SUMMARY
In terms of epidemic prevention and control, although biomedical means are crucial to combating the epidemic, they can only serve as a second line of defense due to their late appearance. Engineering controls are more timely and preventative, but these tools are imperfect, as the protracted COVID-19 pandemic has shown. Source control is always more effective than the recipient and pathway control based on the control hierarchy. Preventing the particles exhaled by infected persons from contaminating the environment plays a crucial role in breaking the chain of transmission of viral aerosols. This study aims to develop a personal breath-responsive breath-taking hood (BR-BTH) to efficiently capture exhaled particles without burdening the wearer's breath.

Keywords: suction hood, source control, capture efficiency, negative pressure.

GENERAL INSTRUCTIONS

The coronavirus spreads like a forest fire. It won't end until the entire forest burns down naturally. Current approaches to combating airborne diseases can be divided into biomedical and engineering tools. Biomedical tools often have belated flaws despite their critical role in fighting viruses. Thus, they can only be used as a second line of defense. For example, mRNA vaccines took most manufacturers over ten months to develop and were used under Emergency Use Authorization (EUA) during the COVID-19 pandemic. Infection control and prevention experts tend to focus only on vaccines. Vaccines are critical in combating infectious airborne microorganisms, but vaccines alone cannot stop the spread of disease.

On the other hand, engineering control tools are more readily available and, therefore, more preventative, making them ideal for frontline defense. However, the combination of biomedical and engineering tools still failed to stop the spread of the virus, suggesting that the two tools combined are still not enough. Therefore, we need new engineering control tools, such as fire extinguishers, to snuff out sparks or small fires to prevent them from spreading and getting out of control. This study aims to develop a source control device called a Breath-Taking Hood (BTH) for infected persons to capture all exhaled aerosol particles and prevent them from contaminating the environment.

METHODS

The BTH consisted of a capture hood with a shield connected via a flexible connecting tube to a filter unit connected to a battery-operated extractor fan, as shown in Figure 1. The filter, fan, and

battery were designed to attach to the waist belt for comfort. The main body of the capture hood consisted of a triangular curved groove (TCG) connecting to a shield, a particle mixing reducer, and a strip. A 3D drafting software and a 3D printer were used to fabricate the hood. The

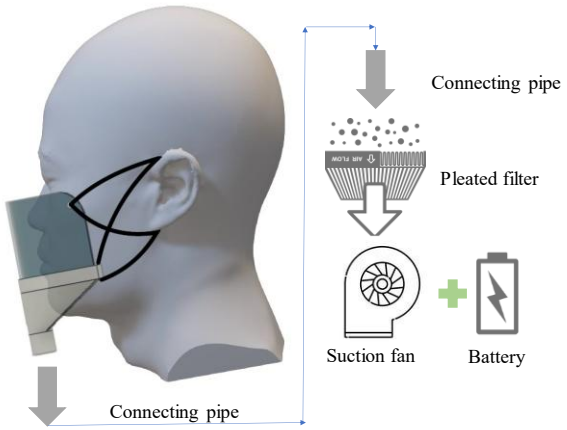

Figure 1. Schematic diagram of wearing a breath-taking hood.

shielding sheet was made of polycarbonate (PC) film. Polyurethane (PU) foams with different porosity and thickness were used as particle mixing reducers, and elastic adjustable cotton threads were used as ear or head strips.

Structural parameters were optimized based on capture efficiency as a function of suction flow rate. The capture Efficiency testing system consisted mainly of a clean air generation system, an exhaled particle generation system, an air extraction device, and a particle measurement instrument. The test chamber dimensions were 60 x 60 x 136.5 cm, and the BTH was worn on a manikin and tested inside the chamber. The aerosol testing chamber was slightly pressurized to prevent external particle contamination. The filtered air with an aerosol number concentration of less than 0.01 #/cm^3 was used to purge the aerosol chamber to minimize the measurement noise. Ultra-clean air was necessary to achieve 99.99% capture efficiency with reasonable accuracy and precision. The flow rate supplied to the chamber also varied to study the effect of approaching velocity on BTH capture efficiency. A nebulizer was used to generate sub-micrometer-sized oil droplets (di-ethylhexyl sebacate, DEHS) to simulate exhaled particles with the count medium diameter around 0.3 μm.

Challenge aerosols were generated using a fixed cyclic breathing flow (15 L/min) of different breathing patterns and the constant suction flow rate of 23.6 L/min, which was the peak flow of the cyclic breathing patterns, to study the effects of respiratory flow and breathing patterns on capture efficiency. A condensation particle counter was used to measure the concentration at the chamber outlet. The capture efficiency was determined by taking the ratio of aerosol concentrations when the suction fan was turned on and off. The target capture efficiency was set at 99.99%.

RESULTS / DISCUSSION

The optimal height, width, and thickness of BTH were 3, 10, and 2 cm, respectively. BTH capture efficiency increased with increasing suction flow rate. The opening area between the top edge of the BTH and the wearer's face significantly affected the suction flow required to achieve 99.99%

capture efficiency. The fixed inspiratory flow rate of 40 L/min applied only when the average respiratory rate was less than 15 L/min and the slot opening area was not greater than 20 cm^2. The PU foam filters, as mixing reducers, effectively reduced the escaping aerosols and the required suction flow rate. The use of foam filter also helped fix the opening area.

The cross-sectional area between the top edge of the hood and the wearer's face was critical to capture efficiency and greatly affected the required suction flow rate. However, as shown in Figure 2, the cross-sectional area varied and was difficult to control. Another disadvantage of the invention was that the connecting tube between the hood and the suction fan and filter unit might disturb the wearer's daily operation unless the tube was tightly secured to the clothing.

Figure 2. Schematic diagram of a human body wearing a BTH.

CONCLUSIONS AND RECOMMENDATIONS

Overall, this constant suction BTH is comfortable to wear has high capture efficiency and can prevent exhaled particles from polluting the environment. High respiratory flows require increased inspiratory flow to maintain high capture efficiency. In this case, a larger fan, battery, and filter are needed to maintain adequate negative pressure in the hood during exhalation.

To further improve the performance of this new device, we propose to attach the filter, fan, auto-feedback control unit, and battery directly to the mask, making it look like a regular elastomeric half-mask respirator. Its appearance resembles commercially available breath-responsive powered air-purifying respirators, but the exhalation valve and inhalation fan directions are reversed. After such adjustment, the suction mask should be able to maintain a slight negative pressure during the breathing cycle. The breath-responsive BTH is designed to hold a slight negative pressure within the hood and is still under development.

