interval being annual, monthly, weekly, daily, and even hourly. However, they may become inefficient and appear as noise if the time interval is not long enough. We conducted an exercise to find out appropriate interval for such ML classification application. We first trained models with annual, monthly features as reported in Figure 3 (left monthly, right annual). It is seen in the graph that monthly features, in total 108 features, significantly outperform the models trained with annual features, with 9 features. moreover, Random Forest in both cases stands out as the best algorithm in this application. Then the most important periods were selected from the year and feature for weekly intervals were extracted and used for training to investigate if weekly intervals can improve modelling outcomes. Weekly analysis with 468 features to 180 features did significantly increase model accuracy. Note that this part of the exercise is not documented in this article due to limitation length of the article.

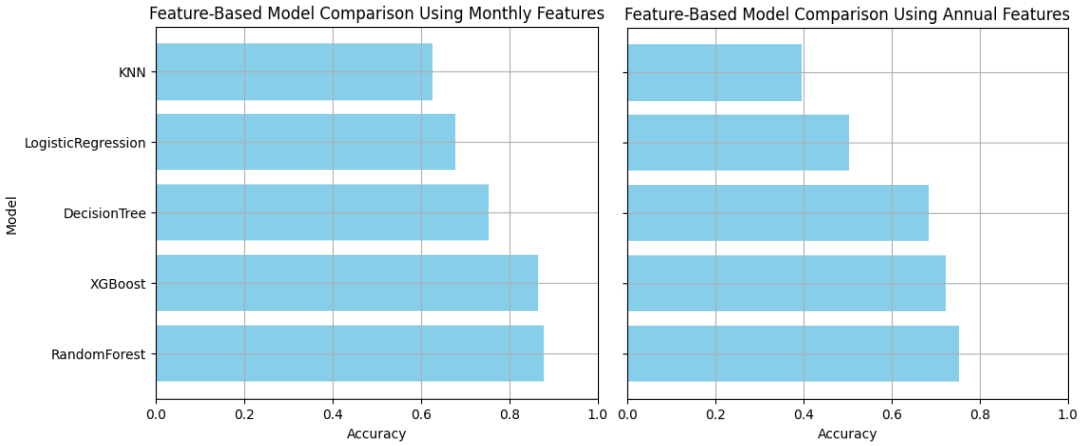

Figure 3 Comparison between different algorithms and different number of features for training ML model. Accuracy refers ratio of correct label prediction to total samples in the test set.

The hyper parameter tuning step improved the model accuracy, 90% in comparison to 85% in initial step. The optimized model was used to predict labels of validation dataset and confusion matrix in figure 4. The confusion matrix for the Random Forest model illustrates the classification performance across five categories: EV+PV, EV_NoPV, NONE, Only_PV, and PV+HP. The diagonal elements represent the number of correctly classified instances for each category, while off-diagonal values indicate misclassifications. PV+HP might have overlapping feature distributions, leading to classification challenges. Overall, the confusion matrix shows that the model performs well in distinguishing the categories, with particularly high accuracy for the "NONE" category. However, some misclassifications occur between EV+PV, Only_PV, and PV+HP. To further continue for production models there are ways to improve the model performance. This includes further feature separation or additional tuning, possibly through more refined feature engineering or hyperparameter adjustments. The general trend suggests that the model can distinguish between distinct groups effectively but struggles slightly when categories share similar characteristics such as PV. Note that Std_M6 means standard deviation the electricity load in month 6 and other features can be read similarly.

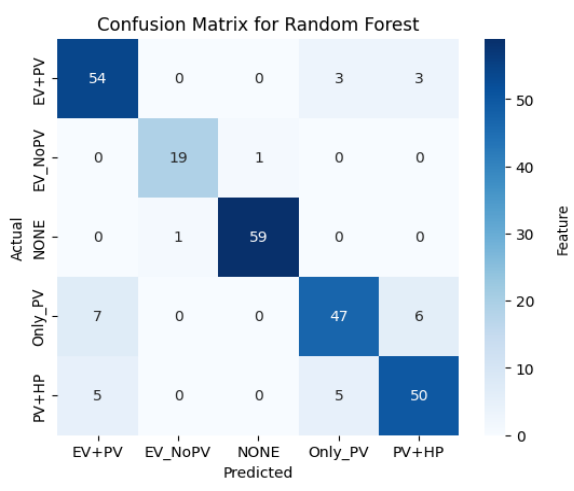

Figure 4 Confusion Matrix for the best model

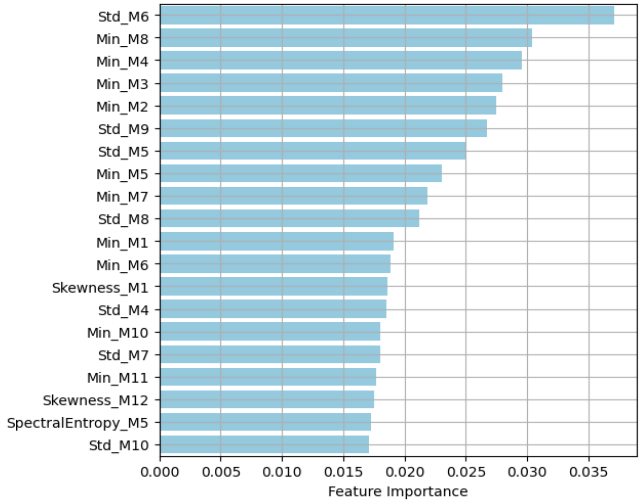

Figure 5 The top 20 most important features for the best model

The cross-validation accuracy averaged 84.33% ± 4.71%, meaning that while the model performs well, there is some variability across different training subsets. The standard deviation of 4.71% suggests moderate fluctuations, indicating that while the model is relatively stable, performance may slightly depend on the data split. Overall, the model demonstrates strong generalization capabilities, particularly excelling in classifying certain categories with high precision and recall.
The bar chart in figure 5 illustrates the top 20 most important features in the Random Forest model, ranked by their feature importance scores. The highest-ranked feature, Std_M6, exhibits the greatest influence on the model's predictions, followed closely by Min_M8, Min_M4, and Min_M3. The distribution of feature importance indicates that both standard deviation (Std) and minimum (Min) statistical measures play a significant role in the model, along with contributions from skewness and spectral entropy. This analysis highlights the key variables driving the model's decision-making process, offering insights into the most relevant factors in the dataset. The results imply significance of statistical features in comparison to frequency-based features. Moreover, it cannot be deducted that only certain months will suffice for training a model in this application. On the other hand, it shows that the model does not require extensive time series with detail that may be in contrast with privacy aspects. Hence, this application can easily be upscaled for use in urban scales. Data providers can simply extract only the statistical parameters and only report those to data users.

4. DISCUSSION

Figure 6 illustrates both normalized time-series signals (left) and their corresponding frequency-based representations (right) for five random buildings with different labels from the dataset. It was previously observed in the results section that statistical features were sufficient for training the model, implying that frequency-based features did not contribute additional information about the labels. To further investigate this, we standardized time series per building and analyzed representative weeks to check whether frequency patterns varied significantly across different labels. The results in these figures suggest two possible conclusions. First, the lack of strong differentiation in frequency-based features across labels indicates that feature-based approaches, such as statistical and temporal metrics, are more effective for classification. Second, this behavior might not be consistent across all the time series, meaning frequency-based patterns may exist but are not generalizable across the entire dataset, limiting their usefulness for model training. Consequently, statistical features remain the primary method for classification, while frequency-domain features do not offer significant improvements in distinguishing between energy consumption behaviors.
An important input to UBEM is installed energy intensive devices in buildings. The provided method will enable energy modelers to generate synthetic data related to large energy consumers only from time series data. These meta data attached to electricity time series will enrich the input data for a more detailed modeling. Detailed models allow for accurate and practical modeling and consequently actionable outcomes.

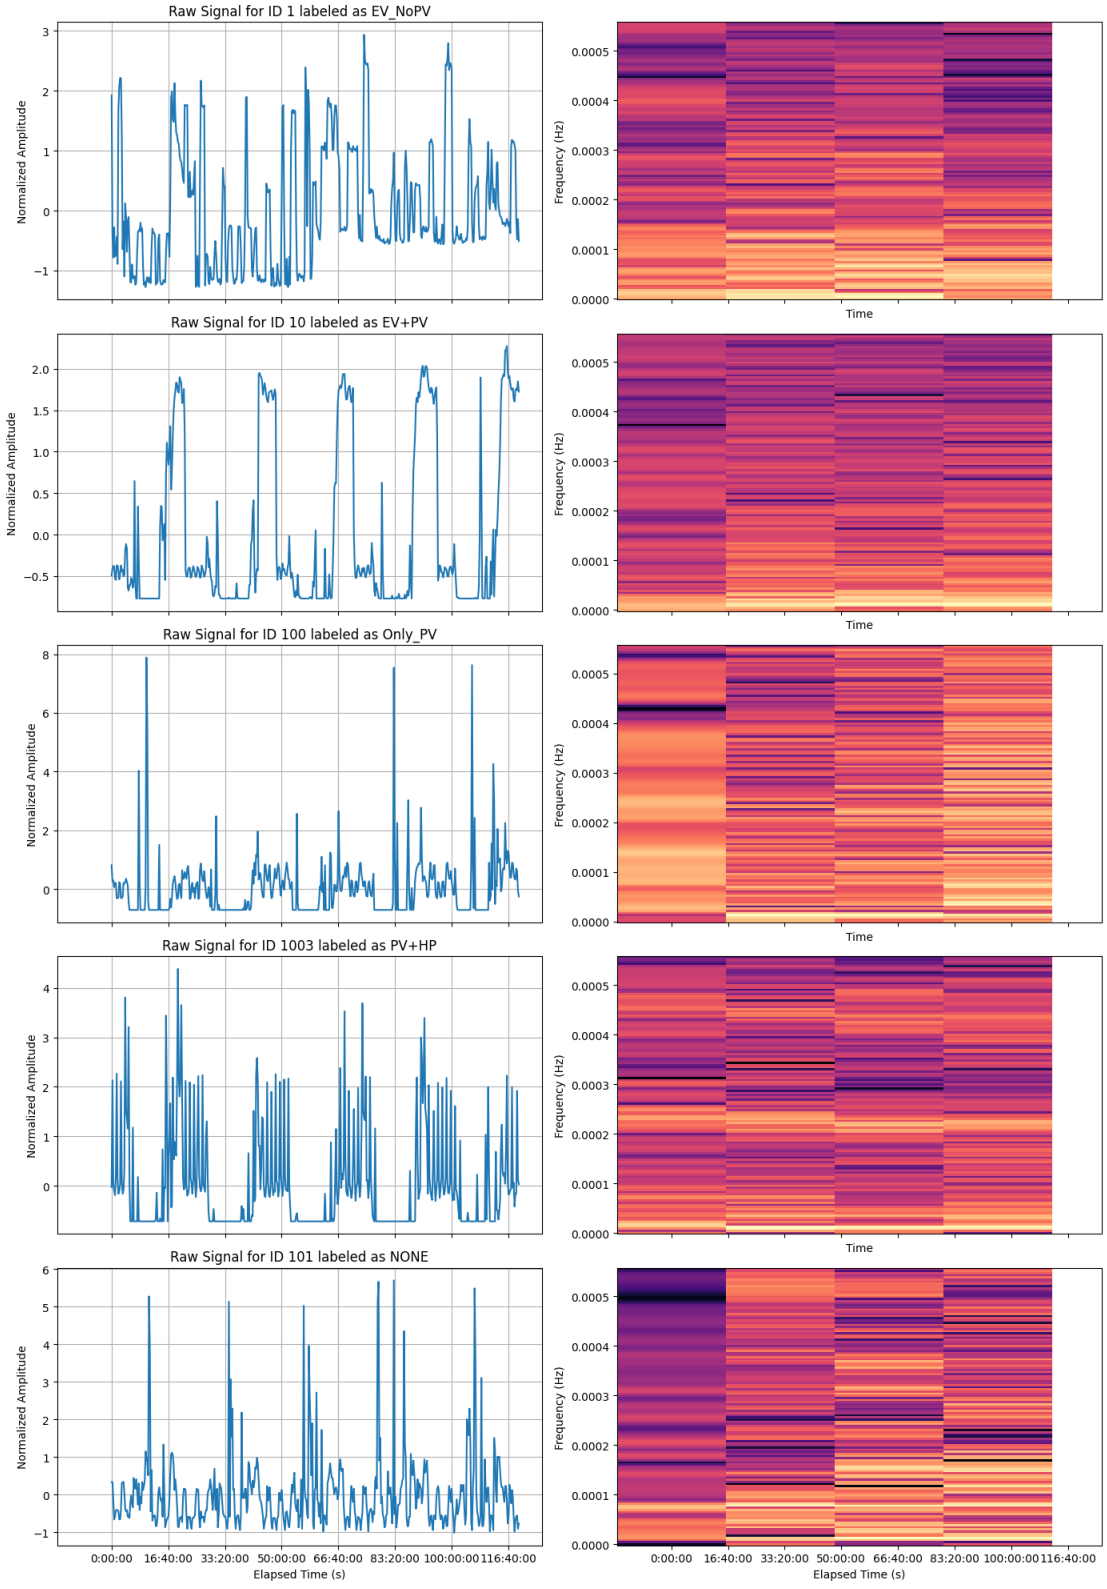

Figure 6 Comparison between raw time-series signals (left) and their corresponding frequency-based representations (right) for different labels.

5. CONCLUSION

This study demonstrated the application of machine learning techniques to identify large electricity-consuming assets, such as solar panels, electric vehicles, and heat pumps, from residential electricity consumption time series. The results showed that statistical features extracted from time series data were highly effective in training the model, achieving an accuracy of over 90%. Frequency-based features, on the other hand, did not provide additional predictive value, indicating that statistical and temporal characteristics are more relevant for classification. The analysis also revealed that monthly features (108 features) significantly improved model performance compared to annual features (9 features), suggesting that a finer temporal resolution enhances predictive accuracy. Additionally, the model demonstrated strong generalization capabilities, although periodic retraining may be required due to seasonal variations. The proposed approach can be instrumental in urban building energy modelling by providing insights into the distribution of high-energy-consuming assets across the residential sector. This can support policymakers and energy providers in optimizing energy management strategies and promoting decarbonization efforts. Future work could explore advanced feature engineering techniques and address potential model drift to further enhance classification accuracy and scalability. An essential input to improve UBEM is the presence of energy-intensive devices in buildings. The proposed method uses electricity time series to generate synthetic metadata for major energy consumers, enhancing model inputs for more detailed and actionable energy simulation outcomes.

SUMMARY

As the construction industry is increasingly reducing resource consumption and waste, modular construction (MC) presents a key opportunity for enhancing circularity. Present research, however, has been focused on optimising production processes, instead of enabling efficient reuse of materials and components. This hinders an exploitation of the full potential of MC to create a circular material flow. Since realisation of circular material flows necessitates close collaboration of various stakeholders in the supply chain network, state-of-the-art knowledge on information sharing and circular processes in the construction industry is synthesised from a supply chain perspective. Furthermore, a Circular Asset Management System (CAMS) comprising a Peer-to-Peer information system and digital tools is proposed. This information system is intended to build upon existing information containers and inform digital tools supporting decision making, thus providing the means to track and trace modular components cycling repeatedly through the supply chain.

Keywords: circular economy, modular construction, Circular Asset Management System (CAMS), supply chain

1. INTRODUCTION

The construction sector has been identified as a priority area in the current effort of transitioning to a circular economy (CE) (Giorgi et al., 2022). However, the fragmented nature of the construction supply chain and the lack of suitable information sharing across stakeholders throughout all life-phases of buildings, are among the main barriers towards full implementation of circular strategies (Giorgi et al., 2022). To overcome this, the development of efficient strategies for information sharing among this distributed network of stakeholders is crucial (Hossain et al., 2020), as well as changes in behaviour and viable business models. While the method of prefabricated modular construction offers significant potential for circularity (Iacovidou et al., 2018), challenges regarding the information flow prevail, e.g. availability, quality, machine-interpretability and upkeep of information during operation phase (BAMB, 2017; Kedir et al., 2021). Modular construction, an off-site construction method employing standardised units, was shown to reduce the risk of acci-

dents by 80%, capital cost by10%, wastage by 76% compared to traditional means of construction by removing 90% of on-site activities in favor of digital and industrialised production processes (Abdelmageed and Zayed, 2020). It thus offers economic and environmental benefits "upstream", while generating digital information as a side-product. However, its potential to create a sustainable construction industry will not be exploited until existing modularity and digital information is leveraged throughout the operations stage and at a building's End of Life (EoL) to extend the service life of used products, ultimately resulting in circular material flows (BAMB, 2017; Iacovidou et al., 2018; Kedir et al., 2021). This necessitates close collaboration of various stakeholders and the ability to track and trace products throughout changing ownerships and multiple use cycles. In spite of the increasing digitalisation of the construction sector and a long history of research on such product-specifying data sets, practitioners still lament the lack of a respective digital solution. The objective is to facilitate storage and continuous updating of high-quality information reflecting the journey of individual building components, which can then be shared among a distributed network of stakeholders (BAMB, 2017).

The aim of this paper is to synthesise the state-of-the-art knowledge on improving information sharing and circular processes in the construction industry, as well as propose a framework integrating digital information and decision supporting tools. Although in-depth reviews on specific aspects of the information flow in the construction industry already exist, a link to supply chain networks in modular construction as found in practice is missing. Moreover, there is a lack of concepts for translating theoretical knowledge into action. With this paper, we intend to fill this gap by relating existing knowledge from the scientific literature to a supply chain network for MC as found in practice, and proposing a Circular Asset Management System (CAMS). Furthermore, we do not focus on the relevance of information flow per se, but explicitly highlight its instrumental role when used to support process planning of different activities throughout the life cycles of buildings.

2. METHODOLOGY

A model of the supply chain network serves as a starting point for this study (see Fig. 1, left). We modelled the supply chain according to reports of industrial partners within the research project *Modular Prefabricated Construction* by *TKI Dinalog*, who confirmed concurrence with their practices, and we assume the model to be representative for the MC industry. Based on this model, various activities posing requirements on the information flow are inferred. The observed activities include, but are not limited to: material acquisition, manufacturing (of new, refurbishment of old modules, and mixed assembly from old and new components), transportation, on-site assembly, operation and maintenance, and EoL processing. Regardless of the life cycle phase in which these activities occur, the necessary information exchanges are characterised by requirements that can be grouped in the following themes: structure, storage, and provision of information, as well as respective standards for harmonisation of practices (see Fig. 1, right). The described methodology is illustrated in Fig. 1.

This information, however, only becomes useful if accessed by respective tools to inform said activities. Following a system of systems approach, we dissect the supply chain network into three kinds of layers: an information layer of distributed digital information, a tools layer represent-

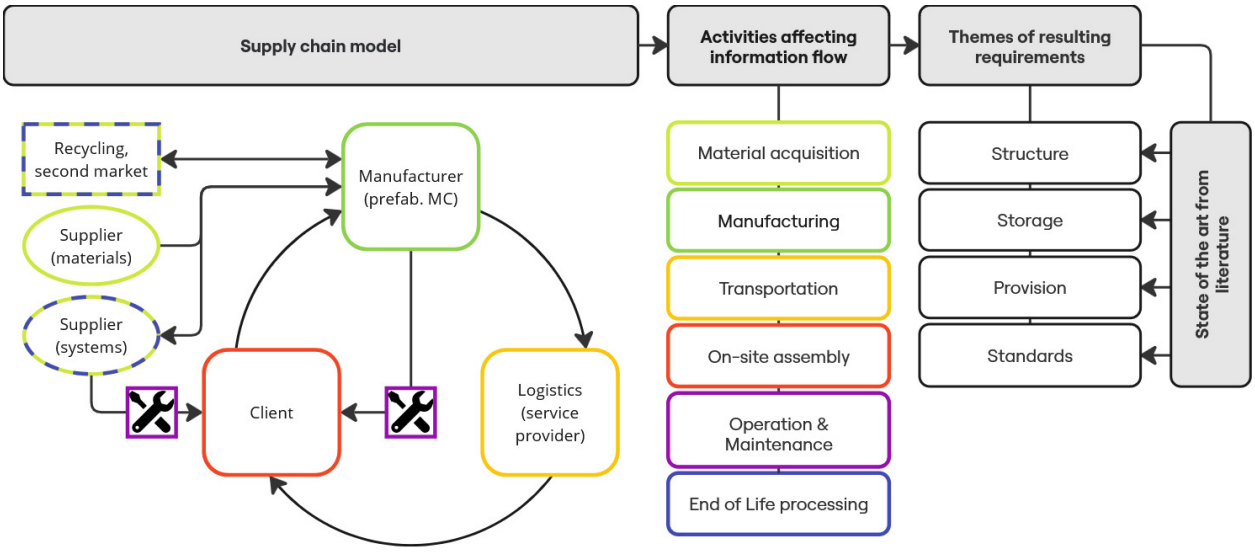

Figure 1. Research methodology: Activities (colour-coded to match elements of the supply chain model) posing requirements on the information flow are inferred from a model of the supply chain network, leading to the synthesis of literature on structure, storage and provision of information, as well as respective standards (own representation).

ing software applications supporting decision making and process optimisation, and the process layer reflecting operational activities of stakeholders. In this system of interdependent systems, the process layer requires information to base decisions on, the information layer feeds the software applications of the tools layer, which finally inform activities of the process layer. Hence, we propose the integration of digital tools with a Peer-to-Peer (P2P) information system, aiming to foster transparency, streamline collaboration, and enhance decision-making capabilities by effectively addressing the challenges of a fragmented linear supply chain and unlocking MC's full potential for realising circular processes.

The information layer and state-of-the-art knowledge in respect to the deducted themes, as gathered from present literature, is presented in the following subsections. The proposed Circular Asset Management System (CAMS), comprising digital tools for optimising processes and streamlining operational flow and the underlying P2P information system, is presented in section 3.

2.1. Information Structure

Material Passports (MP), defined as a digital interface that is specific to a single product and represents a set of information gathered throughout its life cycle (van Capelleveen et al., 2023), have emerged as the dominant concept for structuring and capturing product information in the built environment. Depending on the industry and context, the terms Digital Product Passport (DPP) and Material Passport (specifically common in the built environment) are used interchangeably to describe a data template structuring information such as properties and composition of elements. DPP is used to refer to any passport in the remainder this study, because it aligns more intuitively with the preferred idea of reusing components compared to salvaging them for recycled raw materials, is cross-sectoral and DPPs are backed by a EU regulatory framework (to be elaborated in subsection 2.4). An abundance of research studying DPPs from various perspectives exists, in-

cluding data requirements and their ability to support circular practices. While the comprehensive reviews of van Capelleveen et al. (2023) and Çetin et al. (2023) can be consulted as frameworks on the content of DPPs, it is worth highlighting the need for DPPs to reflect the individual product history (commonly referred to as *track and trace*), as well as transport and storage requirements, so they can support a circular supply chain by informing activities within. Industrialised means of construction, as employed in MC, present a special opportunity to automatically generate DPPs from digital information that is often readily available in existing manufacturing systems and BIM models (Kedir et al., 2021). Since DPPs need to reflect the temporal product history, however, they cannot be treated as static documents but need to capture dynamic data throughout the product's life cycle.

2.2. Information Storage

Projects such as Madaster and Buildings As Material Banks (BAMB) envision a network of information on materials that are currently in use, thus highlighting the need for storing and sharing data (BAMB, 2017). Generally speaking, product information can either be stored in a centralised database (like the Madaster platform), or in a distributed manner in containers related to individual assets (like Asset Information Models). While both approaches are plausible, Sauter et al. (2019) argue against data storage in silos separate from the information owner and in favour of linking distributed sources to establish a distributed network of information. In a small-scale experiment, Byers and de Wolf (2023) experimented with the association of product-specific information to components of a small temporary structure. Struggling with the implementation of dynamic process information, they evolved their system from a relational database to employing a NoSQL database, highlighting the greater flexibility and the ability of their final solution to meet the Create, Read, Update, Delete (CRUD) requirements.