International and national health authorities responsible for infection prevention and control have not learned enough lessons from past COVID-19 outbreaks and continue to rely too much on biomedical tools while neglecting the importance and necessity of engineering control tools. Medical students need to learn more about aerosol science and technology. The infection control and prevention course syllabus should include the basic knowledge of aerosol generation mechanisms, aerosol size dependency, aerosol transmission characteristics, and aerosol removal principles to eliminate the knowledge gaps and control strategy differences during the recent epidemic.

Source control is the most effective approach compared to receptor and pathway control measures. Personal BTH can play a role in stopping the spread of an outbreak in its early stages,

just like a fire extinguisher puts out a small fire. If education and training programs are well promoted and implemented, this novel source control device could make quarantines and lockdowns meaningless and redundant.

How CO_2 concentration and window opening in classrooms of elementary/secondary schools changed during COVID-19 pandemic period in Tokyo, based on governmental hygienic inspection data

Go Iwashita [1]

[1]*Department of Architecture, Tokyo City University, Tokyo, Japan, iwashita@tcu.ac.jp*

SUMMARY
The time series changes in air environment during winter and summer periods in elementary/secondary schools located in Tokyo was analysed by using the local governmental hygienic inspection data. The period of analysis was set from 2007 to 2021.
1) Before the coronavirus outbreak in 2020, the 50th percentile of indoor CO2 concentration in elementary school classrooms was below 1000ppm, while the 95th percentile was around 2000 to 2500ppm, which exceeded the school environmental hygiene standard of 1500ppm. During and after the coronavirus pandemic that occurred in 2020, the 95th percentile value decreased to below 1,500 ppm.
2) Before 2019, the 50th percentile of indoor CO_2 concentration in secondary school classrooms during the winter and summer was between 1000 and 1500ppm, while the 95th percentile was approximately 2500ppm. During and after the coronavirus pandemic in 2020, the 95th percentile of CO_2 decreased to below 1500ppm in secondary school as well.

Keywords: school classroom, CO_2 concentration, coronavirus outbreak

1. 1. INTRODUCTION

In Japan, based on the ``School Health and Safety Act'', environmental health inspections are required to be conducted regularly in school classrooms. Most of the regular inspections are conducted by school pharmacists. The School Health and Safety Act (Ministry of Education, Culture, Sports, Science and Technology, 2018) requires a school principal to take necessary measures to improve each school's environmental health problems based on the school environmental hygiene standards, or otherwise to report on the situation to the local officer in charge of the school management so that the problem can be dealt with. When considering control measures for the indoor air quality in classrooms, such as measures against influenza and COVID-19 infections, it is important to understand the actual situation of the air environment in school classrooms. Therefore, it is useful to obtain and analyse each school's environmental health inspection results mentioned above. However, the inspection results are not made public except by some local governments, making it difficult for the general public to know actual situations of each school's environmental hygiene.
As the COVID-19 infection gradually spread across the country, public elementary and secondary schools in X City started to cancel classes in March 2020, and the school closure continued for three months. In this study, we will examine the impact of new coronavirus infection control measures on the school air environment based on the ``School Environmental Hygiene Inspection Report of X city'', which is a survey of all schools in X city, rather than the limited measurement school studies mentioned above.

2. METHOS

2.1 Survey target area and survey year

The survey target area is X city in the Tokyo metropolitan area. In school year of 2021, there were 62 public elementary schools and 28 public secondary schools in X city. Classrooms in public elementary and secondary schools in X city are equipped with heat pump air conditioner. Since the report on X city used in this study did not mention the installation and operation status of ventilation equipment at the time of inspection, the influence of mechanical ventilation equipment is not considered in the analysis. The survey had been conducted for a period of 15 years from 2007 to 2021. However, the inspection was not conducted in 2013, thus the data only covers 14 years. From 2007 to 2009, school pharmacists of each school conducted an inspection of CO_2 concentration, air temperature, and relative humidity in classrooms once a year during winter. A school principal designated two measurement classrooms in each target school, and school pharmacists conducted measurements in the classrooms. From 2010 to 2021, measurements were conducted once during the summer and once during the winter, and just one classroom was surveyed for each school. Summer inspections were conducted from June to September, while winter inspections were conducted from December to February.

2.2 Inspection method

The classroom air inspection procedures for CO_2 concentration, air temperature, and relative humidity performed by school pharmacists are as follows:

(1) Air sampling 5 to 15 minutes after a class starts
(2) Air sampling 15 to 25 minutes after a class starts
(3) Air sampling 30 to 40 minutes after a class starts

Test items were measured also in the adjacent corridor before or after the measurements in the classrooms (1) to (3), while the outside air temperature was taken with the outside air. In addition to the above inspection items, the following items were measured: number of teachers, number of students, number of inspectors, operating status of cooling/heating equipment, opening status of exterior window, corridor-side door, and corridor-side transom, and so forth.

3. Results

3.1 Winter CO_2 measurement results

Figure 1 shows the time series changes in CO_2 concentration in all measured elementary school classrooms during winter inspections from 2007 to 2021. Figure 1 shows the CO_2 concentration in the 95th percentile, 75th percentile, and 50th percentile for each year in approximately 60 public elementary schools in X city. The numbers shown above the upper abscissa are the numbers of measurement data for each year. The CO_2 concentration used in this figure was the result of air sampling data measured 30 to 40 minutes after a class starts. It can be seen that the CO_2 concentration has decreased significantly since 2020, when COVID-19 infections spread nationwide. There is a significant difference in the CO_2 concentration between a period of two years before the COVID-19 (2018, 2019) and a period of two years during the COVID-19 spread (2020, 2021) ($p<0.0001$).

Figure 2 shows the time series changes in CO_2 concentration in the secondary school classrooms during winter inspections from 2007 to 2021. It shows the CO_2 concentration in the 95th percentile, 75th percentile, and 50th percentile for each year in approximately 30 public secondary schools in X city. As seen in Figure 1, it can be found that the CO_2 concentration has also decreased significantly in secondary schools after 2020, when COVID-19 infections spread. There

is a significant difference in the CO_2 concentration between before and after the COVID-19 pandemic ($p<0.0001$).