2.3. Information Provision

Information gathered on a specific product needs to become available to a distributed network of stakeholders to inform relevant activities while it cycles through a circular supply chain. Aside from collecting and providing information in a centralised database, the concept of Linked Data (LD) relies on establishing logical connections between pieces of openly published information. The work of Tim Berners-Lee and the World Wide Web Consortium (W3C) serves as a framework for publishing accessible and machine-interpretable Linked Data, highlighting the additional benefit of allowing information that is represented following the Resource Description Framework (RDF) to be searched and queried across platforms (Berners-Lee, 2006). Linked Data relies on ontologies as a common language for the semantic representation of data. Such ontologies for DPPs and asset management data were presented by Kedir et al. (2021) and Polenghi et al. (2021), respectively. Sauter et al. (2019) present ontologies for describing elements necessary for a material exchange between different actors of the supply chain network and for classifying materials, products and activities in the context of circular economy. As a demonstration, the demo Madaster DPP is converted to RDF data using said ontologies.

2.4. Standards

The global Building Information Modelling (BIM) standard ISO 19650 (2018) offers a framework for defining information exchanges. It can thus be used by stakeholders to define requirements on their information exchanges in a specific context. It can be applied to define requirements on the

content and means of information exchanges connected to a circular product flow, but only when involved stakeholders are known. Hence, such an application is possible in the modular construction industry, where stakeholders form a more constant network of lasting business relations, but not feasible in project-based supply chains of traditional construction. ISO 23387 (2020) defines requirements on information exchanges on a technical level, specifying data formats, for example. As part of the US-American National BIM Standard (NBIMS-US)[1], the COBie specification is an example for a standardised data template and schema. The standard defines a minimum set of required data attributes that can be extended to fit national regulations or a user's preferences, focusing on the handover of information for operation and maintenance after conclusion of the production phase. The delivered COBie data (non-graphical), together with a graphical model of the asset, forms what ISO 19650 (2018) defines as an Asset Information Model (AIM). The EU Ecodesign Directive[2], which is applicable to products for the building industry, demands the mandatory introduction of DPPs. The directive thereby foresees DPPs to be stored in a decentralised system by economic operators (such as manufacturers) or service providers (such as Madaster). No such system is available yet, indicating the need for research in this regard. The required content of DPPs is to be defined in ISO 59040 (2025). However, a data template from the leading initiative is already available[3] and depicted in Fig. 2.

3. IMPLICATIONS FOR PROCESSES

So far, this paper discussed the information layer necessitated by activities of the supply chain network to feed decision support tools used to improve operational activities. To convert information into an actionable system enabling transformative improvements in operational flows across the MC industry, we propose the integration of digital tools and a Peer-to-Peer (P2P) informa-

[3]PCDS Luxembourg (https://pcds.lu/pcds-system/, accessed 24.01.2025)

tion system within a Circular Asset Management System (CAMS). The envisioned CAMS system is presented in the following section, while its potential for enhancing collaboration, optimising processes, and streamlining operational flow is discussed.

3.1. A Peer-to-Peer Information System

Various different definitions of "Peer-to-Peer" systems exist, but there seems to be a consensus on the key characteristics: they employ a decentralised architecture of interconnected nodes able to self-organise into a network and adjust to changes to that network, and are used for sharing resources, e.g. information (Staab and Stuckenschmidt, 2006). P2P information systems excel in the actuality of information, because direct referral to the source negates the need to manage changes, as well as the flexibility of the system by allowing sources to be added (Staab and Stuckenschmidt, 2006). In the context of the modular construction industry, the nodes of the proposed P2P information system represent strategic elements of the supply chain and are built on existing systems wherever possible. Manufacturers, suppliers and their respective enterprise information systems come to mind, as well as owners of assets and respective information models; the exact architecture will need to be determined in future research. The proposed system aims to enable direct exchange among trusted stakeholders, thus also providing trust in shared information.

Product passports as the dominant concept for structuring product information have been presented in section 2. As for the acquisition of information from existing systems, it is apparent that the transfer of information from a BIM model (where it is often first generated or collected) to a possible DPP is well understood. Furthermore, requirements on the contents of such a DPP for supporting circular product flows have been researched and reviewed and can thus also be deemed readily available. The upcoming ISO 59040 (2025) standard will harmonise the content of DPPs, which is necessary to allow seamless information exchanges across the industry. However, the data template available at this point is only applicable to a product type (think fridge X of brand Y), but not specific to an individual item (*the* fridge you bought). Consequently, it also does not allow to reflect the service history of a specific component. While the ISO 59040 represents a significant step towards harmonising product information and is yet to be published in its final version, the currently available data template thus fails to address an aspect highlighted as crucial in research: the ability of DPPs to reflect temporal data (Munaro and Tavares, 2021). It is noteworthy, though, that both ISO 59040 and the EU Ecodesign Directive foresee DPPs to be stored de-centrally, supporting the proposed P2P approach. The necessary technology to support establishing a P2P network of linked pieces of openly shared data is available in the form of Linked Data technologies and open data (industry) standards by the W3C. While neither ISO 19650 (2018) nor the related COBie specification address the challenges of tracking and tracing items that might be installed in multiple assets throughout their life cycle, it has been shown that the underlying IFC schema can be utilised to link information from DPPs stored at and provided by a manufacturer (Jochems et al., 2024). STEP files, the most common file format of IFC models, are notoriously difficult to extract and share partial data from, though. Using the JSON format would simplify the exchange of partial model data and dynamic updating of models (Berlo et al., 2021).

3.2. Supporting Decision-Making with a Circular Asset Management System

The purpose of providing information via the proposed P2P system is to inform and enable digital tools to support decision-making and streamlining operations in the supply chain. One of the

core challenges of a circular construction industry is the ability to track and trace products cycling through the supply chain (Hossain et al., 2020). Digital Twins (DT) have the potential to be such a tool that builds upon the information layer to illustrate location and individual history of products, i.e. track and trace components. In the context of this study, DTs will refer to virtual representations of the supply chain and assets within, and serve as an example for the synergy between shared information, digital tools and the support of operational processes. During the production phase, DTs of the supply chain reduce overall transportation and logistics costs by enabling real-time monitoring of material movements, thus improving delivery schedules, minimizing waste, and reducing delays and material damages. In the context of Receiver-Led Consolidation programs for example, such digital integration has demonstrated quantifiable impacts: operational savings for carriers ranging from $376,906 to $1,186,128 per day, a reduction of 33,445 to 104,255 vehicle-miles traveled per day, and per-delivery reductions of approximately 6 miles and 50 minutes (Holguín-Veras and Sánchez-Díaz, 2016). Additionally, DTs provide real-time insights into site conditions and module fitment, enabling the rapid resolution of assembly issues, reducing project delays, and improving coordination. (Opoku et al., 2021). Throughout the operation stage, DTs of built assets enable predictive maintenance by collecting and analysing performance data in real time, extending life of on-site facilities and reducing downtime (Lee et al., 2015). Reaching an asset's EoL, the availability of maintenance histories allows data-driven decisions on further processing of components (e.g. reuse, refurbishment or recycling), maximising the lifespan of modular components (Byers and de Wolf, 2023). Consequently, the combination of digital information and appropriate tools can be said to facilitate the coordination of circular material flows. Hence, we propose the integration of P2P information sharing with decision supporting tools – together forming a Circular Asset Management System (CAMS).

4. CONCLUSION

A model of the supply chain network, based on the observation of industry practices, allowed the identification of several themes of resulting requirements on the information flow within (information structure, storage, provision, and respective standards). Apart from advancing research in these areas (focusing on increasing granularity to include product information specific to individual items and scaling up dynamic information systems to connect data from multiple sources across stakeholders), efforts should be funnelled into closing the gap between theory and practical application. Addressing this, a Circular Asset Management System (CAMS) comprising a Peer-to-Peer information system and digital tools supporting supply chain activities was proposed. This information system is intended to build upon existing information containers, creating a network of nodes representing strategic elements of the supply chain. Digital tools can subsequently access available information, and are aimed to support decision making and provide the means to track and trace modular components cycling repeatedly through the supply chain. In future research, the proposed CAMS is intended to be developed further in terms of architecture of the P2P information system and form of information exchanges, and implemented in practice, eventually.

SUMMARY
Urban Heat Island (UHI) effects have a substantial impact on building energy performance as cities expand, with forecasts estimating that. 70% of the world's population will reside in cities by 2050. While building retrofitting has emerged as a significant method for increasing energy efficiency, current modelling approaches mainly depend on meteorological station data, leaving out complex urban microclimatic variables. This study investigates how building location within an urban neighbourhood impacts retrofit outcomes using ENVI-met 5.6 to generate location-specific meteorological data for five distinct urban density contexts integrated into DesignBuilder 7.3 to assess the impact on energy consumption. The results demonstrate that urban location has significant effects on building energy performance, with consumption ranging from 19% above to 13% below the base scenario under peak summer conditions. Retrofit implementations resulted in a significant 59% reduction in energy consumption in the base case. These findings illustrate the crucial connection between urban morphology and retrofit effectiveness, highlighting the importance of designing location-specific optimisation strategies that consider both building features and urban context.

Keywords: Urban Heat Island, Building Retrofit, Urban Morphology, Building Energy Performance, Computational Fluid Dynamics (CFD).

1. INTRODUCTION

Urbanisation is rapidly increasing, with projections indicating that up to 70% of the world's population will live in cities by 2050 (Organization, 2010). This extraordinary urban development contributes to the Urban Heat Island (UHI) effect, significantly impacting building energy performance and prompting a thorough re-evaluation of energy consumption models (Hamdan et al., 2023; Mombeni & Tariku, 2024). Since the early 2000s, advances in computer technology have allowed for detailed analyses of urban climates (Toparlar et al., 2018), indicating the important effect of the urban wind environment (UWE) on building energy usage. The complex

interactions between wind patterns, heat, and humidity within urban settings substantially shape local microclimates (Jie et al., 2023; Sezer et al., 2023). However, current building energy simulations often depend on rural meteorological data, failing to account for these urban complexities (Vuckovic et al., 2018; Yang et al., 2023). The prevalent use of standardised weather files from non-urban locations introduces significant inaccuracies in energy consumption predictions (Brozovsky et al., 2021). Empirical studies have documented the substantial impacts of UHI on building energy performance. Research in Rome demonstrated that urban areas experience an 18% decrease in heating degree days and a 157% increase in cooling degree days, resulting in significant changes to energy consumption patterns (Zinzi et al., 2018). Similar studies in Beijing revealed urban-rural temperature differences of up to $8°C$ leading to an 11% increase in cooling load and a 16% decrease in heating load (Cui et al., 2017). Recent investigations in Qatar project cooling energy consumption increases of $19 - 33.5\%$ by 2050 (Kamal et al., 2023), while studies in Mediterranean climates forecast cooling demand increases of $37 - 88\%$ (Salvati & Kolokotroni, 2023). The integration of microclimate effects into building energy performance simulations has become imperative for accurate assessment and optimisation (Qiu et al., 2024). This integration enables improved engineering applications and more sustainable building designs while supporting climate resilience goals (Stavrakakis et al., 2021; Tsoka et al., 2021). Advanced simulation methodologies combining CFD with building energy modelling have demonstrated enhanced prediction accuracy, with recent studies showing variations of 3.5% for medium office buildings and 0.5% for high-rise buildings (Feng et al., 2024). Recent studies in New Zealand have demonstrated that urban morphology and UHI effects influence seasonal energy demands, with cooling demand effects of 4.35% in summer and heating demand effects of 2.6% in winter (Jalali et al., 2024). These findings underscore the importance of considering local urban characteristics in building energy assessment and retrofit planning, suggesting that standardised approaches may be suboptimal across different urban contexts. This research systematically investigates the impact of urban morphology on building energy performance and retrofit effectiveness through a comprehensive case study in Amman, Jordan. The study analyses a single residential building positioned across five strategic locations within a dense urban neighbourhood, each representing different urban densities. Using advanced simulation tools - ENVI-met for microclimate analysis and DesignBuilder for energy assessment - the research examines how variations in urban context affect building performance metrics, heat transfer mechanisms, and retrofit outcomes. This integrated approach aims to develop location-specific energy optimisation strategies that consider both building characteristics and urban environmental conditions.

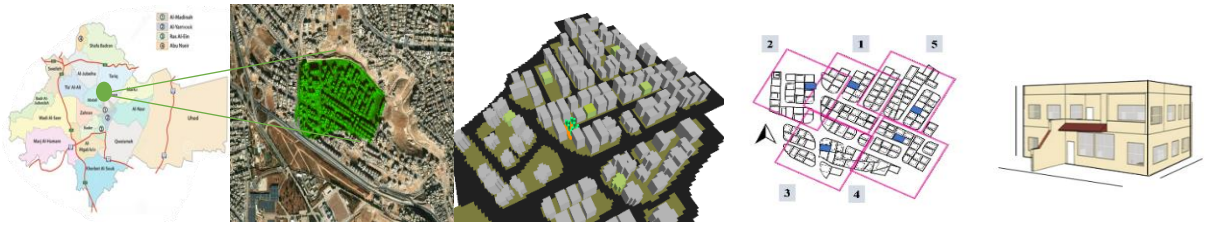
2. METHODOLOGY

A comprehensive methodological framework was used to evaluate the impact of urban morphology on building energy performance and retrofit efficiency in Amman, Jordan. Advanced computational modelling was integrated through a systematic approach encompassing urban context analysis, microclimate simulation, and building energy performance assessment. ENVI-met 5.6 was utilised for comprehensive microclimate modelling, and its computational domain was designed to reflect complex urban interactions. The simulation environment was designed with an ongoing grid resolution of 2m × 2m × 2m, extending vertically to 2.5 times the height of the tallest building to accurately reflect the urban canopy layer. The study evaluated a typical two-story residential building of $450m^2$ as the target building across five urban layouts representing varying density patterns. This systematic approach allowed a detailed examination of how urban

context influences building performance and retrofit outcomes through sequential processes of data collection, simulation, and analysis, thereby providing a strong foundation for better understanding the relationship between urban morphology and building energy efficiency.

2.1 Case Study Area Characteristics

Research was carried out in Amman's Basman neighbourhood (also known as "Dahyat Al-Istiqlal"), a high-traffic region bordered by densely inhabited suburbs. The research region, located at latitude $31.95522° N$ and longitude $35.94503° E$, has around $141{,}423.6\, m^2$ and has heights varying from 890 to 950 meters above sea level (ArabiaWeather, 2024). This location was chosen strategically because it is close (5km) to the official Marka meteorological station, allowing accurate climatic data validation. The district had a variety of urban features, with 132 residential blocks oriented primarily northeast, as shown in Figure 1, which showed the aerial perspective and urban context of the research region.



(a) (b) (c) (d) (e)

Figure 1. a) Basman area in Amman map(ArabiaWeather, 2024), b) The map of the target neighbourhood, c) the perspective of the target district, d) the location of five sub-regions, and e) the base case scenario (target building)

Amman's climate was characterised by distinct seasonal patterns, experiencing approximately 320 sunny days annually (Alrwashdeh, 2021). Since 1960, the city's climate has changed significantly, with temperature increases ranging from $0.3°$ to $1.8°C$ in annual maximum temperatures and $0.4°$ to $2.8°C$ in the lowest temperatures (Environment, 2009). Summer temperatures were frequently reported between $28°C$ to $32°C$, whereas winters were occasionally distinguished by snowfall (Potter et al., 2007). A representative two-story residential building with a total area of $450m^2$ was selected as the case study structure. The building's specifications and operational characteristics were detailed in Table 1, which presented comprehensive information about its location, function, envelope properties, and systems.

Table 1. Building energy characteristic settings

Location & Function	Dahyat Al-Istiqlal, Amman (N31°58'23.28", E35°56'28.78"), Residential, 450 m² (Two floors), 9 occupants (0.0156 People/m²)
Envelope Properties	Wall: U = 2.11 W/m²K, (improve: 0.57 W/m²K), Roof: U = 1.02 W/m²K (improve: 0.55 W/m²K), Windows: U = 5.92 W/m²K (improve: 1.59 W/m²K)
HVAC& Temperature	Direct Expansion (DX), Heating: 21°C (setback 12°C), Cooling: 25°C (setback 27°C)
Energy Use	Internal Heat Gains: 2,897 W (peak load), Lighting: 3,260 W (mixed types)

The urban district was systematically divided into five sub-regions, each measuring 200×200 meters, which were selected to represent varying urban densities and morphological

characteristics. Table 2 presents the physical characteristics of these zones, including the number of blocks, occupied and unoccupied areas, and density metrics. This systematic categorisation enabled a detailed analysis of how urban morphology had influenced building performance across different contexts.

Table 2. Physical characteristics of the case study area

Zone	Number of Blocks	Occupied area (m^2)	Unoccupied area (m^2)	O/U	Average Height (m)	Density

2.2 Microclimate-Building Energy Performance Analysis and Coupling Methodology

The research methodology employed a systematic approach to analyse microclimate conditions and their impact on building energy performance. ENVI-met 5.6 was utilised for comprehensive microclimate simulations across each sub-region, with initial simulations conducted using microclimate data from the Marka Airport Meteorological Station for July 26, 2016, identified as the hottest day in the available dataset. The computational domain was configured using the environmental model shown in Figure 2a, which ensured an accurate representation of both the urban neighbourhood and the target building's geometry.

The integration between microclimate simulation and building energy analysis was achieved through a one-way coupling methodology. This process utilised ENVI-met simulation outputs to create modified weather files for each sub-region using the EnergyPlus Weather Converter tool. The coupling mechanism, depicted in Figure 2b, facilitated the incorporation of local microclimate conditions, including temperature profiles, wind velocities, and humidity levels. These detailed environmental parameters were essential for generating accurate weather files for subsequent energy performance simulations.

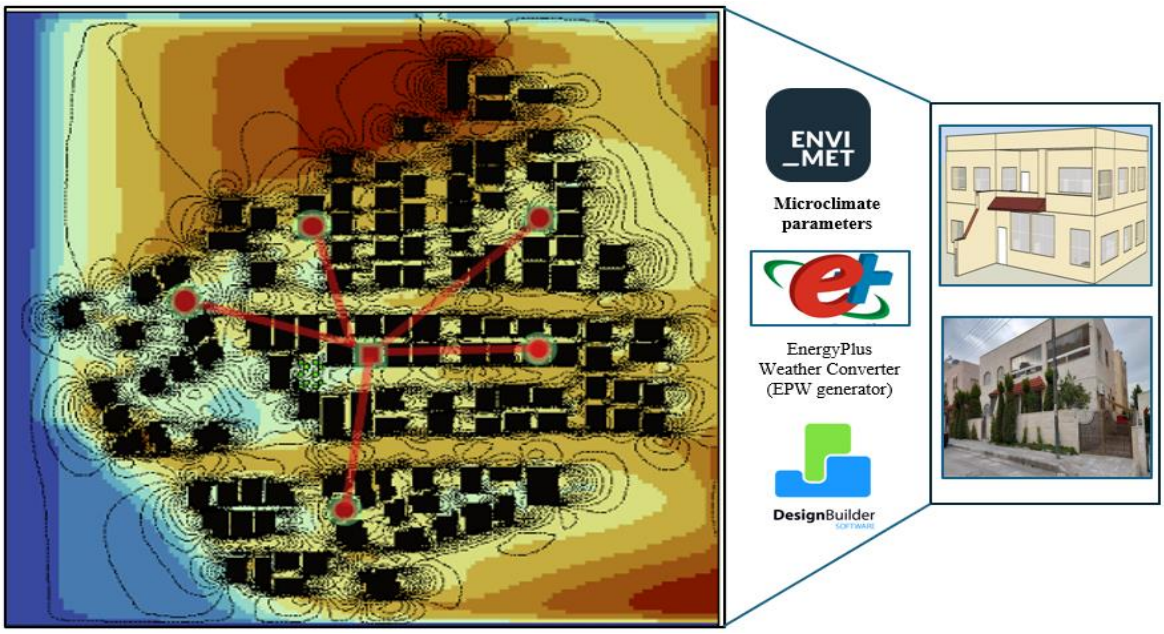
The simulation phase implemented DesignBuilder 7.3 for comprehensive energy analysis, with parameters calibrated using actual building operational data. This methodological framework, while complex in its implementation, provided a solid framework for understanding the interactions between urban form, microclimate conditions, and building energy consumption patterns. The comprehensive approach enabled a detailed evaluation of how urban morphology influenced building energy performance and retrofit effectiveness across varying urban contexts, ensuring reliable and validated results for the study's objectives.

2.3 Retrofit Scenarios

The retrofit analysis methodology included multiple intervention strategies, which were carefully chosen based on established performance standards and local market availability in Jordan (Shamout, 2018). The comprehensive retrofit approach focused on six key building elements, each optimised for maximum energy performance improvement. Thermal envelope enhancement was achieved through EPS insulation implementation, with thicknesses evaluated between 1-10 centimetres. The thermal bridge mitigation strategy employed metal material solutions, while window performance was upgraded using low-emission double-glazing systems that achieved a U-value of 1.59 W/m²K. External shading was optimised through aluminium devices with depths ranging from 80 to 120 centimetres, complemented by lighting system modernisation that utilised

12w LED fixtures. The domestic hot water system was enhanced through the integration of solar hot water collectors.

The optimisation methodology utilised DesignBuilder's genetic algorithm module to systematically analyse these retrofit combinations. The approach examined multiple parameter combinations using 2,000 comprehensive simulations, considering both performance enhancement potential and practical implementation constraints within the local building context. This stringent optimisation approach ensured that the selected retrofit solutions not only maximised energy efficiency improvements but also remained feasible for real-world application in the Jordanian building market.



(a) (b) (c)

Figure 2. a) Microclimate neighbourhood model showing building configurations and density patterns, b) coupling methodology diagram, c) target building model

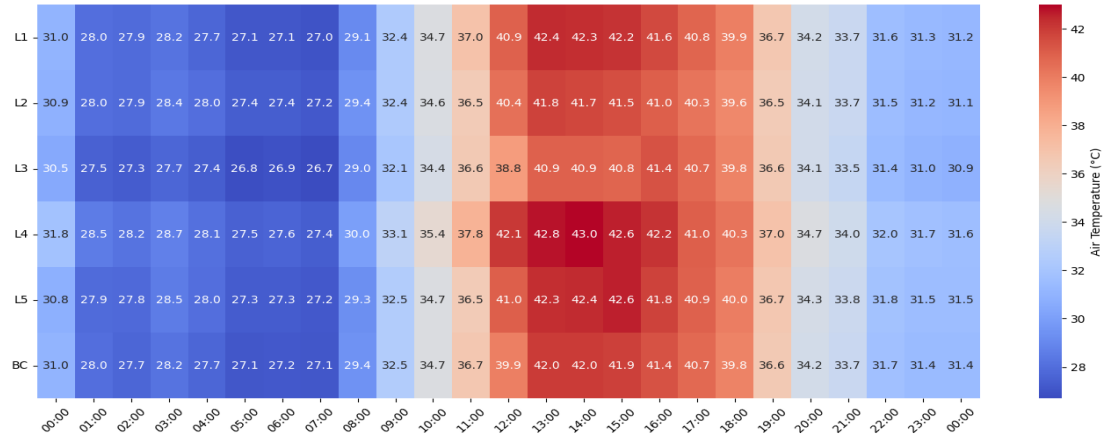
3. RESULT

The results are structured into two main phases. The first phase analyses microclimate variations across different urban densities, including air temperature, relative humidity, wind speed, and long-wave radiation, using CFD simulations. The second phase focuses on the energy performance of the target building, evaluating energy consumption and retrofit effectiveness across five urban locations with varying densities.