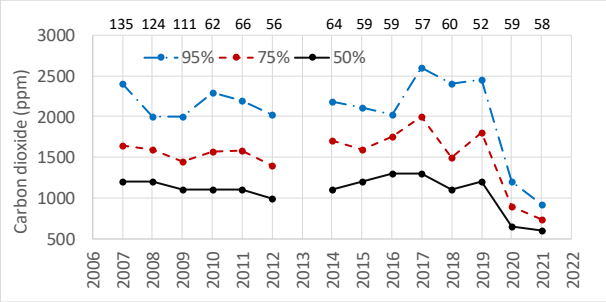

Figure 1. CO_2 concentration in the elementary school classrooms during winter inspections from 2007 to 2021. (CO_2 concentration in the 95th percentile, 75th percentile, and 50th percentile of winter measurements for each year)

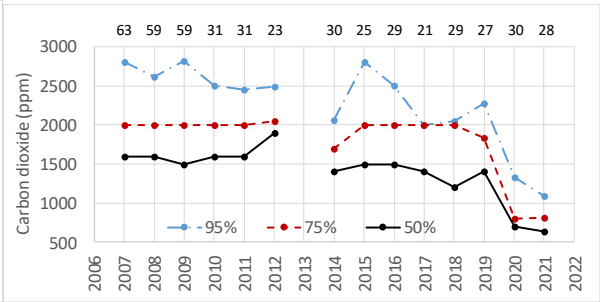

Figure 2. CO_2 concentration in the secondary school classrooms during winter inspections from 2007 to 2021. (CO_2 concentration in the 95th percentile, 75th percentile, and 50th percentile of winter measurements for each year)

3.2 Changes over time in the opening length while windows and doors are remaining open

In the school air inspection conducted for this study, opening length while classroom windows, transom windows and doors were remaining open was recorded when measuring CO_2 concentration, temperature, humidity, etc. The windows, transom windows, and doors in the target elementary and secondary school classrooms in X city are mainly sliding type, so the degree of opening of the windows and doors is recorded in centimetres (cm). The types of opening sections include exterior windows, exterior transom windows, corridor-side doors, and corridor-side transom windows.

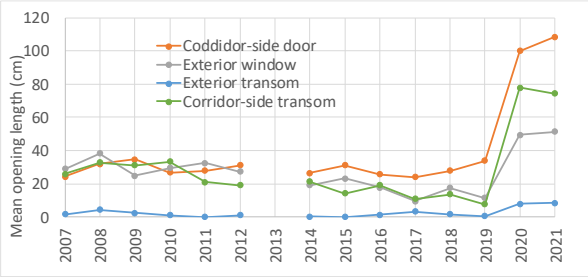

Figure 3 Mean opening length of the elementary school classrooms during winter inspections from 2007 to 2021

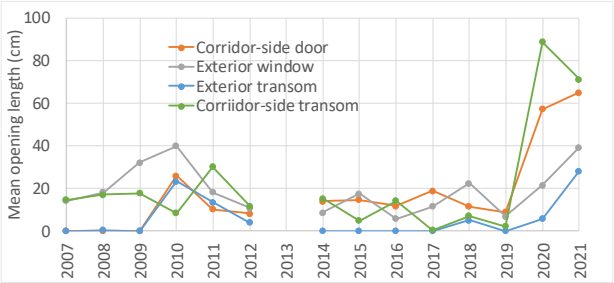

Figure 4 Mean opening length of the secondary school classrooms during winter inspections from 2007 to 2021

Figures 3 and 4 show the changes over time in the average opening length of each opening section observed in elementary school classrooms and secondary school classrooms, respectively, in the winter inspection. Before the COVID-19 outbreak in 2020, all opening sections in the elementary and secondary schools remained open with short length during the winter, while the exterior transoms were usually closed. Apparently, this was due to a risk prevention for falling from open windows, and difficulty of opening the windows. After 2020, the opening length of all opening sections has increased, especially, the corridor-side doors and corridor-side transoms were kept open more widely. On the other hand, the opening length of the exterior transoms in elementary school classrooms did not increase much even during the COVID-19 period.

4. DISCUSSION

When schools reopened during the coronavirus pandemic in June of 2020, the Ministry of Education, Culture, Sports, Science and Technology (MEXT) made a request that each school make sure to maintain an adequate ventilation rate to avoid closed spaces. For elementary and secondary school teachers who are not experts in HVAC, it was not obvious whether their school buildings had mechanical ventilation equipment or not, and even if the buildings were equipped with adequate ventilation system, they were not certain about the capabilities of the equipment. Therefore, it was assumed that they should always keep the windows open for cross ventilation even if their school buildings had mechanical ventilation. In addition, the above-mentioned request by MEXT required thorough ventilation even during the period when air conditioner was operated, therefore, it was thought the ventilation by opening the windows was used while operating air conditioner during heating or cooling period. During the COVID-19 pandemic, there is a risk that heating will become less efficient and room temperature will drop due to the windows being open to heat the room.

5. CONCLUSION

Using the air inspection results from the school environmental hygiene survey in X city, a local government in the Tokyo metropolitan area, we investigated changes over time in CO_2 concentration, room temperature, and openings. As a result, the following findings were obtained.

1) Before the coronavirus outbreak in 2020, the 50th percentile of indoor CO_2 concentration in elementary school classrooms during winter was below 1000ppm, while the 95th percentile was around 2000 to 2500ppm, which exceeded the school environmental hygiene standard of 1500ppm. During and after the coronavirus pandemic in 2020, the 95th percentile value decreased to below 1,500 ppm.

2) Before 2019, the 50th percentile of indoor CO_2 concentration in secondary school classrooms during winter was between 1000 and 1500ppm, while the 95th percentile was approximately 2500ppm. During and after the coronavirus pandemic in 2020, even the 95th percentile of CO_2 has been below 1500ppm.

3) The decrease in CO_2 concentrations during the COVID-19 pandemic was probably due mainly to ventilation through open windows and doors.

4) On the other hand, consideration must be given to the deterioration of the thermal environment due to reduced heating and cooling efficiency caused by opening windows for ventilation.

Inversion identification of heavy gas source strength and dispersion in enclosed workplaces based on a three-dimensional computational fluid dynamics and iterative ensemble Kalman filter model

Shasha Wang [1], Xing Zheng [1], S. Thomas Ng [1]

[1] *Department of Architecture and Civil Engineering, City University of Hong Kong, Kowloon Tong, Hong Kong, China.*

SUMMARY
In the early stages of gas leak accidents, accurately estimating the source strength is crucial for formulating effective rescue strategies. However, CFD modeling methods typically provide reasonable concentration predictions when source information is known. This paper proposes a model that integrates three-dimensional (3D) computational fluid dynamics (CFD) with iterative ensemble Kalman Filtering (IEnKF) to identify the strength and dispersion of heavy gas sources in enclosed workplaces. The developed model can iteratively correct uncertainties of input parameters using limited observational data and then enable accurate estimation of source information. For the case study of hydrogen sulfide (H_2S) leakage in a confined space, the proposed CFD-based IEnKF model can provide reasonable estimates of the H_2S leakage velocity, fresh air supply velocity, and concentration distribution after only two assimilation time steps. The results provide valuable insights for consequence assessment and emergency response in indoor pollutant leakage incidents.

Keywords: Inversion identification, Heavy gas leakage, Iterative ensemble Kalman filter.

1. INTRODUCTION

Indoor environments are crucial for human safety, especially in spaces like biochemical labs, which are at high risk of toxic gas leakage. Most toxic gases have a higher molecular weight than air and are classified as heavy or dense gases. These gases tend to accumulate near the ground or in occupied areas, posing a significant threat to human health. Therefore, accurately predicting the leakage of toxic heavy gases in enclosed workspaces is essential for human safety and effective consequence assessment.

Various studies have investigated the leakage and dispersion behaviours of heavy gases in indoor environments using field experiments, wind tunnel experiments, mathematical and CFD models(Han et al., 2020; Wang et al., 2013). These studies generally focus on forward modeling with known source parameters. However, in most leakage incidents, unknown source parameters present huge challenges. Data assimilation techniques, such as ensemble Kalman Filter (EnKF) and its iterative version (IEnKF), are effective for addressing this issue by using observational data to correct initial uncertainties of input parameters.

Table 1 provides a non-exhaustive overview of EnKF/IEnKF studies on source parameter estimation in various fields. Records were retrieved from Web of Science and Scopus for the period 2000 – 2024 using the query ("Ensemble Kalman Filter" OR "Iterative EnKF") AND ("source

term" OR "source parameter" OR "source inversion"). After retrieval, papers were screened manually by title, abstract and conclusions to exclude irrelevant works; only English-language publications were retained. Owing to space limitations, Table 1 discusses the most pertinent contributions. Key findings include: (1) EnKF is the commonly used method for estimate source parameter, with limited use of IEnKF. (2) While EnKF/IEnKF has been applied across various fields, studies on the inversion of indoor source parameters remain limited. (3) Most studies use simplified dispersion models, with only a few employing complex 3D CFD models. (4) Twin experiments are the most common validation method, with some studies also using field tracer experiments.

This study aims to propose a 3D CFD-IEnKF model for the inversion and identification of heavy gas source strength and dispersion in enclosed workspaces to fill the above gap. The reliability of the proposed model is evaluated through a case study of H_2S leakage in an enclosed workspace.

2. METHODS

Firstly, a 3D CFD model is developed and validated through grid independence analysis and comparison with existing experimental data. This CFD model is then integrated with the Iterative Ensemble Kalman Filtering (IEnKF) method to estimate the H_2S leakage velocity, air supply velocity, and predict the concentration distribution in enclosed workspaces. To assess the

reliability of the proposed model, the twin experiment approach is employed, which involving comparing three sets: the control set, where assumed true values are used as inputs and serve as the ground truth; the data assimilation (DA) set, where initial guess distributions are corrected using the IEnKF method; and the reference set, where initial guess distributions are applied without IEnKF correction. Due to space limitations, only a concise overview of the methodology is presented here. For a detailed description of the methodology, see (Wang et al., 2024).

3. RESULTS & DISCUSSION

The proposed model provides time-series estimations of the H_2S leakage velocity and air supply velocity, as shown in Fig. 1. (a) and (b). The results demonstrate that accurate estimates can be obtained after only two assimilation time steps (2 s): the estimated H_2S leakage velocity (18.2 m/s) has a relative error of less than 7.06% compared to the assumed true value (17 m/s); the estimated air supply velocity (0.89 m/s) has a relative error of less than 11.25% compared to the assumed true value (0.8 m/s). After 13 assimilation steps, the estimated H_2S leakage velocity (17.2 m/s) is nearly identical to the assumed true value.

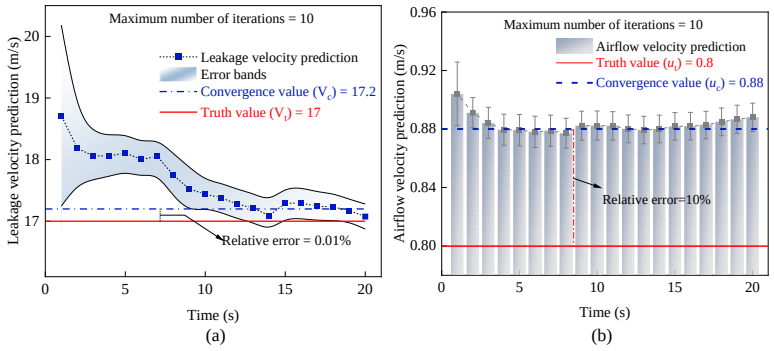

Figure 1. Time-series estimations of (a) H_2S leakage velocity and (b) air supply velocity.

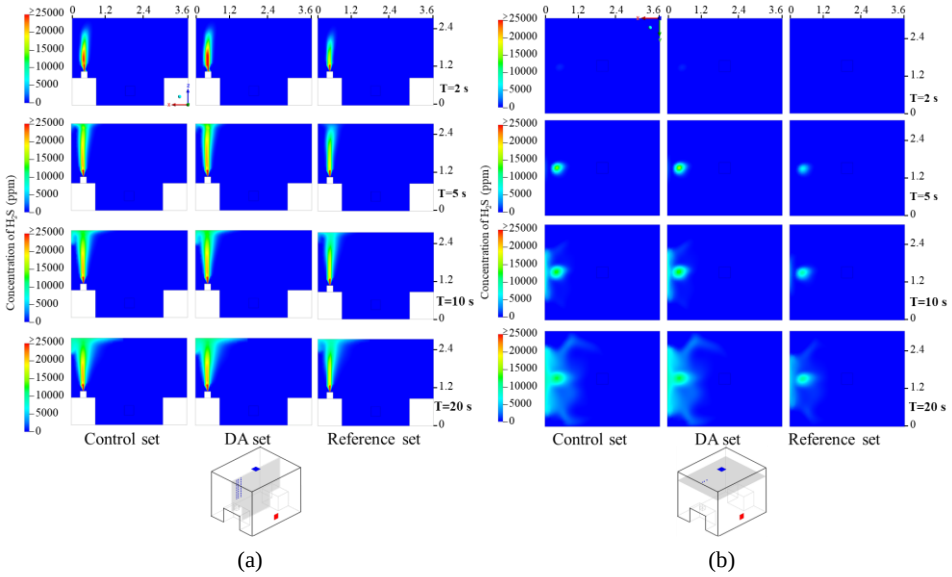

Figure 2. Gas concentration distribution at (a) Y = 1.5 m plane; (b) Z = 2.5 m plane.

4. CONCLUSION

In this study, a 3D CFD-IEnKF coupled model was developed to enable the rapid and accurate estimation of indoor heavy gas leakage source parameters and provide detailed predictions of concentration distributions. The reliability of the proposed model was validated through a case study of H_2S leakage in an enclosed workspace using the twin experiment method. This model can be effectively applied in the initial stages of indoor leakage incidents to offer managers timely feedback on leakage source information and provide valuable guidance for emergency response.