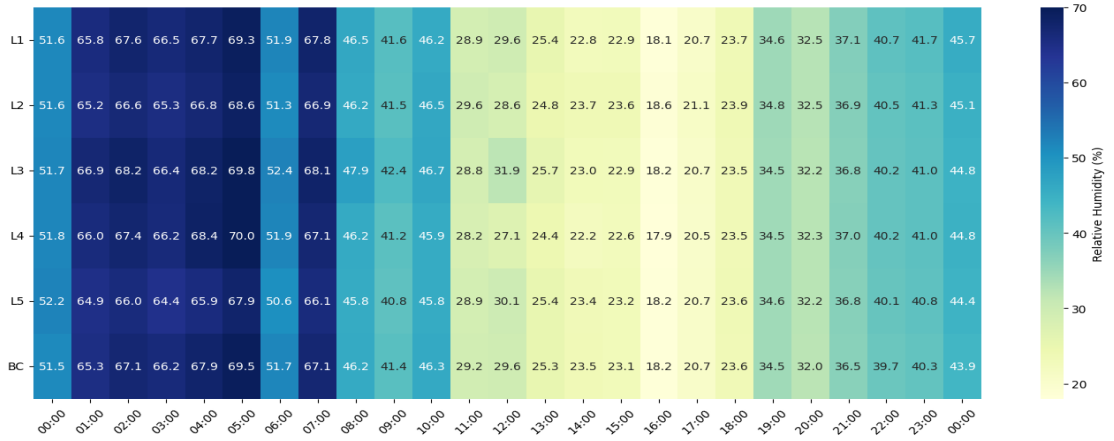
3.1 Impact of Urban Density on Microclimate Parameters

The analysis of microclimate parameters across different urban locations demonstrates significant differences influenced by urban density and morphology. As shown in Figure 3a, air temperature variations show a strong connection with urban density patterns, with Location 4 (highest density) exhibiting temperatures up to $2.2°C$ above the base case during peak hours at noon. Conversely, Location 3 (lowest density) records temperatures $1.1°C$ below the base case at the same period, highlighting the substantial impact of urban configuration on local thermal conditions. Relative humidity patterns, illustrated in Figure 3b, show an inverse relationship with urban density. The

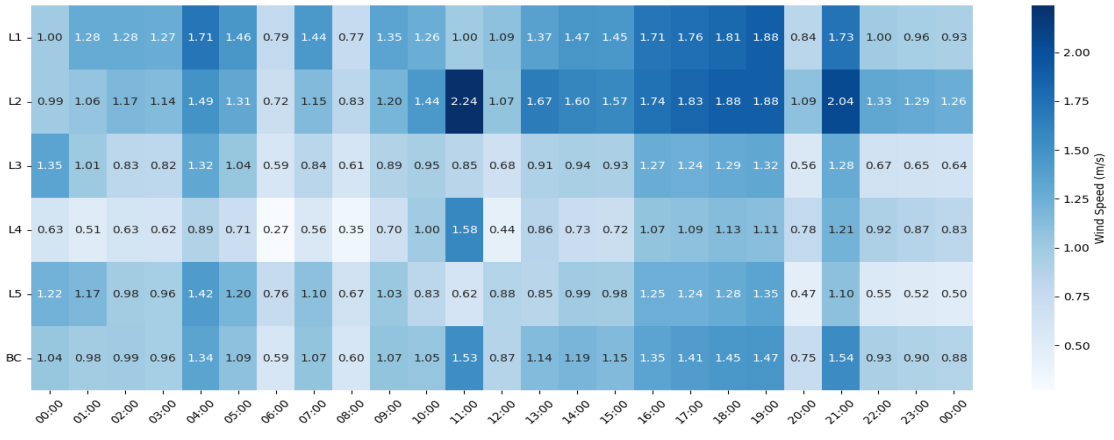
highest density location (L4) records humidity levels 9% lower than the base case during peak afternoon hours, while the more open locations (L1 and L5) maintain higher humidity levels, contributing to more moderate microclimate conditions. Wind speed analysis, presented in Figure 3c, demonstrates significant variations across locations, with high-density areas showing reductions of up to 40% in average wind speeds compared to open urban settings.



3(a)



3(b)



3(c)

Figure 3. a) Air temperature variations across different urban locations, b) relative humidity variations across different urban locations, c) hourly wind speed variations across different urban locations.

3.2 Energy Performance Analysis Across Urban Contexts

The energy consumption analysis shows substantial variations across different urban locations during the hottest day (July 26, 2016). The base case location records a daily energy consumption of $179\ kWh$, while significant variations are observed across other locations. Location 4, characterised by the highest density, demonstrates a 19% increase in energy consumption ($213.01\ kWh$), primarily attributed to reduced wind speeds and increased surface temperatures. In contrast, Location 3, with its more open urban configuration, shows a 13% reduction in energy consumption ($155.73\ kWh$), benefiting from improved natural ventilation and reduced heat island effects.

The impact of urban morphology on retrofit effectiveness is evaluated based on the base case's 59% reduction potential. Location 4's dense urban context limited retrofit effectiveness to approximately 51% improvement (reducing consumption to $104.37\ kWh$), while Location 3's more favourable microclimate conditions enable enhanced retrofit performance, achieving up to 64% reduction (reducing consumption to $56.06\ kWh$). These variations highlight the critical influence of urban morphology on both baseline energy performance and retrofit potential, with denser urban configurations generally showing reduced retrofit effectiveness due to constrained ventilation and increased local heat gain.

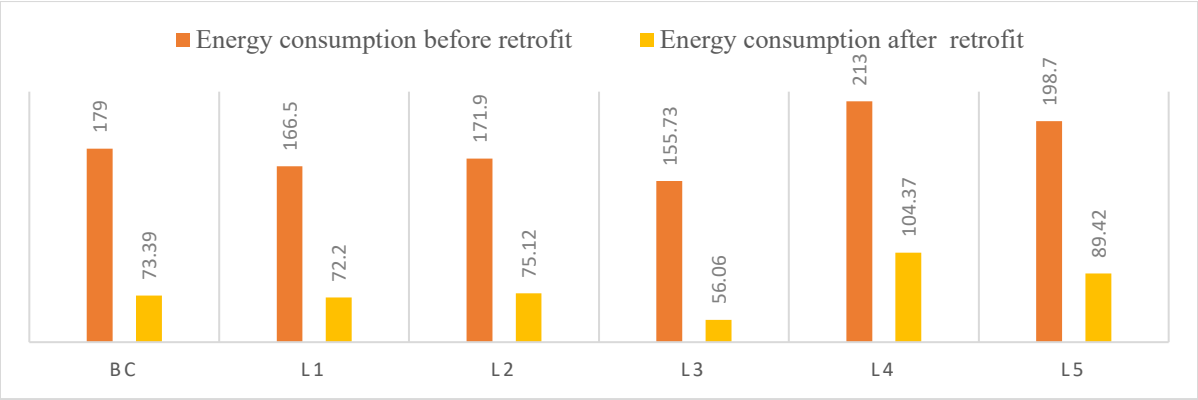


Figure 4. Impact of retrofitting on energy consumption across different urban locations**.**

4. CONCLUSION

This study demonstrated that urban morphology has a crucial impact on building energy performance and retrofit effectiveness in Amman, Jordan. The study found substantial variations in building energy consumption across different urban densities using detailed microclimate and energy analysis, ranging from a 19% rise in high-density blocks to a 13% decrease in more open layouts. The success of retrofit strategies is strongly dependent on the urban context, with high-density areas improving by 51% compared to 64% in more open settings.

These findings highlight the essential function of urban morphology in building energy assessment and retrofit planning. The research concludes that standardised retrofit methods may not be ideal in diverse urban contexts, emphasising the importance of location-specific optimisation strategies that take into consideration both building characteristics and urban conditions. This comprehensive method offers useful information for urban planners and policymakers looking to enhance building energy efficiency in quickly growing cities.

SUMMARY
This study compares buildings with different vertical porosity levels, examining their effects on near-building wind profiles and pedestrian wind velocities, which are critical for ventilation efficiency. We conducted Computational Fluid Dynamics (CFD) simulations using Reynolds-Averaged Navier-Stokes (RANS) equations in ANSYS Fluent to analyze airflow in street canyons. To ensure model reliability, the simulations were validated with experimental data. Results indicate that lower-level porosity, such as Level 1, supports positive ground-level airflow, improving pedestrian-level ventilation without reverse flows. In contrast, higher-level porosity often induces negative ground-level velocities, creating reverse flows that hinder direct ventilation. Smaller porosities are more effective at enhancing ground-level ventilation, while larger porosities improve upper-level airflow. Thus, porosity design should align with specific ventilation needs at different heights. This study highlights the value of integrating building porosity into urban planning to enhance natural ventilation and promote sustainability.

Keywords: Computational Fluid Dynamics (CFD), Building Porosity, Urban Street Canyon

1. INTRODUCTION

Urbanization has intensified built environment density, significantly impacting building energy consumption, air quality, and thermal comfort. High-rise structures disrupt wind patterns, creating stagnation that hinder natural ventilation. Building porosity has emerged as one of the key passive design strategies to enhance airflow, disperse pollutants, and promote sustainable living. Building porosity; through features like permeable facades, void decks, and sky gardens, can facilitate air movement, reduce stagnant zones and improve pedestrian-level ventilation. In tropical cities, where heat and humidity are persistent, building porosity effectively enhances airflow and reduces heat accumulation, and mitigates urban heat, making them essential for sustainable urban environments.

1.1. Problem statement, motivation, and knowledge gap

Building porosity holds significant potential for mitigating urban heat and enhancing passive ventilation, yet it remains under-explored within architectural and engineering fields. Research has historically prioritized other strategies, such as wind catchers, leaving a gap in the systematic study and optimization of building porosity for diverse urban settings. Recent studies

emphasize its critical role in improving natural ventilation and reducing pollutant concentrations, particularly in high-density cities. Despite initial studies on urban microclimates and airflow influenced by building porosity, critical gaps remain in understanding its comprehensive impact on urban airflow patterns and thermal comfort. While prior research has examined street canyon geometry, aspect ratios, and general building configurations on airflow and pollutant dispersion, the specific effects of building porosity—particularly the strategic placement of void decks across different building levels have not been thoroughly investigated. This study employs validated Computational Fluid Dynamics (CFD) simulations to explore the influence of building porosity at varying vertical levels and porosity percentages within urban street canyons (Figure 1). The findings will provide essential insights for optimizing building porosity, and contributing to healthier, more sustainable urban environments.

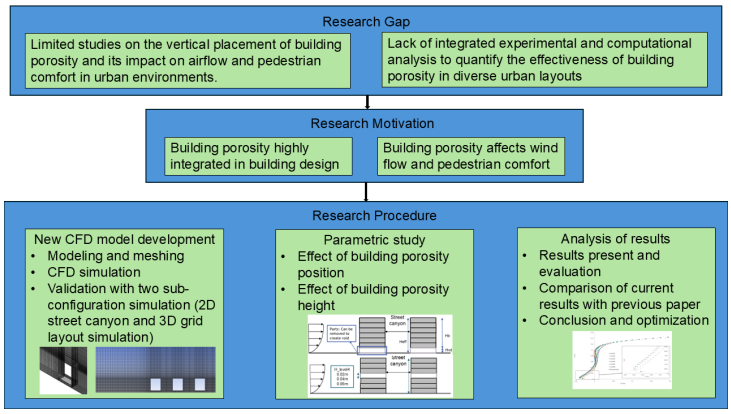

Figure 1. Procedure in this research

2. METHODOLOGY

2.1. Computational domain and grid

CFD simulations were performed at reduced and full scales to ensure the applicability of results to real-world conditions, focusing on achieving Reynolds number independence for accurate flow replication. The computational domain adhered to best practices outlined by Franke et al., 2011 and Tominaga et al., 2008, with upstream and downstream lengths of $5H_{eff}$ and $15H_{eff}$, and a domain height of $5H$ (building model height = 0.14 m). Grid resolution was optimized through sensitivity analysis, details of which are presented in Section 3.1.4.

The grid setup, illustrated in Figure 2 (1), features 2,799,750 hexahedral cells with uniform resolution in the canyon and coarser resolution upstream, above, and downstream. The mesh includes 10 cells per void deck layer, with zero skewness and a maximum expansion ratio of 1.2. These configurations were validated through a mesh sensitivity test to ensure high resolution and reliability of simulation results.

2.2. Boundary conditions

Figure 2 (2) illustrates the boundary conditions applied in this study. A zero normal velocity was imposed on the top surface, while the span-wise (side) surfaces were assigned a stream-wise velocity with a zero-gradient condition. All building walls, including the leeward and windward sides, roofs, and ground surfaces, were subjected to a no-slip boundary condition. The outlet surface was assigned a zero-gradient condition, and atmospheric inlet boundary conditions were applied to the inlet surface, as described in the referenced study Richards and

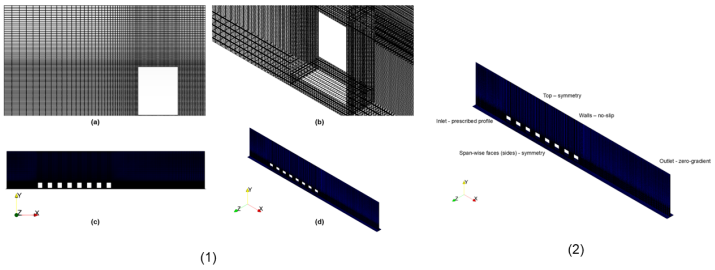

Figure 2. (1) Computational fluid dynamics (CFD) domain mesh: (a) side view of the central plane for the first canyon, (b) 3D view showing only the first canyon, (c) side view of the central plane for the full domain, and (d) 3D view of the central plane for the full domain. (2) CFD domain and boundary conditions for building porosity at level 1 (ground floor), showing the middle plane in the vertical direction (y-axis) and the floor.

Hoxey, 1993. Inlet velocity (U), turbulence kinetic energy (tke), and turbulence dissipation rate (ε) were defined by Equations (1)–(3) below.

$$U = \frac{U_{\text{ref}}}{\kappa} \ln\left(\frac{z+z_0}{z_0}\right) \tag{1}$$

$$tke = \frac{U_*^2}{\sqrt{C_\mu}} \tag{2}$$

$$\varepsilon = \frac{U_*^3}{\kappa(z+z_0)} \tag{3}$$

Where U_* represents the friction velocity calculated using Equation 4, κ is the von Karman's constant (0.41), z is the vertical distance from the ground, z_0 is the surface roughness height, and C_μ is a constant (= 0.09)

$$U = \kappa \frac{U_{(z=z_{ref})}}{\ln\left(\frac{z_{ref}+z_0}{z_0}\right)} \tag{4}$$

Where Equation 1 and Equation 4 can be transformed into a dimensionless velocity profile:

$$\frac{U}{U_{(z=z_{ref})}} = \frac{\ln\left(\frac{z+z_0}{z_0}\right)}{\ln\left(\frac{z_{ref}+z_0}{z_0}\right)} \tag{5}$$

According to previous works from Chew and Norford, 2018, z_0 was set to 0.0002 m, z_{ref} to 0.14, and $U_{(z=z_{ref})}$ to 0.41 m/s for the reduced-scale simulation. For the full-scale simulation, the values were scaled up by a factor of 200, resulting in z_0 = 0.04 and z_{ref} = 28

m. It should be noted that z_0 = 0.04 m corresponds to open terrain, according to the updated Davenport-Wieringa classification Wieringa, 1992. For the full-scale cases, $U_{(z=z_{ref})}$ was set to 2 m/s, consistent with field measurements indicating that a threshold wind speed of 1.5–2 m/s is required to sustain in-canyon vortices.

2.3. Solver settings

All simulations were performed using ANSYS Fluent 2022 R2, employing the steady RANS solver with the standard k-ε turbulence model, chosen for its consistency with experimental results in similar studies. This approach provided a balance between computational accuracy and efficiency. Second-order Gaussian integration with linear interpolation was applied for gradient and divergence schemes, while non-orthogonal corrections were incorporated into the Laplacian schemes. The standard wall function was utilized to enable a coarser mesh, reducing computational costs. Residual tolerances were set to 10^{-5} for all parameters, with convergence achieved when further iterations no longer reduced residuals, in accordance with best practices.

2.4. Mesh independence study

A mesh independence test, illustrated in Figure 3, was performed to ensure that simulation results were not significantly influenced by grid variation. Velocity profiles were extracted from the central vertical plane of the third street canyon, where the void deck is located at the ground floor layer, in accordance with AIJ guidelines Tominaga et al., 2008. Fine and coarse grids were generated using a linear refinement factor of approximately 1.2. The results indicated minimal deviations in U/Uref between the medium and fine grids. Consequently, the medium grid, which satisfied the grid independence test, was selected for the RANS simulations.

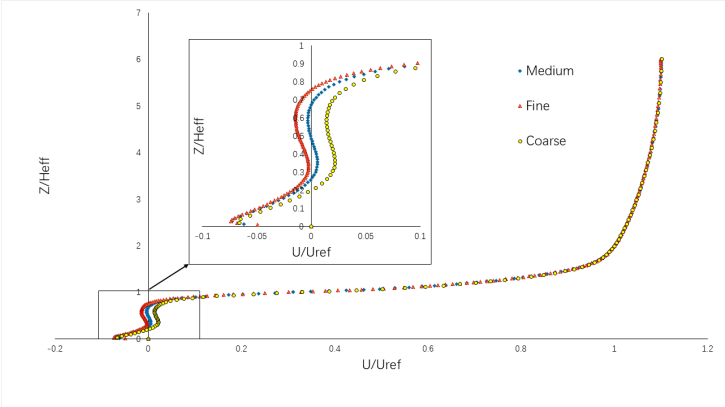

Figure 3. Comparison of normalized stream-wise velocity profiles at three mesh resolutions, extracted along the central vertical plane (y-direction) from the center of the third street canyon in the simulation where the void deck is located on the ground floor layer.

2.5. CFD simulation model

The model comprises seven identical layers, each capable of forming a 0.12 cm high void deck (Figure 4). CFD simulations explore six vertical locations by sequentially positioning the void deck from the ground floor to the sixth layer. This arrangement evaluates the impact of void deck placement on airflow dynamics across the layers.

2.6. Model Validation

To validate the CFD model, a two-step approach was adopted, addressing the absence of experimental data for three-dimensional models with void decks, as recommended by Blocken, 2015. In the first step, two-dimensional buildings with void decks were validated using water channel

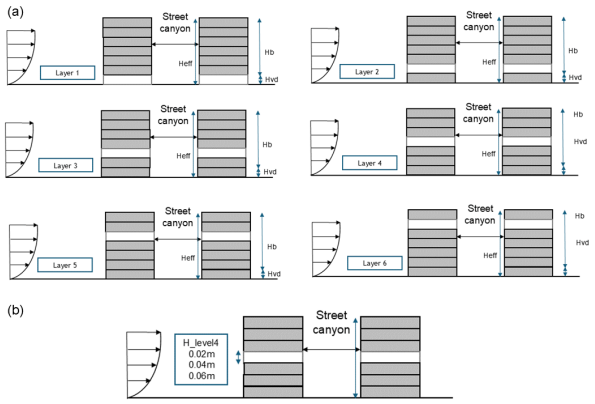

Figure 4. (a) Street canyon with effective height (Heff) formed between two building models, defined by building height (Hb) and void deck height (Hvd). (b) Illustration of level 4 used to analyze varying building porosity heights.

experiments conducted by Chew and Norford, 2018, involving an array of eight lift-up buildings. The second step validated three-dimensional buildings using wind tunnel experiments from Hang et al., 2012, which featured twelve rows of nine rectangular blocks.

For the two-dimensional validation, velocity profiles at the center of canyons 3–6 were compared with experimental data. Figure 5(a) presents the stream-wise velocity profiles at canyon 3, where the buildings feature a void deck height (H_{vd}) of 2 cm and a total effective building height (H_{eff}) of 14 cm. The void decks facilitate airflow penetration near the ground ($z/H_{eff} < 0.14$), with the highest velocity observed in canyon 3, followed by a decreasing trend downstream. The CFD model accurately captures these near-ground flows and the downstream velocity decay. Full-scale simulations, scaled up by a factor of 200, confirm Reynolds number independence, demonstrating the robustness of the results.

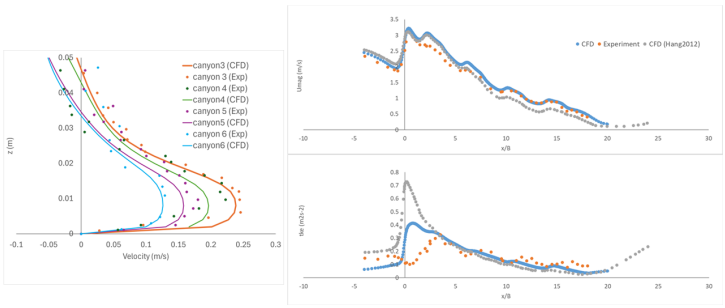

Figure 5. (a) Vertical profiles of stream-wise velocity along the centerlines of the third to sixth canyon, where z denotes the vertical distance from the ground. (b) Top figure: Horizontal profiles of velocity magnitude along the street at an elevation of z/B=1.0, where B represents the building width (B=30mm) in both the wind tunnel experiment and the reduced-scale CFD simulation. The experimental data and dashed-line CFD profiles are sourced from Hang et al., 2012. Bottom figure: Horizontal profiles of turbulence kinetic energy along the street at an elevation of z/B = 1.0.

For the second sub-configuration, Figure 5(b) presents a comparison between CFD results and wind tunnel measurements from Hang et al., 2012 for velocity magnitude and turbulence kinetic

energy (TKE) profiles along the central street between the sixth and seventh building rows at z/B=1.0 (B=30 mm). The CFD predictions show strong agreement with the experimental data, with minor deviations observed in the upstream peak TKE location. The normalized mean-square error (NMSE) values for velocity (0.0106) and TKE (0.2532) fall within the acceptable thresholds defined by Hanna and Chang, 2012, demonstrating the reliability of the CFD simulations in capturing essential flow features. Additionally, CFD results from Hang et al., 2012 are included for further comparison and context.

2.7. Parametric study

This study explores the influence of building porosity on natural ventilation within urban street canyons through two parametric analyses. The first analysis investigates the effect of vertical positioning of porosity, conducting six simulations with openings located at levels 1 through 6 while maintaining a fixed porosity of 100%. The second analysis assesses the impact of porosity height by comparing three configurations with different heights (h, 2h, 3h) at the same vertical position. All configurations ensure a uniform porosity distribution and consistent opening placements across the buildings.

3. RESULT AND DISCUSSION

3.1. Effects of building porosity position

Figure 6(a) presents velocity simulations for the third street canyon, selected for its representative airflow characteristics and minimal surface roughness effects. Ground-level porosity (Layer 1) facilitates steady pedestrian-level airflow without significant reverse flow, thereby improving ventilation and air quality at lower heights. Conversely, higher-level porosities (Layers 4–6) substantially enhance airflow at mid and upper levels but induce reverse flow near the ground, leading to localized stagnation zones and reduced pedestrian-level ventilation efficiency.

The analysis reveals that porosity at the fourth level achieves the highest pedestrian-level velocity (0.0548), whereas porosity at the second level has the least impact (0.0327). These results highlight the critical role of porosity placement in determining ventilation effectiveness. Lower-level porosity promotes direct airflow at pedestrian height, while higher-level porosity improves ventilation at its respective level but may compromise ground-level conditions.

These findings underscore the importance of strategic porosity design to balance improved ventilation at upper levels with maintaining pedestrian comfort and air quality. The study highlights the need to optimize porosity placement in high-rise urban environments to enhance microclimate conditions.

Figure 6(b) depicts velocity profiles (U) as a function of height (z) across street canyon configurations (Canyon 1 to Canyon 7) with porosity positioned at level 4. The main graph illustrates airflow patterns throughout the canyon sequence, while the inset focuses on near-ground velocities ($z<0.06$m), emphasizing pedestrian-level flow dynamics.

Canyon 1 demonstrates the strongest negative velocity near the ground, indicative of pronounced reverse flow or recirculation effects. As airflow progresses through subsequent canyons, these recirculation effects diminish, with reduced negative velocities observed near the ground in Canyons 2 through 7. Above z=0.1m, positive velocities increase, signifying enhanced vertical airflow at higher elevations. From Canyon 4 onward, velocity profiles exhibit minimal

variation, suggesting a reduced influence from upstream conditions.

These results highlight the sequential arrangement of street canyons as a critical factor in urban ventilation. Initial canyons are more prone to recirculation and degraded air quality near the ground, whereas downstream canyons benefit from more stable airflow, leading to improved ventilation and pedestrian comfort. This counterintuitive finding underscores the importance of strategic urban planning to optimize airflow and mitigate pollutant accumulation in densely built environments.