SUMMARY
Emerging respiratory infectious disease agents, like SARS-CoV-2 and influenza, have significantly impacted public health and the provision of medical services. Dental environments have been widely regarded as one of the most vulnerable healthcare facilities owing to the continued ejection of contaminated droplets and aerosol particles in the atomization procedures. The present study aims to combine the Particle Image Velocity measurement and fast Large-eddy Simulation to assess dental spray dynamics, further evaluating the particle removal performance of high-volume suction (HVS). The results are analysed from the contamination areas and fallow time. The dental droplets with a diameter threshold of $72.6\,\mu m$ can escape from the spray core region under the air entrainment, along with two distinctive final fates: suspension and deposition. The placement location of the HVS at the different spray regions can directly affect the particle removal efficiency, fluctuating at around 60%. The average residence time for the dehydrated droplet nuclei and aerosol can be achieved in 6 min. Entering the surgery room early without waiting for fallow time can induce a high exposure index. The results can thus provide suggestions for updating dental guidelines and better prevention for the next respiratory infectious disease, "Disease X" in medical environments.

Keywords: Dental spray dynamics, Particle Image Velocimetry, Large-eddy simulation, Droplet.

1. GENERAL INSTRUCTIONS

Understanding the interaction between humans and the environment, particularly about fluid flow and disease transmission, has long been a focus of research (Prather et al., 2020). Among healthcare facilities, dental clinics are widely regarded as some of the most vulnerable environments. During dental procedures, a contaminated liquid mixture, including mucosalivary fluid and microbiomes, can be aerosolized. Once dental professionals and patients inhale the pathogen-carrying particles, the transmission of infectious diseases would occur. The suspended particles have already instilled fear and uncertainty about cross-infection in healthcare facilities, posing significant threats to the provision of medical services. Investigating the dynamics of dental spray is crucial for creating healthier and cleaner future environments, especially given the aging patient population in urban areas (Guida et al., 2021).

During the COVID-19 pandemic, various mitigation measures and equipment have been developed to reduce human exposure to suspended aerosols. Compared to other engineering control methods, source-control measures can directly reduce the generation and ejection of contaminated droplets. Recent studies have evaluated the particle removal performance of high-volume suction (HVS) systems and air cleaners (Li et al., 2021a). They indicated that this equipment only removes the vortices at the spray surroundings and the ambient small droplets. Due to the limited research on the structures and dynamics of dental sprays, the mitigation measures have not been effectively developed to meet targeted objectives. The advances in computational resources and the development of high-speed cameras promote the investigation of the droplet aerosolization and transmission process. A recent study experimentally captured the formation of multi-phase turbulent clouds during human coughs (Bourouiba et al., 2020). From the Particle Image Velocimetry (PIV) investigation, clusters of larger droplets swirling within the clouds could be transported for 1-2 meters. Additionally, Direct Numerical Simulation (DNS) and Large Eddy Simulation (LES) can provide more comprehensive insights into the flow and development of droplet clouds. However, there is limited research focused on specific dental surgery environments due to the challenges in accurately characterizing droplet properties in these settings.

The present study aims to integrate PIV measurements with LES techniques to gain a new insight into the dental spray structures and dynamics. The findings are expected to update the dental guidelines and enhance prevention strategies for future respiratory infectious diseases in medical environments. The second section of this study introduces the experimental and numerical methods. The third section shows the results and discussion.

2. METHODOLOGY

Figure 1 presents a schematic figure combining the Particle Image Velocimetry (PIV) measurement and large eddy simulation techniques. The ultrasonic scaling, high-speed drilling, and 3-in-1 spraying are conducted on the manikin model, and the ejected droplets can be illuminated by the laser light sheet (Figure 1a). The dental spray core region can be further determined by the angle (red dashed line shown in Figure 1b), which covers the vast majority of ejected droplets. The droplet characteristics, including size range: 5−250 μm; velocity: 2.5 m/s, and distribution angle: 30 degrees, could be obtained from the recorded image sequence analysis by the Image J software. The measured geometric diameter was in line with the aerodynamic diameter (Li et al., 2024), since the density of dental-emitted droplets was also kept at 1 g/cm^3. The computational domain is designed to include two dental professionals and one patient. The droplet characteristics identified in the PIV experiment are used as boundary conditions for the LES modeling. This approach allows for to determination of the spatial distribution of contaminated droplets, the contamination caused by deposition, and the residence time of suspended particles in surgical environments. Detailed descriptions of the experimental and numerical methods are available in our previous studies (Li et al., 2021b; Li et al., 2023a; Li et al., 2023b).

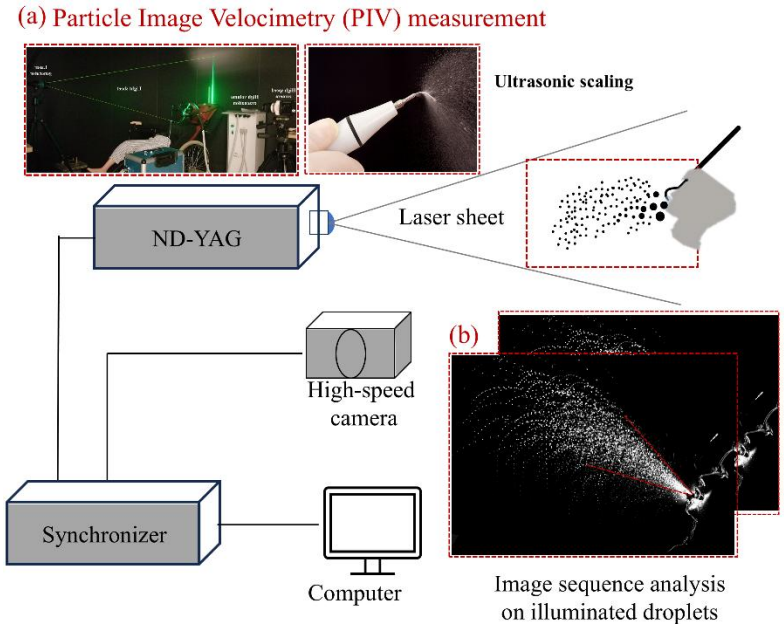

Figure 1. Schematic diagram of the assessment on dental spray dynamics: (a) the Particle Image Velocimetry (PIV) measurement on the illuminated droplets; (b) the droplet characteristics identified in image sequence analysis further serve as boundary conditions for fast large-eddy simulation.