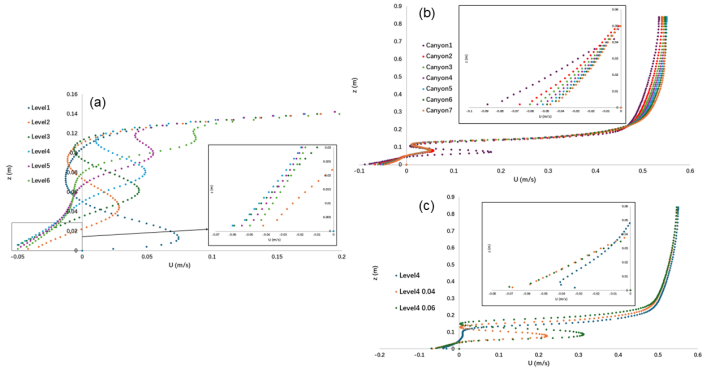

Figure 6. (a) Comparison of stream-wise velocity profiles in the third street canyon for buildings with varying vertical porosity positions, from layer 1 (ground floor) to layer 6. "No porosity" refers to buildings without any porosity. The inset provides a zoomed-in view highlighting near-ground velocity trends. (b) Comparison of stream-wise velocity profiles across all street canyons for buildings with porosity positioned at level 4. The inset focuses on near-ground velocity trends. (c) Comparison of stream-wise velocity profiles for different porosity heights (0.02 m, 0.04 m, and 0.06 m) at level 4 within a street canyon. The inset illustrates near-ground velocity trends.

3.2. Effects of building porosity height

This section investigates the effect of varying porosity heights at Level 4 within a street canyon, focusing on configurations with porosity heights of 0.02 m, 0.04 m, and 0.06 m. Figure 6(c) presents velocity profiles (U) as a function of height (z), highlighting distinct airflow behaviors influenced by porosity height.

Near the ground (z<0.06m), all configurations display negative velocities, indicative of reverse flows. The base "Level 4" configuration exhibits the strongest recirculation effect, while larger porosity heights (0.04 m and 0.06 m) slightly reduce this phenomenon. Above z=0.1m, larger porosity heights enhance airflow, achieving higher velocity magnitudes compared to the base case, thereby improving ventilation at mid and upper levels.

These findings indicate that smaller porosity heights concentrate airflow near the ground, enhancing pedestrian-level ventilation, whereas larger porosity heights promote more uniform airflow distribution across mid and upper elevations. The results emphasize the importance of optimizing porosity height to balance ground-level ventilation with broader airflow improvements within urban street canyons.

4. CONCLUSION

This study investigated the effects of building porosity on passive ventilation in high-rise residential buildings using a combination of experimental data and CFD simulations. The results

Figure 7. Table 1. Minimal velocity values, and maximal velocity values for each building porosity level, values extracted from central line (z-direction) of the central canyons (3-6)

demonstrate that the placement of porosity plays a critical role in shaping airflow dynamics. Porosities positioned at higher levels improve ventilation at upper elevations but can generate reverse flows near the ground, potentially compromising street-level ventilation. Conversely, lower-level porosities enhance pedestrian-level airflow by increasing ground-level velocities. These findings underscore the importance of strategic porosity design to achieve a balance between ventilation performance and the sustainability of the urban microclimate.

SUMMARY
The use of coal-fired power plant waste materials, such as bottom ash (BA) and fly ash (FA), as substitute by-product in concrete production is gaining momentum. However, a comprehensive understanding of their elemental composition and potential environmental impacts is still needed. This study focuses on evaluating the elemental content (Cu, Hg, and Se) of concrete containing FA and BA, employing tank leaching tests. Results revealed that the leaching of trace elements into the environment remained significantly below regulatory thresholds, supporting the suitability of these materials for construction use. The cumulative mass discharge analysis indicated that the flux-time slope for all three elements was below 0.4, suggesting that surface wash-off was the dominant discharge mechanism for these heavy metals. These findings reinforce previous studies, underscoring the viability of FA and BA as sustainable alternatives in concrete production, contributing to the development of environmentally friendly construction practices.

Keywords: Coal ash, Sustainable concrete, Elemental leaching.

1. INTRODUCTION

As coal-fired power plants continue to play a significant role in energy production, the generation of industrial by-products such as bottom ash (BA) and fly ash (FA) has also increased. Globally, approximately 650–800 million tons of FA and 150–250 million tons of BA are produced annually, posing significant challenges for waste management (Rafieizonooz et al., 2024). In many developing countries, efforts to mitigate the environmental impact of these by-products have led to stricter regulations and the promotion of sustainable alternatives in construction materials. Utilizing FA and BA in concrete production not only addresses waste disposal challenges but also supports sustainable development by reducing the consumption of non-renewable natural resources and mitigating environmental pollution (Pant et al., 2024; Samadi et al., 2024).

The incorporation of FA and BA into concrete has shown promising results, including improved long-term strength, reduced dead weight of structures, and lower carbon dioxide emissions (Rafieizonooz et al., 2017). While FA is predominantly used as a supplementary cementitious material (SCM) and BA as a river sand replacement, the combined use of these materials in

concrete remains underexplored (Abbas et al., 2020). Moreover, the environmental safety of these materials, particularly concerning the leaching of heavy metals such as copper (Cu), mercury (Hg), and selenium (Se), requires further investigation to ensure compliance with environmental standards and minimize potential health risks.

Previous studies have reported varying results regarding the leachability of heavy metals from coal ash materials, influenced by factors such as combustion processes, leaching test methods, and ash handling techniques (Gwenzi & Mupatsi, 2016; W. B. C. Silva et al., 2023). While some studies indicate minimal leaching, others highlight the potential risks associated with trace element diffusion (Pant et al., 2019). To bridge these knowledge gaps, it is crucial to investigate the leaching performance of BA and FA comprehensively, especially when used together in concrete mixtures, to ensure their safe and sustainable application in construction projects.

This study investigates the elemental analysis and leaching performance of FA and BA in concrete using a leaching method: the Semi-Dynamic Tank Leaching Procedure (SDTLP). The leaching mechanisms are derived from the relationship among concentrations of heavy metals and leaching time. This finding aim to demonstrate the feasibility of utilizing coal ash as a sustainable alternative for structural concrete in line with environmental and construction standards.

2. MATERIALS AND METHODS

Ordinary Portland cement (OPC) was used in this study, with an initial setting time of 125 minutes and a final setting time of 210 minutes. Its specific gravity, Blaine surface area, and soundness were 3.15, 3990 cm^2/g, and 1.0 mm, respectively. FA and BA were obtained from the Tang Jun-Bin coal-fired power plant. FA was used as a partial replacement for cement, while BA substituted fine aggregate. The chemical composition of OPC, FA, and BA, as detailed in our previous studies (Rafieizonooz et al., 2016, 2022) indicated that FA primarily contained silica, alumina, and iron oxide, with a combined SiO_2, Al_2O_3, and Fe_2O_3 content of 78.82%, classifying it as Class F according to ASTM C618 & ASTM C618-15 (2012). BA also contained significant amounts of silica, alumina, and iron oxide, with smaller quantities of MgO, SO_2, and CaO. The particle size gradation of BA adhered to ASTM C33 / C33M (2013) standards and was previously reported by the authors. BA's irregular shape and porosity resulted in higher water absorption (11.61%) and lower specific gravity (1.88) compared to river sand (7.4% absorption and 2.62 specific gravity). These characteristics highlight the suitability of BA and FA for sustainable concrete production, considering their physical and chemical properties.

The SDTLP was utilized to assess the leaching behavior of BA, FA, and coal ash concrete (CAC) mixtures. Following the guidelines of U.S. EPA 1315 (2013), three cubic specimens of the CAC mixture (100 mm per side), containing 100% BA as a substitution for river sand and 20% FA as a partial replacement for OPC, were fully immersed in individual 10-L containers. Each container was filled with 5.4 L of purified water to achieve a liquid-to-solid ratio of 9:1 (mL/cm^2) based on the thickness of the monolith. Leachate samples were stored and replaced with fresh purified water at intervals of 2 hours, 1 day, 2 days, 7 days, 14 days, 28 days, 42 days, 49 days, and 63 days. Subsequently, they were acidified to a pH of less than 2 using nitric acid and stored at 4 °C for further analysis using inductively coupled plasma mass spectrometry (E. B. da Silva et al., 2018). At the conclusion of the cumulative mass release, average interval flux, the leaching intervals, and

interval mass for each leaching period were calculated using standard equations provided by Garrabrants et al., (2012) and U.S. EPA 1315, (2013), as outlined in Rafieizonooz et al. (2022). This methodology provided a detailed assessment of the leaching properties and environmental safety of the tested materials.

3. RESULTS AND DISCUSSION

The primary outcomes of the SDTLP test, presenting the total concentrations of all three heavy metals, are summarized in Table 1. These results represent the mean values obtained from three samples of the same mix. The analysis revealed that only trace amounts of Cu, Hg, and Se were detected in all samples, with their concentrations decreasing significantly at later leaching intervals, reaching levels too low to be of concern. The minimal leaching of heavy metals observed for these elements, can be credited to the slow release mechanisms. This behavior likely results from the indirect flow paths between the solid and liquid phases and the encapsulation of heavy metals within the concrete matrix. The encapsulant development within the CAC mixture effectively restricted the mobility of these elements, as previously noted by Cao et al. (2017).

Table 1. Primary results of SDTLP test

Element Code	Tank Leaching Test (µg/L)								
	T01	T02	T03	T04	T05	T06	T07	T08	T09
	2 h	23 h	23 h	5 d	7 d	14 d	14 d	7 d	14 d
Cu	0.548	0.098	0.665	1.588	0.49	0.42	0	0	0
Hg	0	38.213	30.145	43.949	0	0	0	0	0
Se	0.575	0.544	0.097	0.427	0.182	0.23	0.21	0.09	0.12

Based on the initial results of the SDTLP test, Cu, Hg, and Se were identified as key heavy metals for further investigation. The monolithic leaching experiment results provided valuable data to analyze the release mechanisms of these elements from the CAC mixture. Fig. 1. illustrates the diffusion concentrations of Cu, Hg, and Se as a function of leaching time (days). Throughout the leaching intervals, the concentrations of Cu, Hg, and Se remained below 1.588 µg/L, 43.949 µg/L, and 0.575 µg/L, respectively, across all extractions. These findings confirm that the release concentrations of all monitored heavy metals were well within the acceptable limits specified by U.S. EPA 1315, (2013).

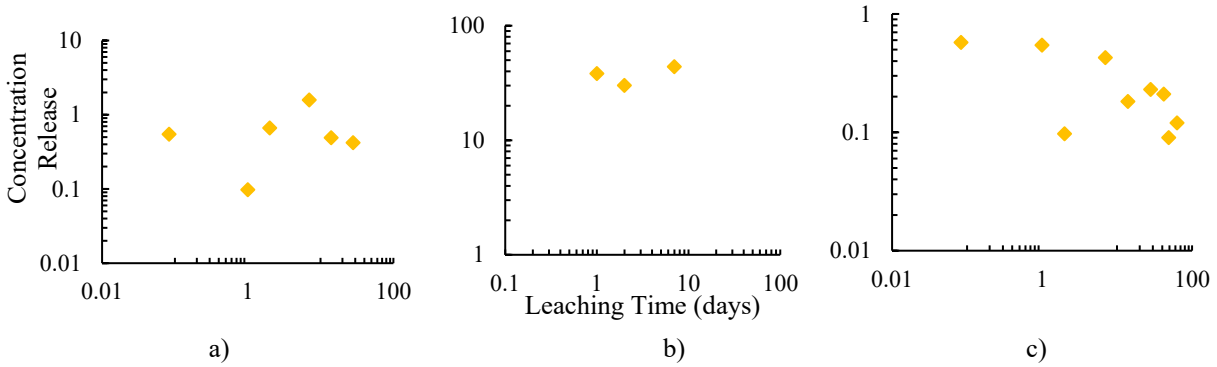

Figure 1. Concentration release of a) Cu, b) Hg, and c) Se versus leaching time

Fig. 2. illustrates the cumulative concentrations of Cu, Hg, and Se in comparison to their respective

standard limits. The data demonstrate that none of the trace elements exceeded the specified standard limitations throughout the entire leaching period. Specifically, the cumulative concentrations at the end of the final interval (63 days) were 0.004 mg/L for Cu, 0.112 mg/L for Hg, and 0.002 mg/L for Se. These values are significantly lower than the standard limitations of 25 mg/L, 0.2 mg/L, and 1.0 mg/L, respectively. These results confirm the environmental safety of the CAC mixture, as the leaching behavior of heavy metals remains well within permissible levels even after prolonged exposure. The minimal leaching of trace elements detected during the sample leaching experiment indicates that these heavy metals were effectively encapsulated and immobilized within the cement paste matrix. This encapsulation can be attributed to the microstructure of the concrete, which prevents the release of heavy metals into the environment. These findings align with previous studies, such as those by Rafieizonooz et al. (2024) and Hayes et al. (2015) which demonstrated that the microstructure of concrete enriched with heavy metals can encapsulate and immobilize these elements.

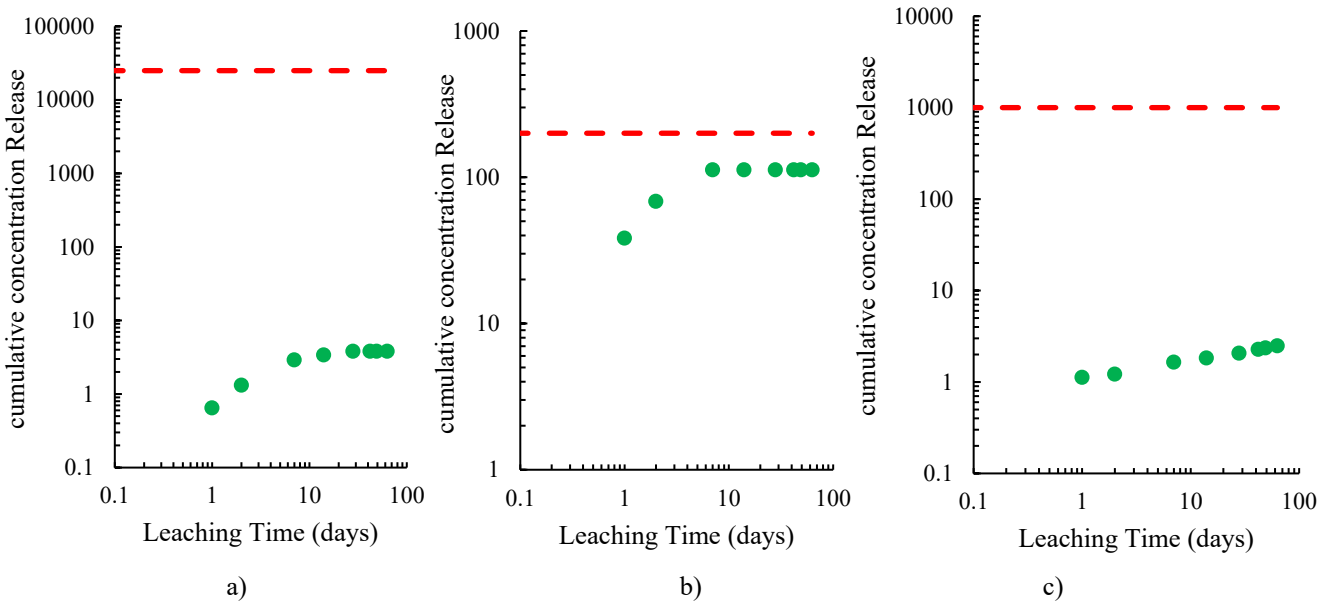

Figure 2. Cumulative concentration release (µg/L) of a) Cu, b) Hg, and c) Se versus leaching time

Fig. 3. illustrates the cumulative mass discharge of trace elements over the leaching period, demonstrating a positive non-linear relationship among the cumulative mass release and cumulative time for the CAC specimens. According to the classification proposed by Goumans et al. (2012), Beard (2002), A. C. Garrabrants et al. (2014), and Rafieizonooz et al. (2024), the release mechanism can be inferred from the slope (s) of log–log plots of cumulative mass discharge versus time. If the slope exceeds 0.8, the mechanism is matrix dissolution; if it falls between 0.8 and 0.4, it is diffusion-controlled release; and if it is below 0.4, the mechanism is dominated by initial surface wash-off. In this study, the calculated slopes for Cu, Hg, and Se were 0.005, 0.115, and 0.003 (mg/m²), respectively—all significantly below 0.4. These results suggest that the primary release mechanism for all the heavy metals was initial surface wash-off. Furthermore, as the experiment progressed, the rate of mass release decreased, confirming that heavy metals were predominantly encapsulated within the concrete matrix.

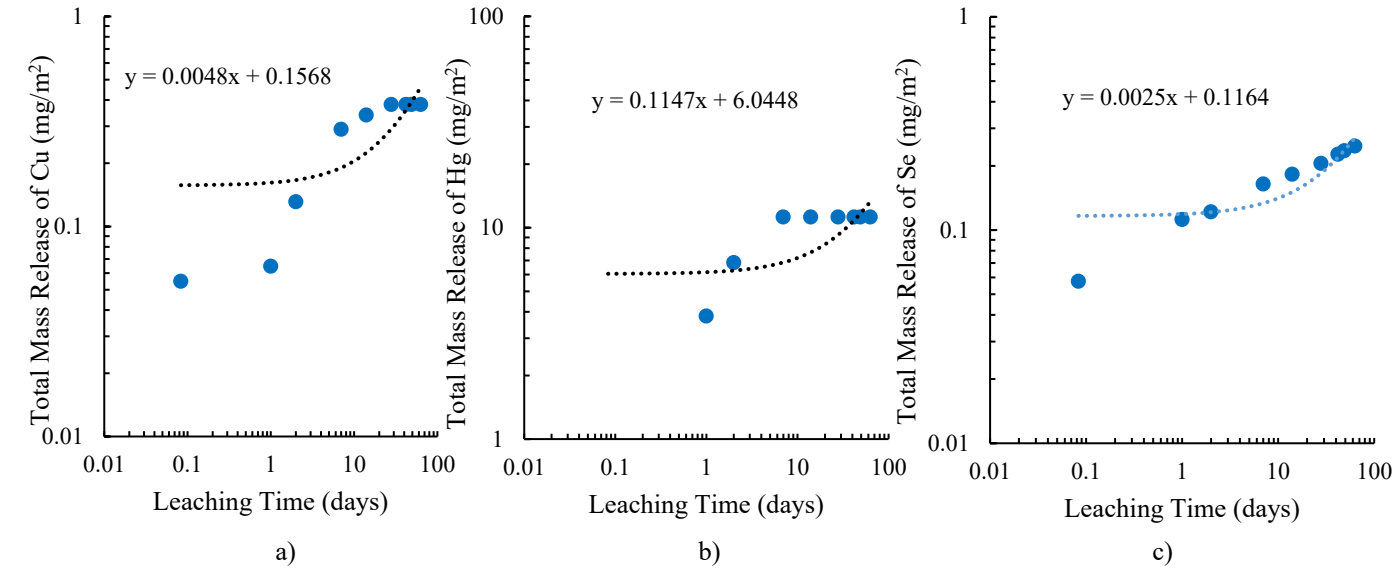

Figure 3. Total Mass Release of a) Cu, b) Hg, and c) Se versus leaching time

The results of the mass interval flux released against test duration, as shown in Fig. 4., further corroborate the findings of this study. The mass interval fluxes of Cu, Hg, and Se on all parts of the exposed surface area of the CAC samples exhibited an inverse linear relationship with leaching time. This trend indicates that as the contact duration increased during successive leaching periods, the mass interval fluxes of all trace elements declined significantly.

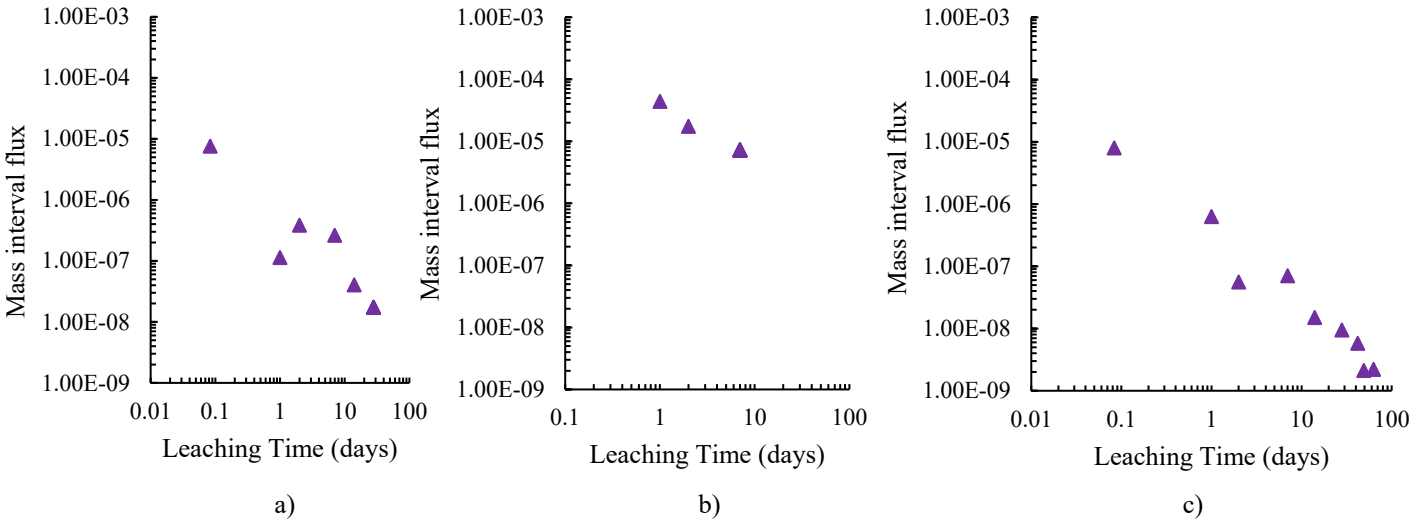

Figure 4. Mass interval flux (mg/m².s) of a) Cu, b) Hg, and c) Se versus leaching time

This observation aligns with the earlier conclusion that the primary leaching mechanism in the CAC mixture is initial surface wash-off. Beyond the initial leaching phase, no significant heavy metal release was detected. These results reinforce the encapsulating ability of the concrete matrix,

effectively preventing further heavy metal discharge during extended immersion periods. In this respect, the microstructure of concrete plays a critical role in the encapsulation of heavy metals by physically entrapping them within its dense matrix and reducing the permeability. Based on the results of the current study, the encapsulation process effectively reduced the leaching of heavy metals under the tested experimental conditions. However, under different environmental conditions—particularly more aggressive or harsh environments—further testing and evaluation are necessary to assess whether heavy metals might gradually accumulate and potentially exceed regulatory limits over extended exposure periods. Considering the results of this study along with previous related works, it can be concluded that utilizing BA and FA from coal-fired power plants contributes to effective waste management and promotes sustainable development. Additionally, it is important to note that these results are based on BA and FA collected from a specific power plant at a particular time. Variations in coal type or combustion conditions can alter the properties of coal ash, potentially leading to different leaching test outcomes. Therefore, continuous leaching testing is essential if these ash materials are to be used in construction applications.

4. RESEARCH GAPS AND RECOMMENDATION

The current study highlights some research gaps that should be addressed in future investigations. One key area is the effect of carbonation on the leaching behavior of heavy metals and trace elements in CAC mixtures. Previous studies, such as Zhang et al. (2022) and Rożek et al. (2019), suggested that carbonation could significantly influence the diffusivity, physical retention, and solubility of these elements; however, its impact remains unexplored in this context. Additionally, while this study used cubic specimens of 100 mm per side, research by Rowe (2005) indicated that increasing material thickness may further reduce the release of heavy metals. The relationship between larger concrete specimens and heavy metal leaching has not been thoroughly investigated. Finally, the leaching behavior of CAC mixtures was assessed under controlled laboratory conditions, but their long-term performance in real-world environments, including exposure to varying pH levels, saline conditions, or cyclic wet-dry scenarios, requires further exploration.

Future studies should address these gaps to enhance the understanding and application of CAC mixtures. Investigating the effects of carbonation and aggressive environment on heavy metal immobilization could provide valuable insights into improving the sustainability of CAC-based materials. Larger specimen sizes should also be studied to optimize material design for practical applications, as thicker structures may demonstrate reduced leaching risks. Additionally, conducting life cycle assessments could offer a holistic view of the environmental and economic benefits of CAC mixtures compared to conventional concrete. Together, these efforts can advance the development of environmentally friendly and durable materials for sustainable construction.

5. CONCLUSION

This study investigated the leaching behavior of heavy metals, including Cu, Hg, and Se, from CAC mixtures using the SDTLP approach. The results demonstrated that the release of these heavy metals remained significantly below the regulatory limits established by U.S. EPA 1315, (2013), indicating the environmental safety of the CAC mixture. The cumulative concentrations of Cu, Hg, and Se after 63 days of immersion were 0.004, 0.112, and 0.002 mg/L, respectively, compared to their standard limits of 25, 0.2, and 1.0 mg/L. The low concentrations observed are attributed to

the encapsulation and immobilization of heavy metals by the cementitious matrix, which hindered their diffusion and solubility in the leachate.

The leaching mechanism was primarily identified as initial surface wash-off, as indicated by the slope values from log-log plots of cumulative mass release versus time, which were below 0.4 for all tested metals. The mass interval flux results further supported this finding, showing a reverse linear relationship between heavy metal flux and leaching time. This behavior confirms that leaching was minimal after the initial surface wash-off phase. The CAC mixture's ability to immobilize heavy metals highlights its potential for sustainable construction applications. Future studies should focus on the effects of carbonation, larger specimen sizes, and real-world environmental conditions to further enhance the understanding and optimization of CAC mixtures for long-term environmental safety and durability.

SUMMARY
This study examines reforestation strategies to enhance wood production and carbon sequestration in Korea, addressing the demand for sustainable materials. wood helps reduce building sector emissions due to its low embodied carbon and CO_2 storage. Using multi-criteria analysis, this research identifies optimal tree species based on site index, material properties (specific gravity, weather resistance), and carbon sequestration potential. A Life Cycle Assessment (LCA) evaluates the environmental impact of wood from selected species, analyzing embodied carbon, energy use, and emissions across its entire life cycle, from growth and harvesting to processing, construction, and disposal. The findings support data-driven reforestation, low-carbon wood use, and eco-friendly construction.

Keywords: Domestic wood, Life Cycle Assessment, Wood exterior cladding, Sustainable construction

1. INTRODUCTION

As the demand for sustainable building materials increases, wood has gained attention as a viable alternative to conventional construction materials due to its low embodied carbon and carbon sequestration capacity. However, Korea's post-war reforestation prioritized fast-growing species, leading to a limited supply of structurally suitable wood and a heavy reliance on imports, which undermines the carbon reduction potential of domestic wood resources. Ensuring a stable and sustainable wood supply requires reforestation with tree species optimized for construction applications.

Reforestation plays a crucial role in enhancing carbon sequestration while supporting the long-term viability of wood as a building material. The selection of appropriate tree species significantly impacts wood yield, material properties, and carbon storage capacity. A data-driven approach to species selection can maximize both economic and environmental benefits, contributing to sustainable forest management and climate change mitigation.

This study applies Life Cycle Assessment (LCA) to evaluate the environmental impact of reforested wood, focusing on carbon emissions and storage across different reforestation scenarios to support low-carbon forest management.

2. METHODOLOGY

In this study, a LCA was conducted in accordance with ISO 14040 and ISO 14044 standards established by the International Organization for Standardization (ISO). LCA is a systematic methodology for quantifying inputs and outputs throughout the entire life cycle of a product and assessing the associated environmental impacts.

The life cycle of a building is generally categorized into production, construction, operation, disposal, and regeneration stages. This study specifically evaluates carbon emissions in the production, construction, and operation stages. The scope of the LCA assessment and the specific boundaries considered in this study are shown in Figure 1.

To assess wood production and carbon sequestration in the study area, seven tree species were selected. show in Table 1, the selected species include five coniferous species, Korean red pine, Pitch pine, Japanese black pine, Japanese larch, and Korean pine and two broadleaf species, Sawtooth oak and Mongolian oak.

The carbon absorption capacity of each tree species was estimated using the methodology outlined in the IPCC guidelines, standardized carbon absorption was calculated by applying factors such as wood density, biomass expansion factor, root-to-shoot ratio, and carbon fraction to the periodic annual increment of each species.

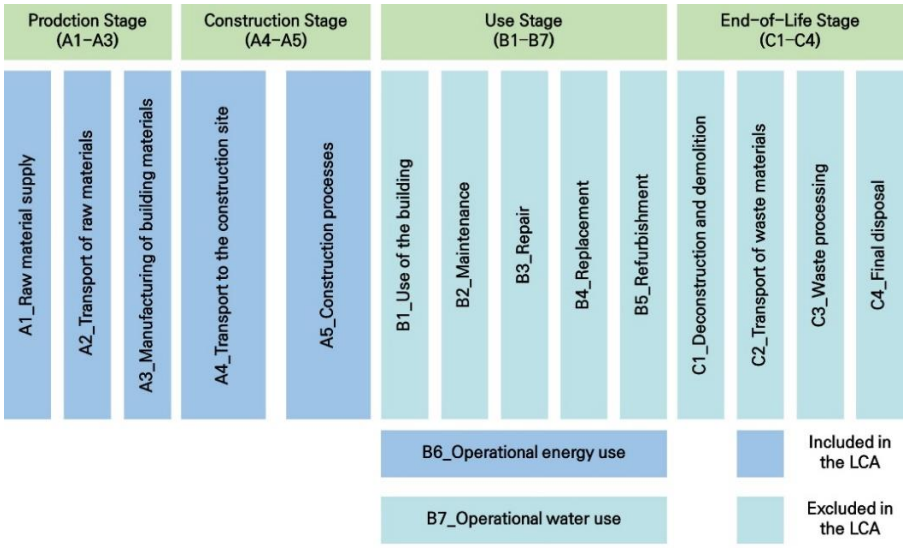

Figure 1. LCA boundaries

Table 1. CO_2 absorption by tree species during their life cycles (Unit: tCO_2/ha/year)

Tree species/ Forest age	10	20	30	40	50	60	70
Korean red pine	3.5	6.9	12.4	6.4	3.3	1.8	1.1
Pitch pine	4.5	13.9	12.4	8.7	5.8	4.1	3.1
Japanese black pine	5.2	10.3	11.5	7.8	5.3	3.8	2.8
Japanese larch	9.1	10.5	9.5	8.5	7.9	7.5	7.2
Korean pine	5.4	11.8	10.8	9.1	7.6	6.5	5.7
Sawtooth oak	11.2	15.9	14.0	12.3	10.9	9.8	8.9
Mongolian oak	8.6	15.0	9.3	8.4	7.5	6.8	6.3

2.1. Study area and suitable wood

The forested area in Yuseong-gu, Daejeon City, which is actively engaged in a wood-friendly city initiative, was selected as the study site. This initiative aims to foster local employment and promote a wood-friendly urban environment by utilizing domestically sourced wood for the construction of wooden streets and buildings. Consequently, cities already implementing wood-friendly urban projects were deemed appropriate for this study.

Among the participating cities, the forests in Yuseong-gu, Daejeon, were selected as the study site due to their extensive forested area within the vicinity of the project. The total forested area in Daejeon spans approximately 781 hectares and is primarily composed of Pitch Pine (41.6%), Mongolian Oak (15.6%), Korean Red Pine (11.6%), Japanese Larch (1.1%), Korean Pine (1.0%), Japanese Black Pine (1.0%), and Sawtooth Oak (0.9%).

To evaluate wood demand in the study area, the wood-friendly city initiative was analyzed, with a particular focus on the development of wood-specialty streets and the promotion of wood utilization in construction. wood -specialty streets incorporate wooden elements such as sculptures, guardrails, benches, and building exteriors, with the latter playing a central role in the project's objectives. Instead of constructing new wooden structures, the initiative primarily emphasizes the integration of wood cladding into existing buildings, thereby increasing the demand for exterior wood materials.

2.2. Configuring the reforestation scenarios

Table 2 shows six reforestation scenarios designed to identify optimal tree species for domestic wood utilization. Alternative 1 (Alt 1) serves as the baseline scenario, representing reforestation without additional selection criteria. Alternative 2 (Alt 2) incorporates species selection based on site index suitability to enhance forest productivity. Alternative 3 (Alt 3) prioritizes species with characteristics favorable for the production of wood exterior cladding. Alternative 4 (Alt 4) emphasizes species selection aimed at maximizing carbon sequestration potential. Alternative 5 (Alt 5) integrates both site index suitability and wood exterior cladding production considerations, reflecting a dual-purpose reforestation strategy. Finally, Alternative 6 (Alt 6) combines site index suitability with carbon sequestration objectives to optimize both forest productivity and climate mitigation benefits.

Table 2. Reforestation considerations for each scenario

Scenario	Considerations of reforestation		
	Site Index	Wood Exterior cladding	Carbon Stock
Alt 1	-	-	-
Alt 2	O	-	-
Alt 3	-	O	-
Alt 4	-	-	O
Alt 5	O	O	-
Alt 6	O	-	O

3. RESULTS AND DISCUSSION

Alt 1 represents the maintenance of existing forests, reflecting the current tree species composition. Alt 2 selected Japanese black pine, Sawtooth oak, and Mongolian oak for reforestation. Alt 3 identified Japanese larch and Mongolian oak. Alt 4 proposed Japanese larch, Sawtooth oak, and Mongolian oak. Alt 5 designated Mongolian oak, while Alt 6 selected Sawtooth oak and Mongolian oak.

Figure 2 shows the production of wood exterior cladding derived from reforestation scenarios in the Daejeon forests. Scenario Alt 3 achieved the highest total wood exterior cladding production at 473.6 m³/ha, representing a 565.1% increase compared to Scenario Alt 1, which produced 71.2 m³/ha. This increase was attributed to the inclusion of Mongolian oak and Japanese larch, which exhibit high suitability for wood exterior cladding production. Scenario Alt 5, emphasizing Mongolian oak, yielded a slightly lower total production of 438.0 m³/ha due to the species' faster growth but lower per-logging yield, highlighting the need to balance growth rates and productivity in reforestation planning.

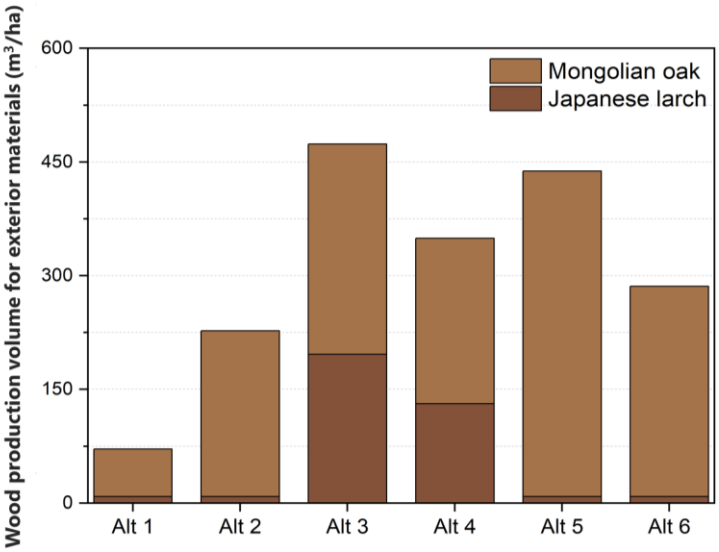

Figure 2. Wood production for wood exterior cladding from 2023 to 2223: Daejeon

SUMMARY
In the ventilation design, we generally determine the ventilation rate assuming well-mixed conditions. However, the assumption of well-mixed conditions is limited because a heterogeneous contaminant concentration field is mostly formed in the indoor environment. One of the main reasons for the heterogeneity of indoor contaminants is the recirculation created by indoor airflow. Therefore, quantitative evaluation using ventilation efficiency indices is effective. In this report, by fusing return probability and travel time, we proposed the average return time concept, which is the time scale of recirculation to a local point. The results show that the average return time was vary depending on source location and airflow. The average staying time of contaminant can include approximately 10% recirculation effect. The recirculation through the shortcut route was confirmed at some locations. By defining the mixing factor at the local point, the intensity of recirculation was evaluated.

Keywords: CFD, Ventilation Efficiency, Return Probability, Travel Time, Average Return Time

1. INTRODUCTION

In ventilation design for controlling indoor heat and contaminants, the ventilation rate is typically determined under the assumption of well-mixed conditions. However, this assumption is inherently limited because indoor environments often exhibit heterogeneous contaminant concentration distributions. One of the primary causes of this heterogeneity is the recirculation created by the indoor airflow. Due to the enclosed nature of indoor spaces, which are characterized by relatively small openings such as supply inlets and exhaust outlets, the airflow field becomes highly complex, often exhibiting multiple recirculation patterns. Recirculation cannot be directly assessed from the flow field alone. To enhance the understanding of recirculation phenomena, Kato et al. (2003) introduced the concept of visitation frequency, which was later refined by Chung et al. (2017) into the return probability concept. Against this background, we extend the discussion and propose a novel ventilation efficiency index, the average return time, which provides a quantitative measure of the timescale of recirculation.

2. VENTILATION EFFICIENCY INDICES

2.1. Return probability (α)

Chung et al. (2017) introduced α and net escape probability (NEP) concept by applying the visitation frequency concept to a control volume (CV). α represents the probability of a contaminant returning to the source domain and is defined as follows:

$$\alpha = \frac{\dot{m}_i}{\dot{m}_o} \tag{1}$$

where, $\dot{m}_i$ and $\dot{m}_o$ are the mass influx and outflux [kg/s] within the source CV, respectively.

2.2. Travel time (TT)

Efthimiou and Bartzis (2011) proposed TT estimation method by using passive/inert and radioactive scalar. The radioactive scalar has same diffusivity and properties as passive/inert scalar, but it has a decay term depending on decay constant (λ) and its own concentration (C_r). Both scalars are generated at the same point and intensity, and, by reading the concentration differences between them as time, TT is evaluated as following equation:

$$TT(\boldsymbol{x}, \boldsymbol{x_0}) = -\frac{1}{\lambda} ln \frac{C}{C_r} \tag{2}$$

where, $\boldsymbol{x_0}$ is source point, $\boldsymbol{x}$ is receptor point and C is passive/inert scalar concentration [kg/m^3].

2.3. Average return time (T_R) concept

TT distribution indicates the average dispersion time of contaminant parcels and, if recirculation is occurred at the source point, TT value at the recirculating region means the average recirculation time sale of contaminants. Therefore, by fusing the concepts of α and TT, we proposed a new ventilation index, average return time, which indicates the time scale for generated contaminants to recirculate back to the source once. By considering the TT value at the inflow and outflow surface, it can be identified. The TT value at the inflow surfaces represents the average travel time of contaminants returning to the source ($\overline{TT}_R$). By applying a geometric series, $\overline{TT}_R$ can be expressed as equation (3). Here, τ_{domain} refers to average staying time of contaminant within the domain. Conversely, the TT value at the outflow surfaces represents the average travel time of the scalar evacuated from the source, denoted as $\overline{TT}_E$ and is defined in equation (4). From equation (3) and (4), T_R can be simply described as equation (5).

$$\overline{TT}_R = \frac{\sum_{n=1}^{\infty}(n\cdot(T_R+\tau_{domain})\cdot\alpha^n)}{\sum_{n=1}^{\infty}\alpha^n} = \frac{T_R+\tau_{domain}}{1-\alpha} \tag{3}$$

$$\overline{TT}_E = \frac{\sum_{n=0}^{\infty}(\tau_{domain}+n\cdot(T_R+\tau_{domain}))(\alpha^n\cdot(1-\alpha))}{\sum_{n=0}^{\infty}((1-\alpha)\alpha^n)} = \frac{\tau_{domain}+\alpha\cdot T_R}{1-\alpha} \tag{4}$$

$$T_R = \overline{TT}_R - \overline{TT}_E \tag{5}$$

Furthermore, by extending this concept to the average staying time of contaminants within the room (τ_{room}), τ_{room} can be decomposed three components: returning to the source, staying within local domain and being direct exhaust from the room, as expressed in equation (6). The scale of τ_{room} can be directly evaluated by using the scale for ventilation efficiency No.1 (SVE1) defined by Kato and Murakami (1988).

$$\tau_{room} = \frac{\sum_{n=0}^{\infty}(T_{DE}+n\cdot(T_R+\tau_{domain}))(\alpha^n\cdot(1-\alpha))}{\sum_{n=0}^{\infty}((1-\alpha)\alpha^n)} = T_{DE} + \frac{\alpha}{1-\alpha}T_R + \frac{\alpha}{1-\alpha}\tau_{domain} \tag{6}$$

3. METHODOLOGY

We conducted isothermal two-dimensional CFD analysis. The incompressible continuity, Reynolds-averaged Navier-Stokes and Scalar transport equations were numerically solved by using ANSYS/Fluent 2023R2 commercial CFD software. The IEA Annex 20 two-dimensional

benchmark test case (Nielsen 1990) was targeted as domain and our geometry is illustrated in Fig. 1. For inflow boundary condition, the inlet velocity (U_{in}) was applied 0.455 [m/s], and turbulent intensity and reference length scale were assumed 10% and one-tenth length scale of the inlet (h/10), respectively. The velocity flow field was initially solved using SIMPLE algorithm, the 2nd order upwind difference scheme for advection term and standard k-ε model. The calculation domain is consisted by an equally spaced structured mesh and the number of grids is 49,120. A mesh independence check was carefully conducted following to previous study (Ito et al., 2015).

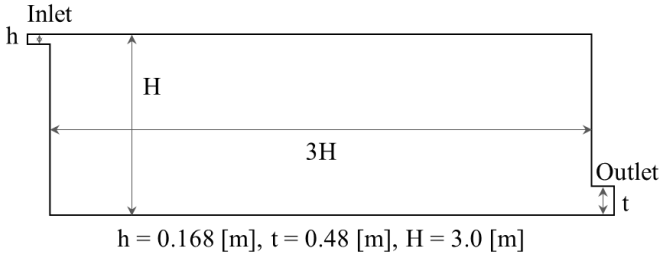

Fig. 1 Two-dimensional geometry of Annex 20 benchmark test (Nielsen 1990)

4. RESULTS AND DISCUSSION

Fig. 2 illustrates the airflow field, with contour values normalized by the inlet velocity and overlaid with streamlines. The air is introduced through the supply inlet located at the ceiling and flows along the indoor walls. Based on the flow field, we coupled it with scalar transport equations to conduct an analysis of the average return time. In this analysis, three points, as shown in Fig. 2, are designated as point sources under separate conditions.

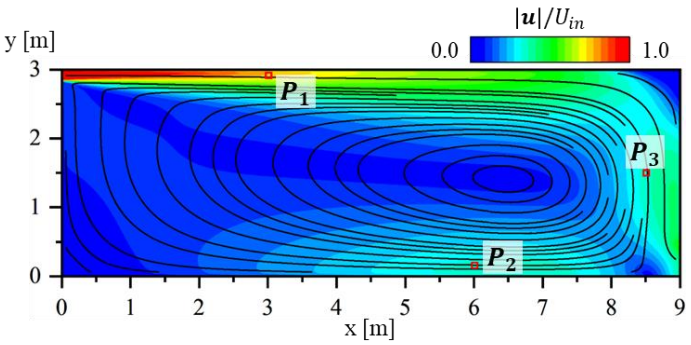

Fig. 3 Airflow field and scalar source descriptions

The results of average return time analysis are summarized in table 1 with all time scales normalized by the nominal time constant (τ_n). Under the condition generated at the P1, the value of T_R is less than τ_{room} and T_{DE}. The contaminants are carried by the main circulation flow, with the majority being discharged directly, while the remaining portion required more time than τ_n to recirculate. On the other hands, under the P2 and P3 conditions, the value of T_R is less than τ_{room} and T_{DE}. This implies contaminants recirculated with the short cut route. Furthermore, by integrating α and T_R indices, the mixing factor (MF) can be newly defined as below:

$$MF = \frac{\alpha}{T_R/\tau_n} \tag{7}$$

This MF value implies the return population of contaminants within the time scale of τ_n with considering both probability and time. The MF value at the P1, P2 and P3 are 0.070, 0.352 and 0.297, respectively. This value directly indicates the intensity of recirculation within the local domain.

Table 1. Results of average return time analysis

	α	$\overline{TT}_R/\tau_n$	$\overline{TT}_E/\tau_n$	T_R/τ_n	τ_{domain}/τ_n	τ_{room}/τ_n	T_{DE}/τ_n
P_1	8.7%	1.38	0.141	1.24	0.020	0.759	0.625
P_2	21.9%	1.04	0.413	0.623	0.187	1.29	0.944
P_3	12.2%	0.721	0.310	0.411	0.222	0.779	0.648

4. CONCLUSION

In this study, by fusing the concept of return probability and travel time, we proposed average return time concept. Considering it with the average staying time of contaminant within the room, we decomposed τ_{room} as three components: recirculation, staying and direct exhaust. By confirming these values, we confirmed the contaminant recirculation behaviour in terms of time. Moreover, we defined mixing factor as the merit indicating the intensity of recirculation. It has the potential to describe the correlation between recirculation and dispersion within the room at a specific local domain or point.

SUMMARY
Due to hourly continuous operation for diluting the large amount of heat induced by the nuclear decay reaction of the waste, ventilation system could consume huge energy inside a nuclear waste storage plant. This study focused on analysing the variation patterns of one of the most important indexes: temperature distribution inside a typical nuclear waste storage plant, when considering of different storage tank layout, air inlet patterns and inflow angle. 16 Computational Fluid Dynamics (CFD) simulation cases determined by the Orthogonal Experimental Design methods when considering several factors including storage tank layout, air inlet patterns and inflow angle were employed. The main heat processes, e.g. conduction, convection and radiation are all included in the simulation. The optimization strategies for the ventilation systems inside the plant were selected from different cases by comparing three key indexes: the maximum wall temperature, the average storage vault internal body temperature and surface-averaged temperature of the nuclear waste storage tank. The results showed that none of the maximum wall surface temperatures exceeded 65°C, that centralized rows would increase local surface temperatures, and that the optimal algorithms were staggered rows of storage tanks with vertical air inlets and outlets located on both sides.

Keywords: nuclear waste storage plant, ventilation, CFD

1. INTRODUCTION

In recent years, energy conservation has become a hot topic, and nuclear energy has gained significant attention due to its clean and efficient characteristics. However, with the global promotion and utilization of nuclear power, the management and storage of nuclear waste have emerged as a challenging issue. In Europe alone (excluding Russia and Slovakia), more than 60,000 tons of nuclear waste are stored (WNWR, 2019). In the United States, 96 operating nuclear power plants have collectively generated over 90,000 tons of nuclear waste (Jacoby, 2020). Currently, research on nuclear waste management has made notable progress. Compared to deep geological storage, repositories are less costly to construct and maintain, and unlike wet storage, they do not require continuous cooling systems or real-time monitoring. Inside storage tanks, nuclear waste releases significant decay heat over a long-term decay process, transferring heat from the inner surface to the outer surface through conduction. The release of decay heat is a continuous and gradual process, unaffected by external changes and without interruptions or power fluctuations. Therefore, each storage tank can be regarded as a constant heat source.

Inside storage repositories, numerous heat sources are arranged in arrays and equipped with a ventilation system featuring downward supply and upward return airflow. Flowing air removes heat through convective heat transfer. The radiative heat transfer between high-temperature heat

sources and wall surfaces is also significant and cannot be neglected. Controlling the wall surface temperature below 65°C (Board, 2001) ensures the structural integrity of the space. The continuous release of decay heat necessitates the long-term operation of the ventilation system, leading to sustained high-load operation of equipment such as fans and motors, which consumes substantial electrical energy. Therefore, studying and optimizing ventilation within storage repositories are essential for improving economic efficiency and ensuring safe storage.

Existing research on repositories primarily employs CFD (Computational Fluid Dynamics) technology, which offers significant advantages in such studies. CFD can accurately simulate complex flow phenomena such as turbulence and natural convection, as well as heat transfer processes including conduction, convection, and radiation. The visualization of temperature and velocity fields facilitates intuitive analysis of fluid flow and heat transfer. Additionally, CFD can replace hazardous and low-tolerance physical experiments, while its flexible parameter adjustment capabilities enhance the efficiency of optimization design. Numerical simulations of repositories predominantly focus on natural convection. Several studies (Chen and Chen, 2021, 2024; Kim et al., 2015; Lin et al., 2024) have used the k-ε turbulence model and the Discrete Ordinates (DO) radiation model, accounting for solar radiation, to investigate velocity and temperature fields within repositories. Lin et al. 2024 demonstrated that the spacing between heat sources affects the radiation view factor but has an insignificant impact on facility temperature. Chen and Chen, 2021, 2024 conducted sensitivity analyses of velocity and temperature fields, examining factors such as the presence of sunlight, windows, fans, and door positions. Their findings indicate that under natural convection, the maximum temperature inside the building does not compromise structural integrity. Kim et al. 2015 optimized repository design through numerical simulation by introducing dimensionless temperature and convection-radiation heat transfer ratios. They analyzed the effects of tank spacing, inlet length, and arrangement patterns on heat transfer, concluding that non-uniform staggered arrangements improve spatial efficiency and ensure thermal safety. Mishra et al. 2022 and Mishra et al. 2025 explored the influence of factors such as inlet position, shape, and duct edge roughness on air velocity and temperature fields, thermal efficiency, and air exchange rates. Ratiko et al. 2018 employed multi-objective optimization, considering thermal safety and cost, to refine repository design, combining numerical simulation with genetic algorithms to determine optimal configurations. Kim et al. 2014 combined the k-ε turbulence model and the Discrete Transfer Radiation Model (DTRM) to simulate repositories of various scales. They constructed a 1/4-scale repository model for experimental validation and evaluated scaling effects using dimensionless temperature, dimensionless residence time, Euler number, and Richardson number.