2.1. Particle Image Velocimetry (PIV) Measurement

The PIV measurements and dental atomization procedures were carried out in the experimental chamber at the Hong Kong Polytechnic University. A thermal manikin, featuring 24 individually controlled body segments, was positioned on the dental chair. The surface area and sitting body height of the manikin were $1.6\,m^2$ and $1.35\,m$, respectively. A laser light sheet was projected across the dental treatment area, with a high-speed camera positioned perpendicularly to capture the interaction. Synchronization between the high-speed camera and the laser generator ensured precise timing. The captured image sequences were initially analysed using an adaptive PIV algorithm to determine droplet velocity patterns. Subsequently, Image J software was utilized to assess droplet size distribution and identify the core of the dental spray. Further analysis details can be found in our previous study (Li et al., 2021b). Overall, the dental-contaminated droplets are generally located in the range from $5-250\,\mu m$, while the velocity fluctuates at around $2.5\,m/s$. The droplet composition model can be regarded as the combination of 98.92% water, 0.9% glycerin, and 0.18% salt (Li et al., 2025a).

2.2. Large Eddy Simulation

To accurately simulate the transmission patterns, it is essential to consider the evaporation process and the composition of dental-contaminated droplets in the present study. Firstly, the dental liquid mixture was assumed to be well-mixed during the dental atomization procedures, with a mean stimulated salivary flow rate of $1.4\,mL/min$ and a water supply flow rate of $60\,mL/min$. As droplets evaporate, their non-volatile components form droplet nuclei that can remain suspended in the clinical environment for extended periods. The following equations describe the nondimensional evaporation rate of the l-th droplet:

$$\frac{dm_{p,i}}{dt} = -\pi d_i Nu \ ln\left(1 + B_{m,i}\right) \frac{1-\psi_i}{Re_{in}Sc} \quad (1)$$

$$Nu = \frac{hd_p}{k_\infty} = 2.0 + 0.6Re_d^{1/2}Pr^{1/3} \quad (2)$$

$$B_{m,i} = (Y_{p,i} - Y_{f,i})/(1 - Y_{p,i}) \quad (3)$$

where, $m_{p,i}$ is the mass of i-th droplet. Nu refers to the Nusselt number. k_∞ and Pr are the thermal conductivity and Prandtl number of the continuous phase (air), respectively. h is the heat transfer coefficient, which is defined based on the Ranz-Marshall model (Ranz et al., 1952). Owing to the small variation in the air temperature, the thermodynamic characteristics of the air were treated to be constant. $B_{m,i}$ indicates the Spalding mass number. $Y_{p,i}$ and $Y_{f,i}$ are the mass fractions of water vapor in the droplet and the surrounding air, respectively. Sc is the Schmidt number. The heat balance between the droplet and gas phases related to the convective and latent heat transfer can be obtained as follows:

$$m_p c_p \frac{dT_p}{dt} = hA_p\left(T_g - T_p\right) - L\frac{dm_p}{dt} \quad (4)$$

where c_p and A_p refer to the specific heat and surface area of the droplet, respectively. T_p and T_g indicate the droplet and gas temperature, respectively [Li et al., 2022a; Li et al., 2022b].

3. RESULTS AND DISCUSSION

3.1. Human Micro-environment and Airflow Patterns

Figure 2 illustrates the velocity streamlines and airflow patterns in the dental surgery environment. Cooling air exits from the ventilation inlet and travels along the ceiling surface. Airflow separations occur due to impingement with the room walls. After interacting with the human thermal plume and respiratory flow, the mixed air is expelled through the ceiling exhaust. The maximum velocity for the mannikin thermal plume is around $0.23\ m/s$. To accurately assess the human exposure index, it is essential to precisely simulate airflow interactions within the human micro-environment.

Figure 3 presents the local mesh refinement in the human breathing zone, highlighting nasal inhalation and exhalation characteristics. To unravel the temporal evolution of the multi-phase turbulent cloud during the ultrasonic atomization procedure, the mesh refinement near the dental treatment region is created with the finest cell size maintained at around 0.0008 m. Five layers of prismatic cells are created to guarantee that the y+ value remains below 1. The aforementioned grid can provide a good resolution for unravelling the dental spray dynamics. Nasal exhalation flows can disrupt the rising thermal plume, while ambient particles may be drawn into the inhalation flow. These localized airflow patterns significantly influence the distribution of suspended droplets and aerosol particles, particularly those with small aerodynamic sizes. The following sections will evaluate the relationship between droplet propagation patterns and flow field characteristics.

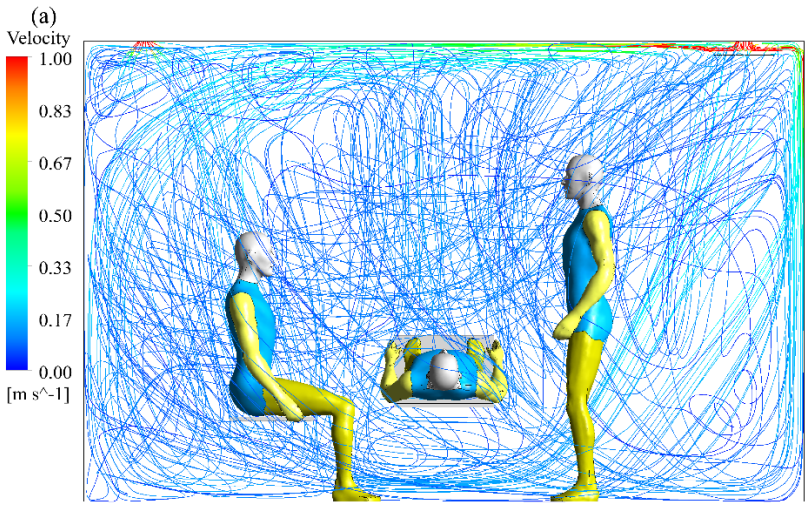

Figure 2. Velocity streamlines and airflow patterns in the dental surgery environment, streamlines colored by the velocity magnitude