In summary, numerical simulation studies on repositories have primarily focused on natural convection, with limited analysis combining forced convection and radiation models for large-scale repositories. This study uses a specific repository as a prototype, considering operating conditions where the storage tanks are loaded to one-third of their full capacity. Building on previous research, it examines the effects of tank arrangement, outlet position, and inlet angle on heat transfer efficiency. The k-ε turbulence model and the S2S (Surface-to-Surface) radiation model are employed for CFD simulations, and orthogonal design experiments are used to analyze 16 simulation cases. The significance of this study lies in its ability to provide a detailed analysis of the temperature distribution on wall surfaces, identify the key factors influencing spatial and maximum wall temperatures, and evaluate performance based on standardized temperature metrics. Ultimately, it proposes an optimal energy-saving solution.

2. METHODS

A computational domain including inlets, outlets, and nuclear waste storage tanks was established for numerical simulation, as shown in Figure 1. The internal dimensions of the repository are 15.4 m (length) × 5.4 m (width) × 2.4 m (height). Each storage tank has a diameter of 0.2 m and generates 396 W of heat. The ventilation system adopts a downward supply and upward return configuration. Existing studies have demonstrated that the Realizable k-ε model developed by Shih et al., 1995 has the capability to accurately predict and simulate various flow conditions (Lateb et al., 2013). The model demonstrates good numerical stability and predictive capability when dealing with complex wall boundaries and recirculation regions (Ahmadi-Baloutaki and Aliabadi, 2021). Its precision, computational efficiency, and robustness make it well-suited for indoor environment modeling (Ahmadi-Baloutaki and Aliabadi, 2021). The primary radiative heat transfer in the repository occurs between the high-temperature heat source surfaces and the walls. The S2S (Surface-to-Surface) radiation model, designed to analyze radiative heat transfer between arbitrarily complex surfaces in enclosed spaces, effectively describes this process. The medium filling the space between surfaces is a non-participating medium, meaning it does not absorb, emit, or scatter radiation. The three core governing equations are included in CFD simulations: the continuity, momentum, and energy equations, collectively encapsulated in Eq. (1). The heat transfer equation of S2S radiation model is represented by Eq. (2).

$$\frac{\partial(\rho\phi)}{\partial\tau} + div(\rho U\phi) = div(\Gamma grad\phi) + S \tag{1}$$

where ρ is the fluid density (kg/m^3); ϕ is a general variable that represents the velocity components u (m/s), v (m/s), and w (m/s) in the momentum equation, or temperature T (℃ or K) in the energy equation; τ is the time (s); div indicates divergence; U is the velocity vector; Γ is the generalized diffusion coefficient; grad represents the gradient; and S is the generalized source term.

$$J_k = E_k + \rho_k \sum_{j=1}^{N} F_{kj} J_j \tag{2}$$

Where, J_k represents the total radiation energy leaving surface k, E_k denotes the emissive power of surface k, ρ_k represents the emissivity of surface k, F_{kj} represents the view factor between surfaces k and j, J_j represents the radiation energy emitted from surface j.

Therefore, this study employs the Realizable k-ε model to simulate airflow within the repository and uses the S2S model to simulate the radiative heat transfer process between surfaces.

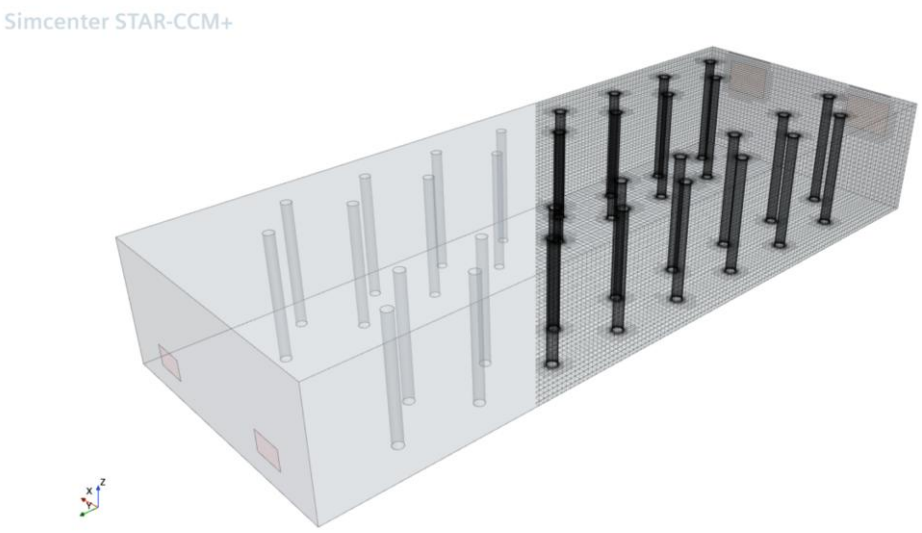

Figure 1. Geometric model diagram

The simulation was conducted using the commercial CFD software STAR-CCM+ 2302. A grid independence test was performed, as shown in Figure 2 a). Considering both the accuracy of the numerical simulation and computational efficiency, a grid size of 846,000 cells was selected for the simulation. During the simulation, it was assumed that the 32 storage tanks act as constant heat sources. The specific boundary types and parameters are listed in table 1. The simulation was performed under steady-state conditions.

Table 1. Boundary condition

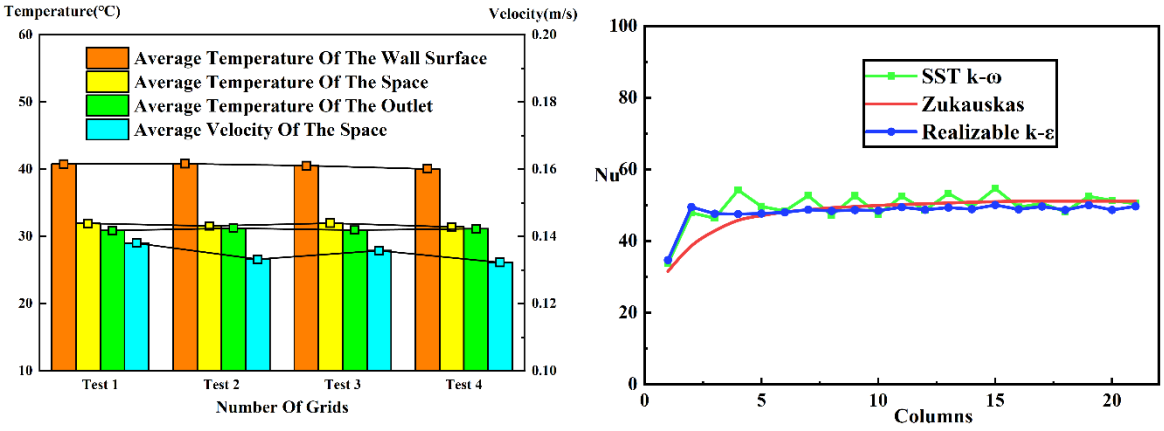
Boundary Name	Boundary Type	Parameter	Values
Inlet	Velocity Inlet	Velocity	1.33m/s
		Temperature	18℃
Outlet	Pressure Outlet	-	-
Wall	Wall - Convection	Ambient Temperature	25℃
		Convective Heat Transfer Coefficient	8.7W/m^{2}K
		Surface Emissivity	0.85
Heat Source	Wall - Heat Source	Heat Power	396W
		Surface Emissivity	0.5

In this study, the typical Reynolds number of the airflow within the storage vault is approximately 11,000, indicating a turbulent flow regime. The heat transfer mechanisms primarily involve convective heat exchange between the surface of the storage tanks and the surrounding air, as well as radiative heat transfer between the tanks and the surrounding walls. The gas is assumed to be incompressible, and a gravity model is included to account for buoyancy effects. Due to the relatively large temperature differences in the system, the Boussinesq approximation is not applied. The ideal gas law is used to capture the temperature-dependent density variations, allowing for a more accurate representation of buoyancy-driven flow behavior.

The arrangement of storage tanks within the repository resembles that of a tube bundle heat exchanger. A corresponding model was established and validated against the Zhukauskas empirical correlation for tube bundles:

$$Nu_f = 0.35\left(\frac{S_1}{S_2}\right)^{0.2} Re_f{}^{0.6} Pr_f{}^{0.36}\left(\frac{Pr_f}{Pr_W}\right)^{0.25} \quad (2)$$

Dong et al. 2010 detailed the geometric dimensions and boundary conditions, and the results demonstrated that the numerical model effectively simulates the turbulent heat transfer process. Compared with the SST k-ω model, the simulation results of the Realizable k-ε model show better agreement with Zhukauskas empirical correlations. The model validation error was found to be less than 5% (Figure 2 b)).



a) Mesh independence test b) Model validation

Figure 2. Mesh independence test and model validation results

The orthogonal experimental design was established with three factors: tank arrangement, outlet position, and inlet angle. A mixed orthogonal experimental table was constructed accordingly (Figure 3.).

No.x	Factor 1 Arrangement Type	Factor 2 Outlet Position	Factor 3 Inlet Angle
1	1	1	1
2	1	2	2
3	1	1	3
4	1	2	1
5	2	1	2
6	2	2	1
7	2	1	1
8	2	2	3
9	3	1	3
10	3	2	1
11	3	1	1
12	3	2	2
13	4	1	1
14	4	2	3
15	4	1	2
16	4	2	1

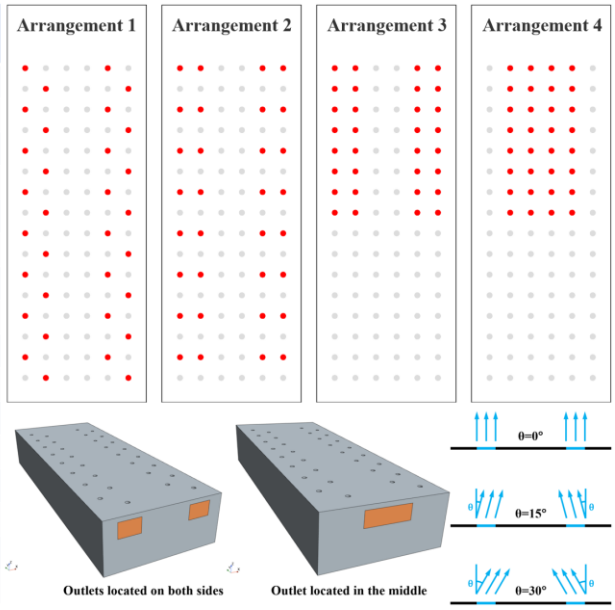


Figure 3. Orthogonal experiment table and influencing factors diagram

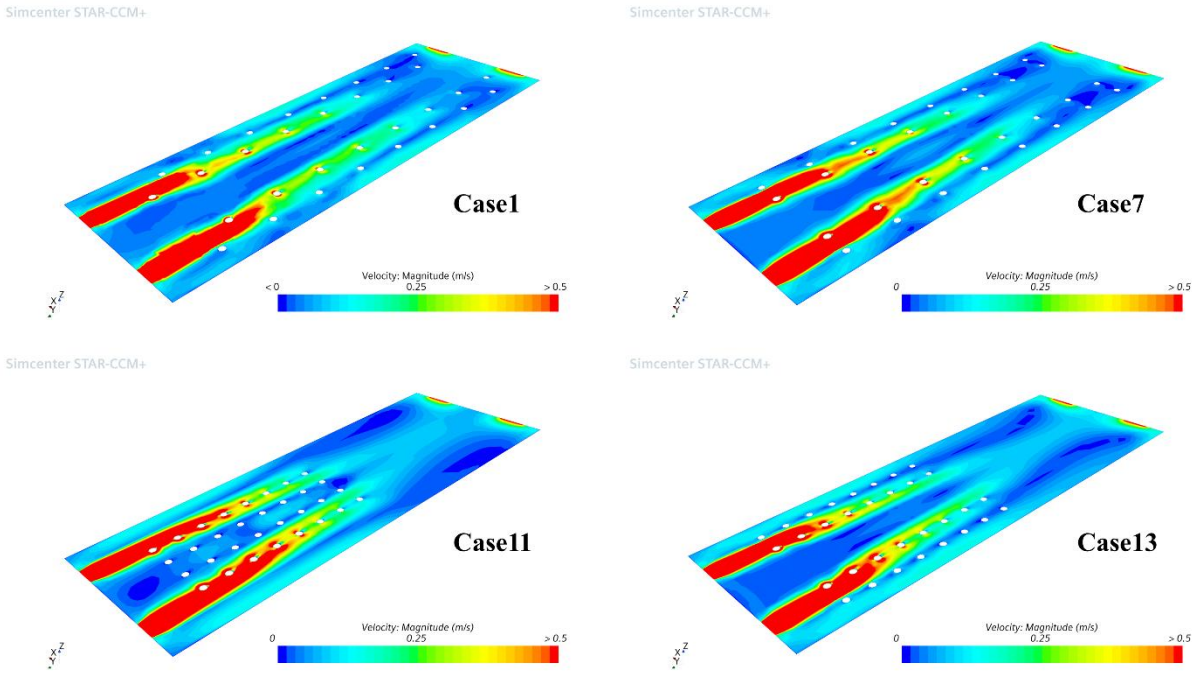
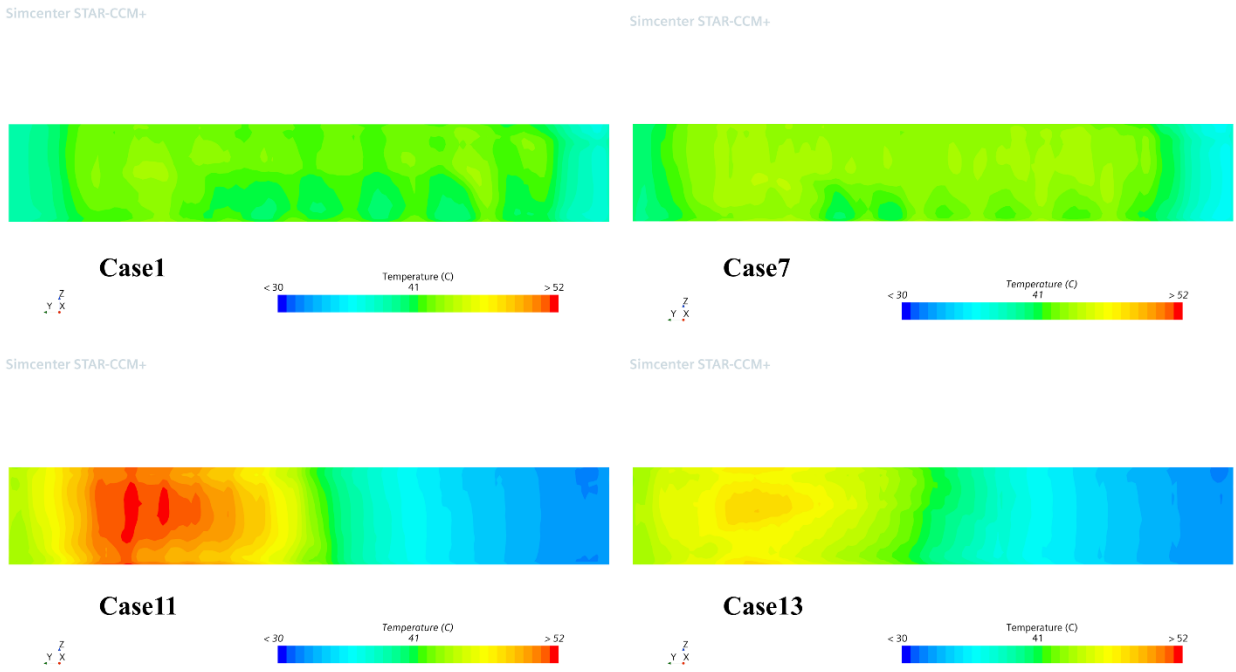
3. RESULTS

The Figure 4 display the velocity contour maps of the inlet-outlet diagonal cross-section and the corresponding wall surface temperature contour maps for four typical cases (case 1, case 7, case 11, and case 13).



a) Velocity Contour Plot of the Inlet and Outlet Diagonal Section



b) Temperature Contour Plot of Wall Surface

Figure 4. Velocity and Temperature of Typical Cases

A range analysis was conducted on the 16 orthogonal experimental cases, and the results indicate that the storage tank arrangement is the most influential factor affecting the maximum wall surface temperature, followed by the inflow angle, while the outlet position has a relatively minor impact. Centralized layouts tend to cause heat accumulation in the central region of the repository, resulting in elevated local wall temperatures. In contrast, staggered or uniformly distributed layouts facilitate better heat exchange between the air and the storage tanks.Due to the combined effects of tank arrangement and inflow angle on the spatial structure of the vault, these two factors significantly influence the temperature of the tank surfaces by shaping the airflow distribution. For the average spatial air temperature, the inflow angle plays the dominant role, as it determines the coverage and penetration of airflow throughout the space.

In summary, the storage tank arrangement governs the locations of local heat accumulation, while the inflow angle determines the overall heat transfer efficiency. The coordinated optimization of these two variables is essential for ensuring thermal safety and achieving energy-efficient operation.

4. DISCUSSION

From the velocity contour maps, it can be observed that due to the tank arrangements, the airflow in uniformly distributed cases (case 1 and case 7) extends further and merges only near the end of the repository. In contrast, for concentrated distributions (case 11 and case 13), the airflow merges in the central part of the repository, with reverse flow occurring along the wall surfaces.

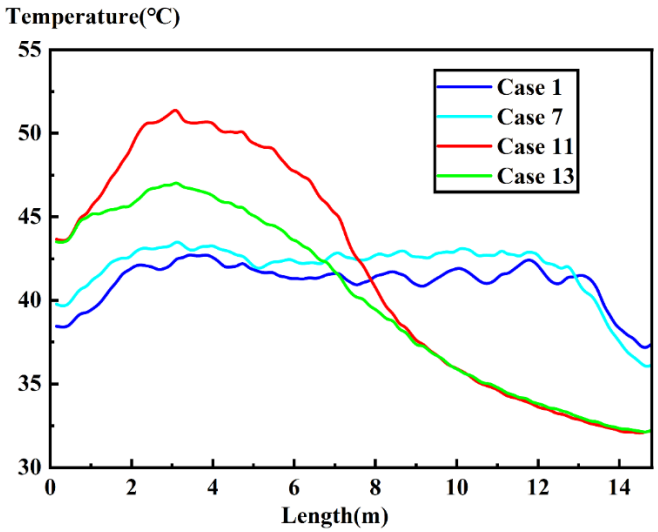


Figure 5. Wall Surface Temperature Distribution of Typical Cases

The simulation results indicate that the wall surface temperature in all cases remains below 65℃. In the uniformly distributed cases (case 1 and case 7), the heat sources closest to the wall are aligned in odd-numbered rows, and the temperature variation between rows 1 and 15 is relatively

stable. The average wall temperature for case 1 is 41.68°C, with a fluctuation of less than 2.6%, while case 7 exhibits a slightly higher average temperature with a fluctuation of 4.2%. Additionally, case 1 shows a wavelike temperature distribution with approximately 8 peaks, attributed to the closer proximity of heat sources in odd-numbered rows to the walls compared to even-numbered rows.

In concentrated distribution cases (case 11 and case 13), heat sources are primarily concentrated in the first eight rows. Compared to case 1, the average wall surface temperature increases by approximately 16.7% and 7.1%, respectively. This difference arises because the heat sources in configuration 4 are more densely located in the central two rows. Between rows 9 and 16, where no heat sources are present, the average wall surface temperature decreases by about 15% compared to configuration 1, with both cases showing nearly identical temperatures.

The maximum wall temperature, average heat source surface temperature, and average spatial temperature for all 16 cases were analyzed and evaluated. Range analysis reveals the following: The position of the outlet has a negligible impact on these temperature metrics. The wall surface maximum temperature is primarily influenced by the arrangement of heat sources, followed by the inlet angle. Both the heat source arrangement and the inlet angle significantly affect the average surface temperature of the heat sources. For the average spatial temperature, the inlet angle has a more pronounced impact.

Using standardized temperature metrics for evaluation, the results indicate that the layouts in case 1 and case 7 are more effective for heat dissipation and reducing wall surface temperatures, while the layouts in case 9 and case 12 perform the worst.

5. CONCLUSIONS

The distribution of wall surface temperatures is closely related to the arrangement of heat sources. For concentrated arrangements (case 11 and case 13), the average temperature in the front rows is 16% and 7% higher than that of the dispersed arrangement, respectively, while the average temperature in the rear rows decreases by 15%.

The arrangement of heat sources has the greatest impact on the maximum wall surface temperature, followed by the inlet angle. Both the arrangement and the inlet angle significantly influence the average surface temperature of the heat sources. However, for the average spatial temperature, the inlet angle has a more pronounced effect.

Using standardized temperature evaluation methods, the 16 cases were assessed. Case 1 exhibited the best performance, followed by cases 4, 7, and 6. Conversely, cases 9 and 12 showed the poorest heat transfer performance and should be avoided under practical operating conditions.

Filter application as air quality improvement strategy for particulate matter

Lisa Corneillie [1], Klaas De Jonge [1], Jelle Laverge [1]

[1]*Ghent University, Ghent, Belgium, lisa.corneillie@ugent.be*

SUMMARY
Particulate matter (PM) is widely recognized as one of the most hazardous pollutants affecting human health and life expectancy, as evidenced by numerous studies. Since individuals spend the majority of their time indoors, reducing indoor exposure to PM is essential for safeguarding overall health. This study utilized dynamic simulations in Dymola to assess the performance of ventilation filters in lowering indoor PM concentrations in a three-bedroom apartment. The findings indicate that maintaining PM levels below the World Health Organization's (WHO) guideline values requires the use of a HEPA filter within the ventilation system, coupled with keeping windows closed. To further mitigate PM generated during cooking, a high-efficiency cooker hood or air purifier can complement the ventilation filter. Additionally, opening nearby windows during cooking can help reduce exposure to PM. However, despite the implementation of filtration systems, the disability-adjusted life years (DALYs) attributed to PM exposure remain three times higher than those associated with other indoor pollutants.

Keywords: Particulate matter, filter performance, indoor air quality, DALY

1. INTRODUCTION

Annually, two million deaths are attributed to particulate matter (PM) inhalation and its associated health effects (Lu et al., 2023). These health effects range from miscarriages and respiratory problems to heart deficiencies and cancer. Given that individuals spend approximately 90% of their time indoors, the majority of these health impacts are linked to indoor PM concentrations (Kim et al., 2023). Air filters can be employed to mitigate exposure to indoor PM; however, questions remain regarding their effectiveness in real-world environments. Laboratory tests of these filters often neglect various parameters that influence indoor PM concentrations, which may lead to an undue sense of security regarding their performance in practical settings. Consequently, the objective of this study is to examine whether filters can sufficiently reduce indoor particulate matter concentrations in a realistic residential environment.

To achieve this goal, a filter component was developed, and an existing multi-zone model was adapted to incorporate particulate matter. Subsequently, a series of simulations was conducted to evaluate the influence of various parameters. The parameters investigated include variable outdoor PM concentrations, the performance of different filter types, the impact of cooking-related PM, demand-based ventilation, and window operation. Finally, the number of disability-adjusted life years (DALYs) per 100 000 individuals resulting from PM2.5 exposure under different scenarios was calculated. This was then compared to the DALYs attributable to other indoor pollutants to assess the significance of particulate matter when a filter is present.

2. METHODOLOGY

To accurately evaluate filter efficiency, it is essential to create a virtual environment specifically designed for this purpose. In this study, dynamic simulations were conducted in Dymola using the Modelica language.

2.1 Filter component

The first step in creating such an environment is modelling a filter component in Dymola. This component was developed based on the current testing standard for high-efficiency filters, NBN EN 1822-1 (2019). Its testing method provides an efficiency curve, and an initial pressure drop. By adhering to this mandatory standard, the model allows comparison of other filters when manufacturers make relevant data available. Applied data is thus treated as potential output data from the testing standard. The filter component can be configured with various PM size fractions and their corresponding filter efficiencies, as derived from the efficiency curve of the testing standard. The number of size fractions can also be adjusted as needed. In this study, four size fractions were used: PM0.1, PM1, PM2.5, and PM10. It is important to note that overlap exists between these size fractions, representing a long-standing research gap in PM guidelines and measured data. Unfortunately, this issue could not be resolved within the scope of this study.

Additional considerations must also be addressed. First, the tested velocity is determined by the manufacturer. Since filter efficiency is highly dependent on velocity, comparing filters evaluated under different velocities presents significant challenges. Second, the humidity condition specified in the testing standard is relatively broad. As humidity influences particle settling rates, variations in humidity could also lead to discrepancies in efficiency. Future updates to the standard should include specified testing velocities to facilitate more consistent comparisons between filters.

The resulting filter component requires the filter efficiency and the initial concentration of pollutants as inputs, and it outputs the remaining particle concentration. The component was validated using data from the Out2In project (Herreweghe et al., 2019).

2.2 Multi-zone model

In the next step, an existing multi-zone model developed in Dymola by De Jonge (2023) was adapted to incorporate particulate matter. To achieve this, PM tracers were added to both the air medium and the outdoor air. Each tracer was assigned a decay rate derived from the literature, ranging from 1.1/h to 151/h. Additionally, the outdoor PM concentrations for the different tracers were made variable. These concentrations were obtained via irCELine.be for PM1, PM2.5, and PM10. For PM0.1, interpolation could be performed; however, due to the unknown size distribution of PM and its significant geographic variability, this approach would not provide an accurate representation of the associated health effects. Using the same data as for PM1 is therefore regarded as a worst-case scenario, assuming all particulate matter within its size fraction belongs to PM0.1. Should more precise data become available in the future, this approach should be revised for greater accuracy.

The overall model represents a three-bedroom apartment with approximately 120 m^3 of living space. The Dymola model is composed of nine separate zones, one for each room, while the communal hallway is excluded. A graphical representation of the model is provided in Fig. 1.

Figure 1. Floorplan of the 3-bedroom apartment.

2.3 Base scenario

To evaluate filter performance within this model, a baseline for comparison must first be established. This baseline scenario assumes the apartment is unoccupied, yet functional as though it were. By making this simplification, particulate matter generated by occupant activities is excluded at this initial stage. Additionally, all windows in the apartment remain closed. Air purification is provided by a mechanical ventilation system with heat recovery (MVHR) operating continuously at a constant flow rate. No filter is included in this ventilation system, and the building is assumed to have good airtightness. The outdoor PM concentrations are sourced from a measuring station in Vilvoorde. The results of this baseline scenario serve as a reference point for the subsequent case studies.

3. CASE STUDIES

In the subsequent phase, several factors influencing indoor PM concentrations were analysed. For each case study, the baseline model was adapted, as necessary. Additionally, various combinations of case studies were simulated. In total, fifteen simulations were conducted, including the baseline scenario. The case studies were categorized into five distinct groups, each addressing a specific influential factor.

3.1 Category A: Variable outdoor concentration

To examine the influence of varying environments within Belgium, three additional sites were selected, each representing distinct surroundings potentially associated with different PM size distributions. These sites included the city center of Ghent, the Antwerp ring road, and a rural area (Moerkerke). The base scenario site was located just outside the Brussels ring road (Vilvoorde).

3.2 Category B: Filter type

Secondly, three filter types with varying efficiencies were evaluated in the developed environment. The efficiencies of a coarse 60% filter and an ePM1 55% filter were derived from data collected during the Out2In research by Buildwise, where filters were evaluated at a face velocity of 0.5 m/s (Herreweghe et al., 2022). The efficiency of an H13 filter was determined using a mathematical approach (Chen et al., 2019) at a velocity of 0.164 m/s. Table 1 provides an overview of the efficiencies used. These filters were subsequently incorporated into the overall multi-zone model, with a filtration efficiency of 10% assumed for O_3 across all filters.

Table 1. Filter efficiencies for each filter type.

Size fraction	Coarse filter *[%]*	ePM1 55% filter *[%]*	H13 filter *[%]*
PM0.1	42.32	53.58	99.95
PM1	40.58	31.07	99.99
PM2.5	50.67	41.26	99.99
PM10	63.99	58.48	99.99

3.3 Category C: Indoor PM source

In the next case study, a family of four was introduced into the apartment. Cooking was identified as the most significant and universal indoor PM source, while smoking, being a lifestyle choice, was excluded. Consequently, a cooking schedule consisting of three basic hot meals was developed as a worst-case scenario, as shown in Table 2. The emissions associated with these meals were linked to the family's occupancy schedule and repeated weekly (O'Leary et al., 2019). To determine the size distribution of cooking-related PM, a lognormal distribution was assumed, with a mode diameter of 0.04 μm and a standard deviation of 0.005 μm (Pikmann et al., 2023). This analysis indicated that nearly all cooking-related PM could be attributed to PM0.1. Based on these findings, a PM source schedule was constructed. The emission rate for lunch was tied to this schedule, and conversion factors were applied to differentiate between the meals. A cooker hood, capable of eliminating 70% of PM emissions directly, was also included in the scenario.

Table 2. Emission rate and duration for the selected meals (Source: O'Leary et al., 2019).

Meal	Average Emission Rate *[μg/min]*	Duration *[minutes]*
Breakfast	220	3.85
Lunch	1900	28
Dinner	3200	17

3.4 Category D: Demand based ventilation

An occupant-based ventilation system was also analyzed. In the selected system, the flow rate is adjusted based on the bathroom's humidity and the kitchen's CO_2 concentration (De Jonge, 2023). However, elevated humidity levels accelerate the settling of particulate matter, which could negatively impact PM concentration.

3.5 Category E: Window opening schedule

The opening of windows introduces additional PM from the outdoor environment. Since a ventilation system equipped with a filter does not alter this concentration, all particles from outside enter the room directly. To assess this influence, a window-opening schedule, detailed in Table 3, was developed, and a window component was modelled using research by Verbruggen et al. (2021). This component applies Phaff's equation, combined with window usage and temperature differences, to simulate airflow through the window.

Table 3. Window types and opening schedules.

Window	number	Type	Opening Winter	Opening Summer
Large window living room	1	Closed	Always closed	Always closed
Small window living room	2	Slide	Always closed	Open 9-5
Window kitchen	3	Turn	Always closed	Always open
Small window bedroom 1	4	Tilted	Open 8-9	Always open
Big window bedroom 1	5	Tilted	Open 8-9	Always open
Window bedroom 2	6	Tilted	Open 8-9	Always open
Window bedroom 3	7	Tilted	Open 8-9	Always open

4. EVALUATION

4.1 WHO target values

All findings are evaluated against the World Health Organization's (WHO) 2021 guideline values for the average annual PM concentration, which emphasizes health impacts. However, the WHO underscores that no safe threshold exists for PM, and concentrations should be minimized as much as possible. The WHO provides guidelines for PM2.5 and PM10, but not for PM1 and PM0.1, so interpolated values were calculated. The used values are shown in Table 4.

Table 4. Guideline values by the WHO, and interpolated values.

Pollutant	Averaging period	Concentration [µg/m³]	Pollutant	Averaging period	Concentration [µg/m³]
PM_{10}	Calendar year	15	PM_1	Calendar year	4
$PM_{2.5}$	Calendar year	5	$PM_{0.1}$	Calendar year	3

4.2 DALYs

The disability-adjusted life years (DALYs) were calculated for several key scenarios, representing the average number of healthy years lost per 100,000 individuals due to premature death or disability caused by pollutant exposure over one year. Due to the availability of effect factors, this analysis includes only PM2.5, excluding PM10. Furthermore, the assessment focuses on the kitchen, where the most significant impact is anticipated. The total DALYs were calculated using Eqs. (1) and (2) (Guyot et al., 2024), employing a time-resolved calculation method for DALYs based on the work of De Jonge (De Jonge & Laverge, 2022):

$$DALYs(t) = \int_{t_0}^{t} \frac{DALYs}{time}(t) \quad (1)$$

$$\frac{DALYs}{time}(t) = EF_{marginal} * IR(t) \quad (2)$$

Here IR(t) represents the intake rate [kg/s], and EF is the effect factor [DALY/kg]. The effect factors for PM2.5 and the other pollutants can be observed in Table 5 (Morantes et al., 2024). The intake rate is determined using Eq. (3).

$$IR(t) = V_{br}(t) * C_{exp}(t) \quad (3)$$

In this equation, $V_{br}(t)$ is the breathing rate over time, assumed to be 16m³/day and $C_{exp}(t)$ is the exposure concentration profile. To construct this profile, the initial worst-case assumption for PM0.1 was replaced with the percentage distribution of the outdoor PM measured in the Out2In study, ensuring no double accounting of concentrations (Herreweghe et al., 2019).

Table 5. Effect factors for various pollutants (Morantes et al., 2024).

Pollutant	EF marginal (median) [DALY/kg]
PM2.5	118.6111
Formaldehyde	18.0351
Ozone	4.2638
Nitrogen dioxide	15.7924
Benzene	0.1268
Toluene	0.0016
Naphthalene	0.6718
Limonene	0.0175

5. SCENARIO ASSESSMENT

5.1 WHO guidelines

For the base scenario, the average annual concentrations of PM exceed the WHO's recommended limits. For PM1 and PM0.1, the averages are approximately 7 µg/m³, compared to the recommended values of 3–4 µg/m³. For PM2.5, the difference with the guideline is around 4 µg/m³ (9 µg/m³ versus a guideline value of 5 µg/m³). For PM10, the difference is minimal. Overall, WHO indoor air quality guideline values are continuously exceeded.

Simulations of indoor PM concentrations under varying outdoor levels revealed that the variation in Belgium is insufficient to significantly influence overall average values. However, minor differences in size distribution are observed based on location. Traffic-heavy areas exhibit higher fine PM levels, while rural areas show elevated concentrations of coarse PM.

The introduction of various air filters had a substantial impact on PM concentrations. Installing an ePM1 filter, designed for smaller particle ranges, effectively reduced concentrations of the most harmful particles to just above the guideline values. However, achieving concentrations below the WHO threshold was only possible with an H13 filter. Adding an indoor PM source, such as cooking, caused a significant increase in the concentration of the smallest particles. High peaks (up to 300 µg/m³ during cooking) were observed, contributing notably to the average concentration. Filters have no effect on these peaks. In comparison to cooking-related PM, the overall reduction in average PM concentration due to filters is minor. Thus, additional source control measures are necessary to mitigate this indoor PM source.

A demand-based ventilation system, adjusted according to occupant activity, significantly increases indoor PM concentrations, particularly in wet rooms. Continuous ventilation systems allow for faster reduction of peak concentrations. A more tailored ventilation schedule, adapted to PM peak periods or integrated with PM sensors, could address this issue. The addition of air exchange through open windows substantially affects indoor air quality. Without a filter, opening windows has little to no effect or a slight positive impact. However, with a filter, the negative impact of window opening increases with the efficiency of the filter. Open windows also function as a source control for cooking-related PM, but if left open for too long, their negative effects outweigh the benefits. Figure 2 summarizes the key scenarios analysed in this study.

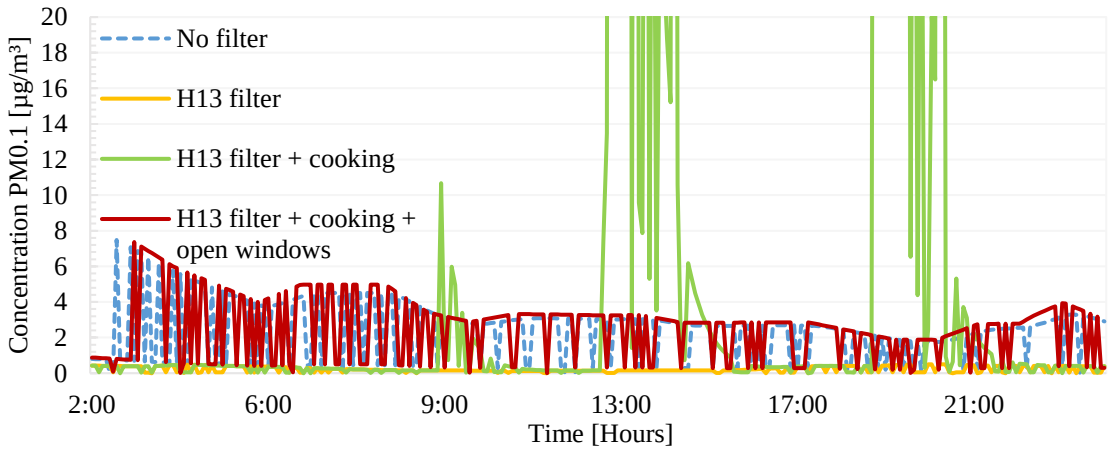

Figure 2. Comparison of daily PM concentration in different scenarios (close-up).

5.2. Health Impact of Mitigation Measures

The calculation of DALYs for PM2.5 in the kitchen across different scenarios demonstrates that air filters can significantly reduce the health impact of particulate matter. Even when cooking and/or window opening occurs, the improvements initiated by a (HEPA) filter remain highly significant in all scenarios. Figure 3 provides a comparative overview of these scenarios. For instance, the inclusion of an H13 filter in the apartment with an indoor source, results in a reduction of 1 300 DALYs.

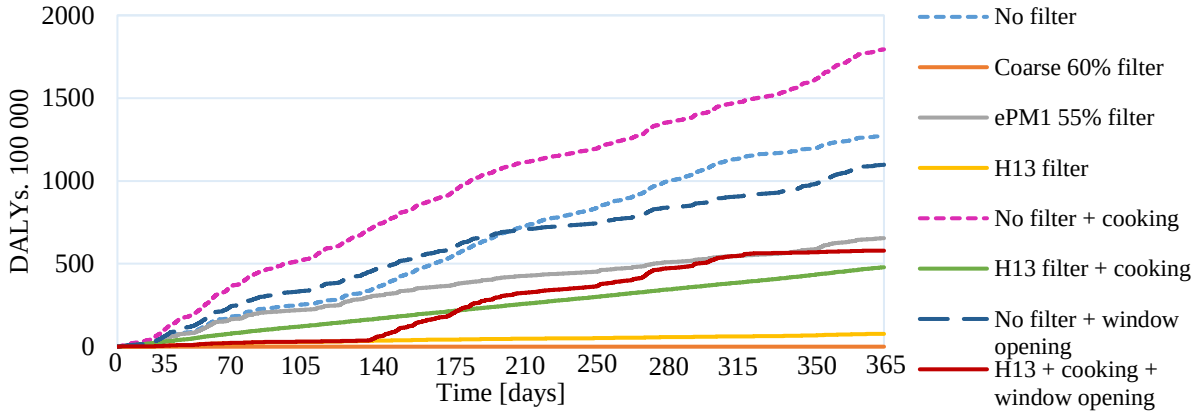

Figure 3. Number of DALYs for PM2.5 in function of the time in the kitchen.

5.3. Other pollutants

The existing multi-zone model includes various other pollutants, such as VOCs, NO_2, and O_3. A DALY assessment for the most realistic scenario—incorporating a filter, occupants, and open windows—highlights the critical importance of particulate matter. The number of DALYs for PM2.5 substantially exceeds those for other pollutants under the same conditions. Apart from PM, NO_2, O_3, and formaldehyde are the most harmful pollutants, as shown in Figure 4.

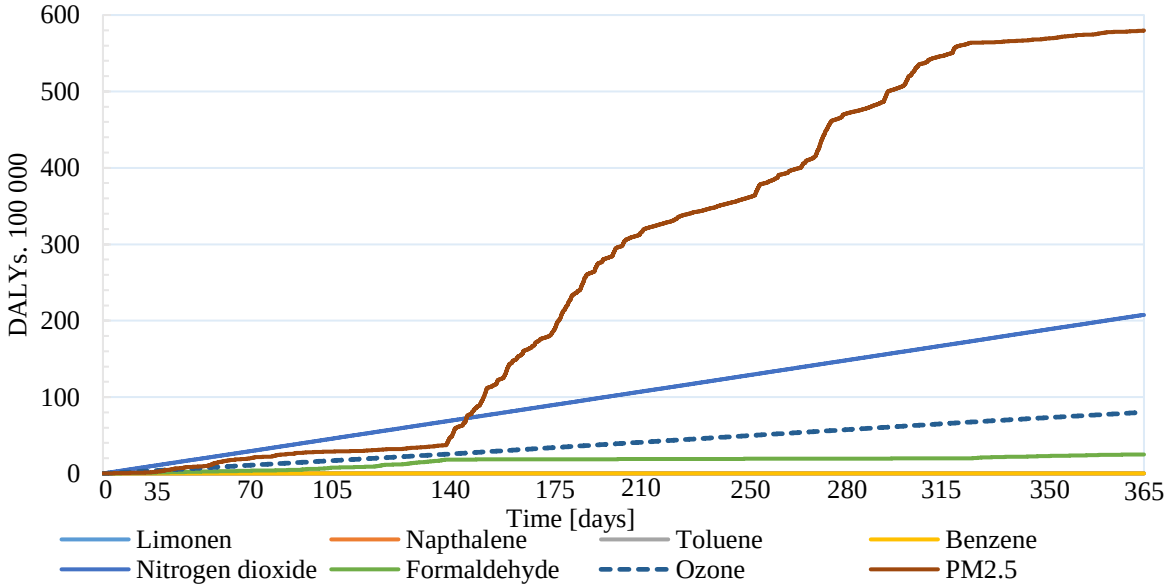

Figure 4. Number of DALYs for various pollutants per 100 000 people in the kitchen.

6. CONCLUSIONS

Particulate matter is a dominant contributor to various adverse health effects. Despite broad consensus on this issue, indoor PM concentrations in an apartment in Belgium, regardless of location, consistently exceed WHO recommendations when no mitigation measures are implemented. Filters offer an effective strategy for improving air quality, but only high-efficiency filters sufficiently reduce concentrations. To maintain their effectiveness in real-world conditions, windows should remain closed as much as possible. Moreover, local PM peaks caused by cooking cannot be offset by filtered air alone. To ensure a healthy environment during meal preparation, implementing local source control measures, such as a high efficiency cooker hood, air cleaners or briefly opening windows, is essential. The evaluated demand-based ventilation strategy proved inadequate, as it failed to reduce peaks quickly enough. Nevertheless, even with a filter in a continuous ventilation system, the DALYs attributable to particulate matter in real-life settings remains significant. Other indoor pollutants pose much less risk to human health. As such, further research into strategies for reducing indoor PM concentrations is essential.

SUMMARY
Metal-Organic Framework (MOF) materials present a promising solution to enhance energy efficiency and improve indoor air quality (IAQ) in buildings. This research examines the ability of a MOF material to passively control formaldehyde – a harmful indoor pollutant – by integrating laboratory testing and predictive IAQ modeling.

Laboratory experiments used the microporous Al pyrazole carboxylate, denoted Al-3,5-PDA or MOF-303, that was previously identified as a highly efficient material to capture traces of formaldehyde in air without releasing it before 50°C. The formaldehyde adsorption performance was evaluated in a continuous 28-day small-scale chamber test, followed by a 7-day desorption phase. Tests were performed using an Al-3,5-PDA paper sheet at the formaldehyde concentration of 50 - 500 µg/m^3 to assess the material's adsorption performance. Evaluating of the long-term performance of MOF material in room-scale tests would provide valuable insight into their effectiveness in real-world scenarios. However, due to their high adsorption capacity and the significant cost of experimental specimens, it is too expensive to conduct long-term saturation tests or room-scale implementation. To compensate for the lack of the long-term test data, an IAQ simulation model was developed by integrating the tested adsorption capability via a multizone CONTAM software. This model used the parameters derived from short-term, small-scale tests to simulate large-scale, real-world applications. This model not only can enable more accurate forecasts of effectiveness under various scenarios, but also can reduce the cost to conduct extensive tests.

Simulations were carried out at room scale with interior walls coated with the Al-3,5-PDA. The simulation demonstrated a 47% short-term reduction of formaldehyde levels by coating 10 m^2 of wall surface in a 30 m^3 room at 23 °C and 50% relative humidity. The results confirmed that Al-3,5-PDA's high formaldehyde adsorption capacity, taking 150 days to reach saturation. These findings highlighted the potential of Al-3,5-PDA to effectively adsorb

formaldehyde and reduce ventilation demands, contributing to energy savings and the improvement of IAQ in buildings. This study integrated short-term laboratory data into a scalable IAQ model, providing a cost-effective approach to predict performance of MOF materials in real-world building environments.

Keywords: Metal-Organic Framework, Formaldehyde, Indoor Air Quality, Model-based Testing and Evaluation.

1. INTRODUCTION

Formaldehyde is an indoor air pollutant that commonly found in various household and commercial products such as furniture, textiles, and building materials (Wang and Zhang, 2009; Xu et al., 2012; Zhou et al., 2018). Chronic exposure to formaldehyde can lead to respiratory issues, eye irritation, and cancer risk. This emphasizes both the increased risk within enclosed environments and the importance of effective removal strategies in indoor environments. Although removal is essential, effective technologies for removing formaldehyde in living spaces remain limited.

Metal-Organic Frameworks (MOFs) have emerged as a novel class of materials with significant potential for formaldehyde removal (Achenbach et al., 2025; Vikrant et al., 2019; Wang et al., 2016). This study evaluates Al-3,5-PDA, also known as MOF-303, for its effectiveness in removing formaldehyde from indoor environments. Al-3,5-PDA was shown to exhibit outstanding results in laboratory conditions through breakthrough tests (Sadovnik et al., 2024), single-pass removal efficiency tests (Sadovnik et al., 2024), and small-scale chamber tests (Won et al., 2024) through a unique moderate chemisorption mechanism between the pyrazole and hydroxy moieties decorating its micropores, while not releasing formaldehyde at ambient conditions and being regenerable in water. However, its formaldehyde removal effectiveness in real-world applications remains unproven. Evaluating the long-term performance of Al-3,5-PDA in room-scale tests would provide valuable insight into their real-world effectiveness of formaldehyde removal. However, conducting long-term saturation tests or room-scale implementations can be expensive due to their high adsorption capacity and the significant cost of experimental specimens. To overcome these limitations, this study employs the method of model-based testing and evaluation (Zhang et al., 2019). This study developed an IAQ model by integrating laboratory testing with predictive IAQ modelling. Data from short-term, small-scale tests conducted to evaluate Al-3,5-PDA's performance under specific conditions were used to derive parameters in order to present its long-term performance in controlled environments and large-scale room conditions. This simulation enables us to predict the Al-3,5-PDA’s effectiveness for passive formaldehyde control in actual living spaces, offering crucial insights into its practical applications.

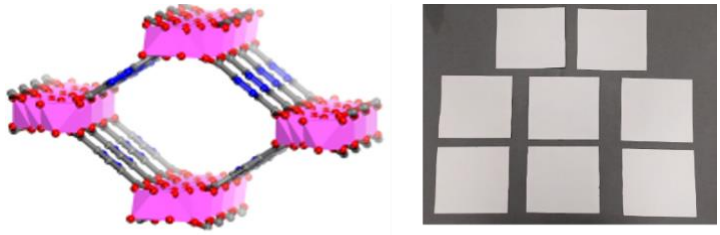
2. LABORATORY TEST

This study focused on deriving the model parameters to represent adsorption dynamics based on the chamber test results. While the detailed methodologies and findings were presented in a prior publication (Won et al., 2024), this section emphasizes the controlled testing approach and data acquisition processes essential for parameter estimation. The laboratory test evaluated the effectiveness of Al-3,5-PDA in adsorbing formaldehyde by using a 50 L sorption test system. The MOF was shaped as a 20 cm by 22.5 cm paper sheet (with a ca. 75 wt % MOF loading), following a green scalable protocol previously reported by some of us (Tignol et al., 2024), that was placed on a sample holder in the chamber so that the formaldehyde gas could be exposed to both surfaces of the sheet. Two distinct formaldehyde concentrations were applied at 23 °C and 50% relative

humidity: 114 μg/m^3 as a low concentration test and 316 μg/m^3 as a high concentration test. This setup aimed to assess how adsorption effectiveness varies under different formaldehyde concentrations. With formaldehyde injected into the chamber, the Al-3,5-PDA was subjected to continuous formaldehyde adsorption for 28 days. After that, the Al-3,5-PDA was allowed to desorb formaldehyde for 7 days by introducing only clean air into the chamber.