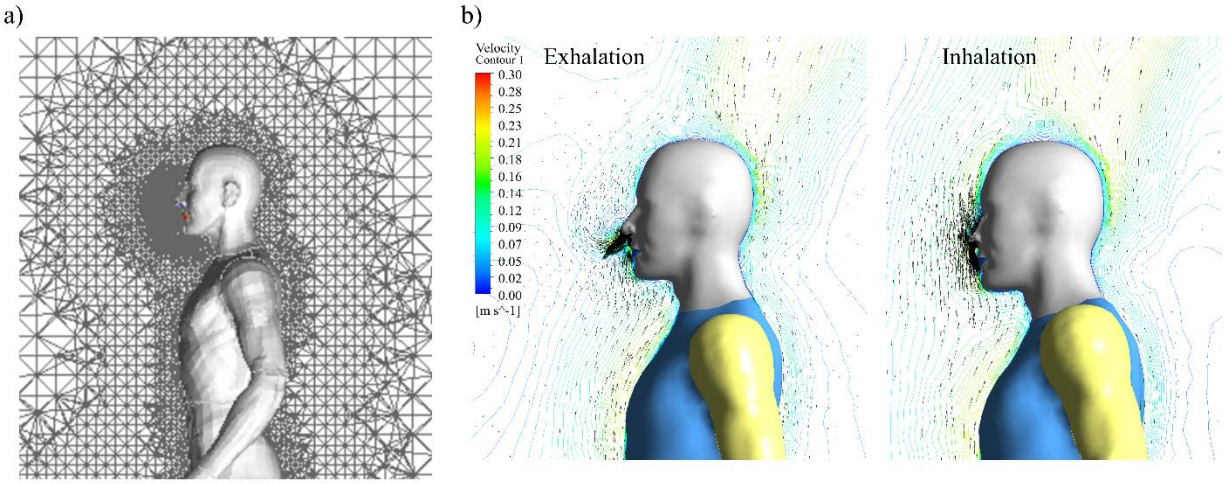

Figure 3. Local mesh and the nasal inhalation/exhalation characteristics

3.2. Dental Spray Dynamics and Residence Time

Figure 4 illustrates the spatial-temporal distribution patterns of contaminated droplets during the ultrasonic procedure. The red triangular area indicates the dental spray core, as determined by PIV visualization. At the moment of $T = 3s$, some small particles, depicted in blue, can escape from the core region of the dental spray and form a surrounding shear layer. The maximum size of these escaped particles is identified as $15.4\,\mu m$. Based on the mass fraction ratio of the dental-contaminated droplets and the corresponding equivalent size ratio (21.2%), the initial droplet size can be calculated as $15.4 \div 21.2\% = 72.6\,\mu m$. Consequently, dental droplets with a diameter threshold of $72.6\,\mu m$ can escape from the spray core region due to air entrainment, leading to two distinct final fates: suspension in the air or deposition on surfaces. The droplets swirling within the cloud will gradually lose their water content, forming stable droplet nuclei. The roll-up effect of small droplets is noticed at T=6.0 s, with the high-velocity magnitude. This region can be referred to as the recirculation area, and the surrounding airflow entraining the pathogen-carrying

droplets can lead to contamination near the patient's head. The placement region of the HVS significantly affects particle removal efficiency, particularly in the spray core region and the surrounding shear layer. Our previous PIV visualization indicated that the removal efficiency fluctuated around 60% (Malmgren et al., 2021; Li et al., 2024; Li et al., 2025a) when the HVS was placed near the surrounding shear layer. Plenty of droplets in the core region cannot be removed, especially for those with high velocity and larger diameters. Therefore, the development of targeted mitigation measures should be based on the identified dental spray dynamics, along with the detailed guidelines. The results obtained in the present study can inform updates to dental guidelines during atomization procedures to enhance safety and effectiveness.

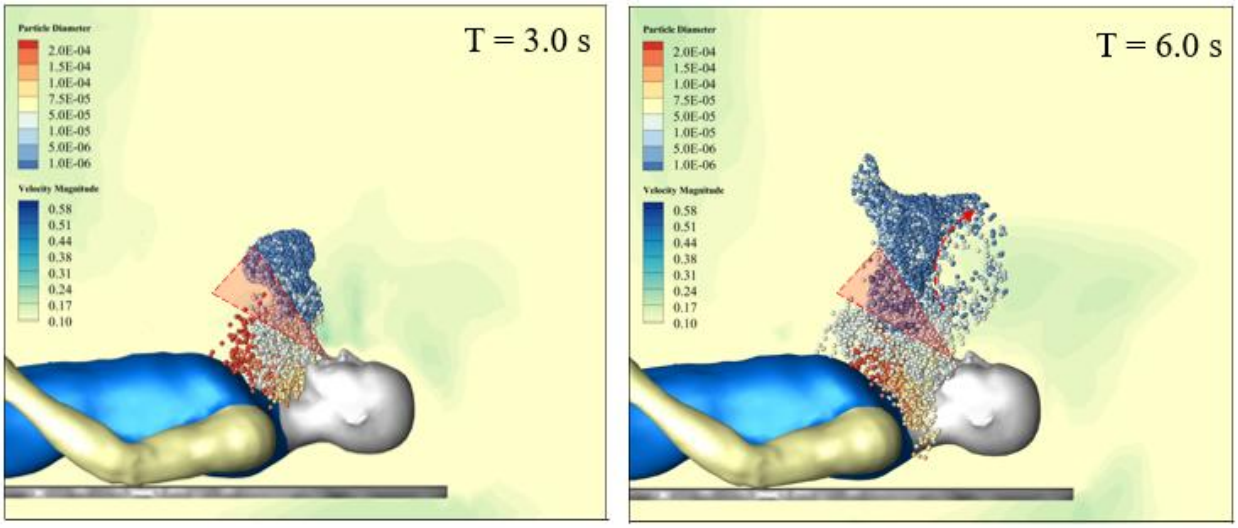

Figure 4. Dental spray dynamics and the dispersion patterns of contaminated droplets during the atomization procedures

Figure 5 illustrates the average residence time of droplets across different size distributions. For large droplets (greater than $100\ \mu m$), the residence time is generally less than 1.0 second. In contrast, aerosol particles smaller than $10\ \mu m$ can remain suspended for over $300\ s$, with a 50% increase in residence time for particles of $10-20\ \mu m$ ($200\ s$). Due to the prolonged airborne lifetime of these suspended particles, entering the surgery room prematurely, without allowing for adequate fallow time, can result in a high exposure index. Determining the proper fallow time based on the discrepancies between dental procedures and environmental conditions is also the warrant for future research (Li et al., 2021c). The results on the residence time of suspended particles are obtained based on a single realization, only for the ultrasonic scaling in a single dental surgery. Different medical procedures, ventilation rates, and clearance mechanisms can also lead to discrepancies in the particle residence time and human infection risks. The default Discrete Random Walk stochastic model in the ANSYS-Fluent code can induce time-varying deposition velocities and overestimate deposition rate, accounting for the discrepancy in the settling of micron-sized nuclei in the present study (Mofakham et al., 2020). Future research should consider a large number of droplets and numerous realizations to account for the turbulent flow and chaotic nature. The continuous random walk model based on the normalized Langevin equation is also warranted to further assess the particle dispersion and deposition in dental surgery environments.