3. MATERIAL ADSORPTION MODEL AND IAQ MODEL

Al-3,5-PDA is a water stable and microporous 1D channel hydrophilic MOF material (see Figure 1) that exhibits a unique affinity for formaldehyde based on a chemisorption mechanism recently elucidated (Sadovnik et al., 2024); remarkably, the formaldehyde adsorption is favored in the presence of water. The adsorption processes involved the interplay between adsorption and adsorbate transportation to the surface, with each step potentially limiting the overall adsorption rate. The adsorption behavior of Al-3,5-PDA has been modeled using two distinct frameworks: the Equivalent Diffusion Model (EDM) (Liu et al., 2020) and the Empirical Surface Adsorption Model (ESAM) (Pétigny et al., 2021). The EDM focused on the diffusion of adsorbate molecules through the material's structure, assuming that the process could be effectively represented as a diffusion-controlled process. This model primarily emphasized the ability of the material to transport adsorbate molecules to the adsorption sites, but it did not fully capture the actual adsorption mechanism. The ESAM focuses on the relationship between the surface characteristics of Al-3,5-PDA and its capacity to adsorb formaldehyde. Based on experimental data, this model provided an empirical approach for describing how surface concentration influences the overall adsorption process.



a. Crystal structure of Al-3,5-PDA b. Al-3,5-PDA paper sheet

Figure 1 View of (a) the crystal structure of Al-3,5-PDA. $AlO_4(OH)_2$ octahedra, oxygen, carbon atoms are in pink, red and grey, respectively (hydrogen atoms have been omitted), and (b) tested paper sheet of Al-3,5-PDA.

3.1 EQUVALENT DIFFUSION MODEL

In the EDM, formaldehyde was adsorbed on the Al-3,5-PDA surface, governed by the partition coefficient (K_{ma}), which represented the ratio of the formaldehyde surface concentration ($C_{m,s}$) to the air-material interface concentration (C_s). For the chemisorption, the K_{ma} of Al-3,5-PDA was expected to be significantly higher than that of typical building materials, which relied solely on physical adsorption. Once adsorbed, formaldehyde then diffused deeper into Al-3,5-PDA, governed by the diffusion coefficient (D_m). The EDM assumed that the diffusion rate of formaldehyde within the Al-3,5-PDA was equal to the rate of the chemical reaction, as formaldehyde was removed from the surface. The in-material diffusion process for formaldehyde can be described by Eq. (1).

$$\frac{\partial C_m}{\partial t} = D_m \frac{\partial^2 C_m}{\partial y^2} \tag{1}$$

where C_m was the concentration of formaldehyde in the material (μg/m^3); D_m was the diffusion coefficient of the VOC in the material, which was assumed to be constant (m^2/s); t was the elapsed time (s); y was the vertical coordinate from the centre to the top surface of the material (m).

3.2 EMPERICAL SURFACE ADSORPTION MODEL

The study adopted the ESAM from Pétigny et al., (2021), which was designed to model formaldehyde adsorption by active wall/ceiling materials. The ESAM approach treated sorption as instantaneous process due to its significantly faster timescale compared to mass transfer processes (Pei and Zhang, 2010; Yang et al., 2001), similar to the mechanism observed in formaldehyde chemical adsorption (Pétigny et al., 2021). The equilibrium state could be quantified by a relationship between the adsorbed mass concentration per unit surface area, denoted as M_s, and the gas-phase concentration at the interface, C_s. Testing revealed that the sorption characteristics was represented by a polynomial function (Pétigny et al., 2021), providing a robust framework to understand and model the adsorption process of Al-3,5-PDA.

$$M_s(C_s) = aC_s^2 + bC_s \tag{3}$$

where a and b were constants from the regression analysis of the M_s vs. C_s data obtained from the saturation tests conducted in the small-scale chambers.

3.3 MODEL FOR A SINGLE ZONE

An IAQ model was implemented to predict formaldehyde concentration in a single zone, extending chamber test condition until equilibrium reached, and then incorporated the results into real-life settings. The methodology employed a mass balance equation (Eq. (4)) to model formaldehyde concentration in air, assuming perfect mixing in the single zone. The equation's key principle stated that the rate of change in total formaldehyde mass was equal to the difference between external introduction and exhaust removal, adjusted for surface adsorption. Surface adsorption was considered a sink term influenced by material area and adsorption rate.

$$\mathrm{V}\frac{\partial C_{a,i}}{\partial \mathrm{t}} = \mathrm{Q}\left(C_{a,o} - C_{a,i}\right) - \sum_{1}^{N} A_i \, \mathrm{S_i} \tag{4}$$

where V was the volume of the single zone (m^3); Q was the ventilation flow rate (m^3/s); $C_{a,o}$ was the formaldehyde concentration in the inlet air which was typically equal to the outdoor air concentration in real building scenario (μg/m^3); $C_{a,i}$ was the formaldehyde concentration in the single zone (μg/m^3); A_i was the material surface area of the adsorption sink (m^2); S_i was the adsorption rate of the adsorption sink (μg/(m^2·s)); and N was the total number of adsorption sinks.

The sink term of Al-3,5-PDA was determined by the EDM and the ESAM. The adsorption rate was governed by the convective mass transfer process, which described formaldehyde transports from bulk air to the air-material interface, controlled by the convective mass transfer coefficient and concentration gradient.

$$\mathrm{S_{MOF}} = \mathrm{h_m}\left(\mathrm{C_{a,i}} - \mathrm{C_s}\right) \tag{5}$$

where, h_m was the convective mass transfer coefficient (m/s); $\mathrm{C_i}$ was the concentration of formaldehyde at the interface (μg/m^3). $\mathrm{C_s}$ was correlated to concentration of formaldehyde on the material surface, which can be derived from the EDM and the ESAM.

4. RESULTS

4.1 MODEL PARAMETER ESTIMATION AND ADSORPTION PROCESS ANALYSIS

This study focused on estimating model parameters derived from chamber test results and evaluating how different models reflected the actual adsorption process of formaldehyde onto Al-3,5-PDA. The previous findings provided baseline data for adsorption behavior under controlled conditions (Won et al., 2024). Based on these findings and our previous test data, the results (Figure 2) show that neither low and high concentration test reached Al-3,5-PDA's adsorption capacity. The increase in formaldehyde concentration within the chamber corresponded to a decrease in adsorption rate, highlighting the effect of adsorbed formaldehyde on subsequent adsorption processes.

For the EDM, parameters K_{ma} and D_m were determined through regression analysis, following a methodology outlined by (Liu et al., 2020). The results revealed that K_{ma} values for EDM under low and high concentration tests were 1.47×10^5 and 3.24×10^5 respectively, indicating a significant surface adsorption effect compared with conventional building materials. These findings aligned with the observation that adsorption primarily occurred at the surface due to chemical reactions, leading to a thin adsorbed layer with high capacity. While the D_m values showed a significant difference between the low and high concentration tests, this suggested that the assumed diffusion process did not accurately reflect the actual adsorption behavior. Furthermore, this indicated that, compared with the surface effect, in-material diffusion was not the dominant process governing formaldehyde adsorption on Al-3,5-PDA. Overall, the EDM effectively represented the chamber tests in both the adsorption and desorption phases (Figure 2).

For the ESAM, parameters M_s and C_s were calculated based on chamber test data. The results indicated that parameter a was significantly smaller than b, suggesting that the first-order adsorption-desorption model effectively described early-stage adsorption behavior (Figure 2). The equilibrium constant $K_e = M_s/C_s$ remained relatively constant over the 28-day test period, implying a steady-state condition where adsorption and desorption processes reached the dynamic equilibrium.

4.2 SIMULATION FOR SATURATION CONDITION

Due to the high costs and impracticality of conducting a one-year laboratory test, the EDM was employed to simulate formaldehyde adsorption over extended periods. The results, presented in Figure 3, demonstrated the evolution of formaldehyde concentration under two exposure conditions. Both simulations revealed that the adsorption process followed a characteristic curve where formaldehyde concentration increased over time and approached saturation. Regardless of the initial exposure level, the adsorption exhibited rapid uptake initially, followed by a slower approach towards equilibrium. The findings indicated that both low- and high-exposure concentration conditions led to saturation within approximately one year. These results validated the applicability of diffusion models for long-term predictions and provided valuable insights into practical applications without costly experimental testing. The ability to simulate extended exposure scenarios aided in assessing the long-term effectiveness of adsorptive materials.

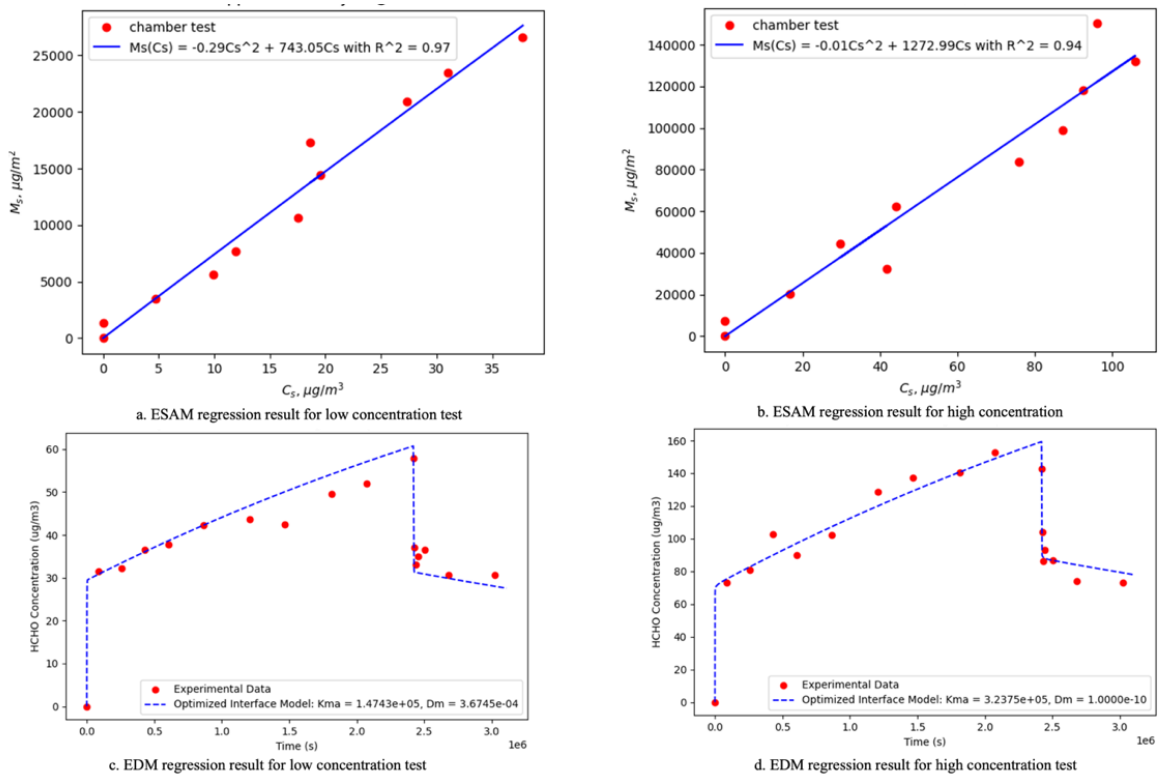


Figure 2 Regression test results of the ESAM and the EDM under low and high formaldehyde concentration tests. (a) Results for ESAM under low concentration test. (b) Results for ESAM under high concentration test. (c) Results for EDM under low concentration test. (d) Results for EDM under high concentration test.

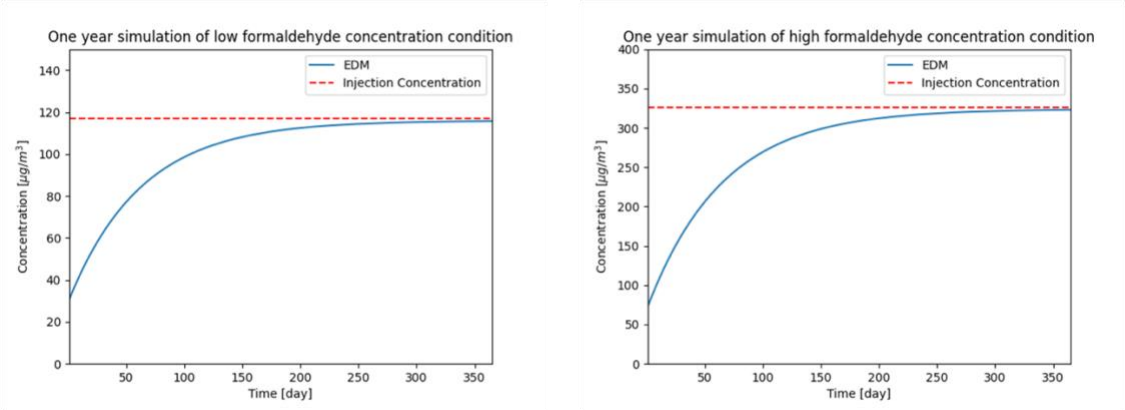
For ESAM, saturation conditions can be determined by solving a quadratic function. The highest surface concentration was achieved at this peak point. By analyzing the total amount of formaldehyde injected, the time required to reach saturation could also be estimated. For low concentrations, this time was approximately 300 days, aligning with EDM results of about one year. However, for high concentrations, ESAM suggested a much longer time of around 13 years, which conflicted with EDM findings. This discrepancy may arise from the limitations of short-term tests in accurately estimating long-term conditions over a year. Further investigation was needed to reconcile these differences and ensure accurate modeling of adsorption processes over various timescales.

4.3 SIMULATION OF Al-3,5-PDA IN A REAL-WORLD INDOOR ENVIRONMENT

This study evaluated the performance of Al-3,5-PDA as a formaldehyde adsorbent in a realistic indoor setting. The simulation replaced a 10 m² gypsum wall with the MOF wallpaper in a 30 m³ room, mimicking a typical small office space. The indoor formaldehyde concentration was set to 32 μg/m³, representing the 95th percentile of residential levels in the United States (United States Environmental Protection Agency, n.d.). Ventilation rate followed ASHRAE 62.1 standards, reflecting normal office conditions with 0.68 air change per hour. The simulation performed at 23 °C and 50% relative humidity, representing typical indoor environment condition. The results in Figure 4 indicated that Al-3,5-PDA effectively reduced formaldehyde levels over time through adsorption. Equilibrium was reached at approximately 150 days, demonstrating Al-3,5-PDA's capacity for sustained formaldehyde mitigation in indoor environments. These findings

highlighted the potential of Al-3,5-PDA as an alternative of conventional gypsum walls, offering a passive and efficient solution for enhancing indoor air quality. The simulation supported the feasibility of using Al-3,5-PDA based materials in real-world applications where extended control of formaldehyde was desired.



a. Simulation results of EDM for one year under low exposure concentration

b. Simulation results of EDM for one year under high exposure concentration

Figure 3 One-year simulation by EDM of formaldehyde adsorption under low and high concentration

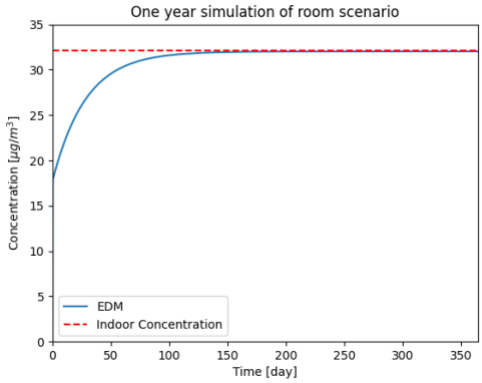


Figure 4 One-year simulation of formaldehyde adsorption in a room scenario

5. CONCLUSION

This study demonstrates the effectiveness of a multi-model approach in enhancing our understanding of adsorption behavior and highlighted the importance of validating models under varied conditions to ensure their reliability in real-world applications. The analysis showed the strengths and limitations of each model. The ESAM, which relied on second-order adsorption characteristic derived from small-scale chamber tests, provided practical predictions for short-term adsorption. However, its reliance on empirical data may lead to inaccurate estimation in longer durations. The EDM, a physics-based approach, offered more generalizable predictions by incorporating mass transport limitations. It was well-suited for capturing complex interactions under conditions beyond those tested in controlled environments, making it more reliable for long-term forecasting. The findings underscored the importance of combining empirical and physics-based models to enhance predictive accuracy and material assessment. It was crucial to ensure reliable results in real-world applications where conditions could vary widely.

This research presented the potential of Al-3,5-PDA (or MOF-303) as an effective adsorbent for

improving indoor air quality. It emphasized the need for comprehensive testing and model validation to ensure accurate predictions. Future studies should focus on scalability, long-term durability, and performance under dynamic environmental conditions to further refine modeling approaches and optimize material implementation in diverse settings.

ACKNOWLEDGEMENTS

SUMMARY
This study investigates how exhaust hoods and natural ventilation openings contribute to the removal of cooking pollutants and the improvement of indoor air quality in typical Taiwanese kitchens. Using a validated Computational Fluid Dynamics (CFD) model, various scenarios were simulated, including three common kitchen layouts, the effects of opening the front or back doors, and the operation of the exhaust hood. The aim was to evaluate how these different configurations influence indoor air quality during kitchen. The results indicate that different kitchen layouts may slightly impact removal efficiency. Overall, the level of remaining particulate matter is primarily influenced by natural ventilation openings. Layouts which the direction of the two doors is horizontal to the stove direction effectively remove cooking pollutants during the cooking process. It is crucial to minimize disturbances caused by natural ventilation during cooking.

Keywords: Indoor Air Quality, Computational Fluid Dynamic, Kitchen Hood, Natural Ventilation Openings

1. INTRODUCTION

Cooking is a major contributor to the release of volatile compounds and pollutants (Spengler et al., 1983). Without proper ventilation, pollutant levels can rise significantly (Kang et al., 2019). Several studies has shown that using an exhaust hood can effectively reduce the amount of air pollutants produced during cooking (Sun et al., 2021; Lunden et al., 2015; Rim et al., 2012). In most cases, natural make-up air is often used to compensate for air when exhaust hoods are running. This air typically enters through windows and doors. Research has indicated that adequate natural make-up air in the kitchen during cooking can effectively lower pollutant concentrations, though too much ventilation may cause pollutants to spread to adjacent rooms (Liu et al., 2021). This highlights the importance of assessing and analysing indoor airflow and ventilation. However, the impact of kitchen layouts and ventilation openings on indoor air quality has not been thoroughly discussed. This study is using computational fluid dynamics tools to examine how the use of kitchen hoods and ventilation openings affects indoor air quality during cooking. This analysis aims to provide researchers with a deeper understanding of the risks of human exposure to harmful particles and the influence of natural make-up air on indoor air quality.

2. METHODOLOGY

CFD simulations were conducted using ANSYS Fluent (2021 R1) to analyze airflow, heat transfer, and particle motion under transient conditions. The RNG k-ε model was used for turbulence due to its suitability for interior airflow prediction (Eom et al., 2023). Radiation was

modeled with the Discrete Ordinates (DO) model, and particles with the Discrete Phase Model (DPM). For further model details, refer to the ANSYS Fluent user guide.

2.1. CFD model

Figure 1 presents three typical Taiwanese residential kitchen configurations (3.10 m × 2.37 m × 2.27 m), with two doors serving as natural make-up air openings. Case H aligns the doors horizontally with the stove, Case V aligns them vertically, and Case C places them at a cross angle. All kitchen elements were precisely measured and incorporated, with material properties carefully defined. The model includes a stove with heating plates, an exhaust hood with two outlets, and a human model (1.80 m tall) positioned 25 cm from the stove to simulate cooking. Minor structures like small items, pipelines, and wires were simplified to enhance efficiency and improve spatial analysis. Table 1 outlines the boundary conditions for openings, heat sources, and walls. Further model details can be found in Chen et al. (2025).

2.2. Case description

This study investigated the effect of natural air openings and the exhaust hood on indoor air quality in a kitchen by comparing simulation results of different scenarios. The evaluation was based on calculating the mass of suspended particulate matter over a fixed 615 seconds transient simulation. Nine cases were analysed to assess differences in pollutant residue levels in the kitchen during cooking, considering the exhaust hood was used and whether the front and back doors were open. Table 1 summarizes the details of the boundary conditions for both open and closed conditions. Table 2 provides detailed information on the simulation cases. In all cases, cooking was performed using a user-defined heat source from 0 to 615 seconds, as shown in Figure 6. During this period, the exhaust hood was in operation, and the front door was open while the back door remained closed, consistent with the validation case.

Table 1. Boundary conditions.

Name	Type	Description
Exhaust hood	Velocity	2.3 m/s
Heat source	Wall / Temperature	20℃ ~ 220℃ (Details in Figure 1 (d))
	Particle / DPM	Diameter: $2.0*10^{-7}$ m Temperature: 220℃ Velocity: 0.1 m/s
Front door	Pressure-inlet for natural ventilation	0 Pa
	Wall / Convection for closing	22.0 ℃
Back door	Pressure-inlet for open conditions	0 Pa
	Wall /Convection for closed condition	16.0 ℃
Window	Wall /Convection	16.0 ℃
Indoor wall	Wall / Convection	22.0 ℃
Outdoor wall	Wall /Convection	16.0 ℃
Human	Wall	36.5 ℃

Table 2. Detailed information about the simulation cases.

Case	0 ~ 615s	
	Front Door	Back Door
Case H1/V1/C1	Close	Open
Case H2/V2/C2	Open	Close
Case H3/V3/C3	Open	Open

3. RESULTS AND DISCUSSIONS

In this study, we simulated 9 cases: three kitchen layouts with three doors situations. Figure 2 shows the mass accumulation proportion of particles during cooking process. The mass accumulation proportion (%) is calculated by taking the highest accumulated particle mass during cooking process as 100%.

3.1. Impact of kitchen layout and natural air openings

Comparing the 9 cases, it can be observed that CaseH, the direction of the two doors is horizontal to the stove, effectively removes cooking pollutants during the cooking process. The mass accumulation proportion of particles in the domain remains below 10%. On the other hand, the CaseV kitchen layout, the direction of the two doors is vertical to the stove, results in poor exhaust efficiency. This is likely due to the airflow path between the two doors being closer to the stove. The airflow significantly affects the particle expulsion efficiency.

Overall, excessive natural ventilation during cooking does not necessarily lead to better pollutant expulsion efficiency, as can be clearly seen in Case V3 and C3. The possible reason is that excessive airflow can interfere with the path of pollutant expulsion from the stove to the exhaust hood, leading to the occurrence of air mixing due to excessive natural ventilation. In addition, if the temperature of the natural ventilation is lower, as seen in Case V1 and C1, it can also result in a reduced pollutant expulsion efficiency from the exhaust hood.

3.2. Limitations

The simulation results have certain limitations. Our study highlights that incoming air directly affects pollutant distribution. We modelled the inlet as a pressure inlet without wind speed, but natural ventilation can be influenced by outdoor wind, which should be considered. Additionally, the presence of individuals alters airflow and pollutant dispersion based on their position and height. Food ingredients also vary, producing different pollutants that affect their spread. These factors should be accounted for in future simulations.

4. CONCLUSION

This study examined the impact of kitchen layouts and natural ventilation openings on indoor air quality using CFD simulations. The results indicate that while kitchen layout influences pollutant removal efficiency, natural ventilation plays a more significant role in determining air quality during cooking. Specifically, configurations where doors align horizontally with the stove enhance pollutant removal, whereas excessive ventilation can disrupt airflow, reducing exhaust efficiency. The findings emphasize the need for a balanced ventilation strategy—ensuring sufficient fresh air intake while minimizing disturbances that may hinder pollutant expulsion. Future studies should incorporate factors such as wind effects on natural ventilation, variations in pollutant characteristics from different cooking methods, and the influence of human presence on airflow dynamics to enhance simulation accuracy and practical applicability.