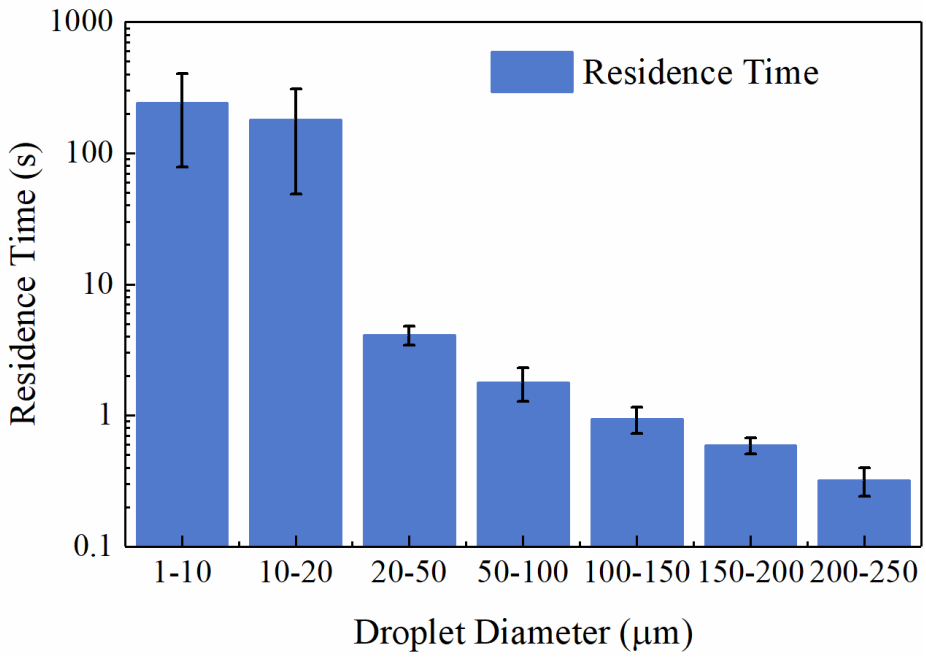

Figure 5. Average residence time of droplets in different size distributions

4. CONCLUSIONS

The contaminated liquid mixture, which includes mucosalivary fluid and microbiome, can become atomized during medical procedures. The presence of suspended particles has raised concerns about potential airborne transmission between subsequent appointments. Providing new insights into the dynamics of dental atomization can contribute to creating cleaner and healthier future environments. Droplets with a maximum size of $72.6\,\mu m$ can escape the core region, with two distinctive final fates: deposition or suspension. Source-control measures should be target-developed based on the analyzed spray dynamics. This study aims to support the development of evidence-based guidelines for dental environments, enhancing prevention strategies for future respiratory infectious diseases, such as the hypothetical "Disease X."

SUMMARY
Combining water and cement, which are the most used materials worldwide, can support the development of sustainable energy-harvesting applications. This study demonstrates a hydrovoltaic device based on the building material that generates electricity utilizing humidity difference between surfaces of cement samples for hydrovoltaic energy generation. The moisture flow inside the electrode nanochannels of the cement supercapacitors composed of nickel foam (NF) with carbon nanotubes (CNTs) can generate a voltage difference of up to 40.1 mV for a surface area of only 6.25 cm^2. Such a device can bring the idea of a positive energy balance of buildings and structures into reality.

Keywords: cement, CNT, hydrovoltaic, Nickel foam, relative humidity

1. INTRODUCTION

Recently, a new emerging type of energy known as “hydrovoltaic power generation”, which can be scaled from small to large spaces, has attracted much attention as an alternative way to power low-power electronics and Internet of Things (IoT) devices. Hydrovoltaic generators produce electrical energy from water or moisture flow through hygroscopic substances and active materials (Jiao et al., 2022; Lim et al., 2024). The hygroscopic substance is a hydrophilic material that absorbs water from surroundings, such as salts (H. Li et al., 2023), hydrogels (C. Liu et al., 2022; Yossef et al., 2024), and silica aerogel (Tian et al., 2024). Active materials can be carbon-based nanomaterials such as carbon nanotubes (CNTs) (Ding et al., 2017a; Z. Zhang et al., 2018), carbon nanofibers (Tabrizizadeh et al., 2021), carbon black (Xue et al., 2017) and graphene [23–25], and their active research area extents to metal oxides (Ji et al., 2019; Jin et al., 2020), organic metal frameworks (MOFs) (Z. Li et al., 2021; Q. Ma et al., 2020; X. Ma et al., 2021) and conductive polymers (Xie et al., 2022).

As shown in Table 1, hydrovoltaic energy generation has many applications, including sensors (Hui et al., 2020), electronics (Yun et al., 2019) and environmental aspects (Chen et al., 2024). However, hydrovoltaic energy generation has not been applied to building applications yet.

This study aims to develop a hydrovoltaic device based on cementitious material as a hygroscopic substance and CNTs as an electrically active material for construction applications. The roles of the NF and deposition of CNTs are investigated, and a discussion of the hydrovoltaic energy generation in cement material is outlined in this paper.

2. SAMPLE PREPARATION

In this study, the components and materials used are a 1.6 mm thick sheet of porous nickel foam (Ni-foam, MSE Supplies LLC, USA), single-walled carbon nanotubes (SWCNTs, Tuball OCSiAl, Luxembourg), isopropanol (99.8% purity, Merck), acetone (Avantor), hydrochloric acid (37% purity, Avantor/VWR), and Pika cement (Finncement, Finland).

The nickel foam sheets (NFs) were cut into 25 x 25 mm^2 electrodes and divided into three groups (A, B, and C). The process of electrode preparation was meticulous. First, NF sheets were cleaned using 1 mol hydrochloric acid (HCl) for 55 minutes, then washed with acetone and distilled water multiple times. Then the sheets were labeled, and their weights were measured. The A group represented bare nickel foam electrodes without any additional active material. For the needs of the B and C groups, CNT/isopropanol solution was dispersed using ultrasonication for 10 minutes, rested for another 10 minutes, and the treatment was repeated twice. In the B group, the NF sheets were directly drop-cast into CNT/isopropanol solution, while in group C, the solution was sprayed into NF using an airbrush using the dry and spray method, where the NF sheet was sprayed, left to dry, and then sprayed and dried again. Upon preparation, all samples were left overnight in a vacuum chamber. Then, the weight of the sample was measured again to determine the mass of the active material.

Electrodes were placed in a 3D-printed mold of thermoplastic polyurethane (TPU) with NF electrodes placed on the sides, and the mold was opened from the top to cast cement paste in a 5mm thick grove while tape held the NF sheets in their places during casting. After casting, two wooden plates kept the NF sheets in their place as shown in Figure 1. The output samples with a thickness of 5 mm should match the dimensions of the NF sheets (25 mm x 25 mm). Cement paste

was prepared using a 0.45 water/cement ratio and placed using a small spatula with the same thickness. The samples were wrapped with a plastic sheet and left to cure overnight, then they were un-molded and cured in 95% RH until testing.

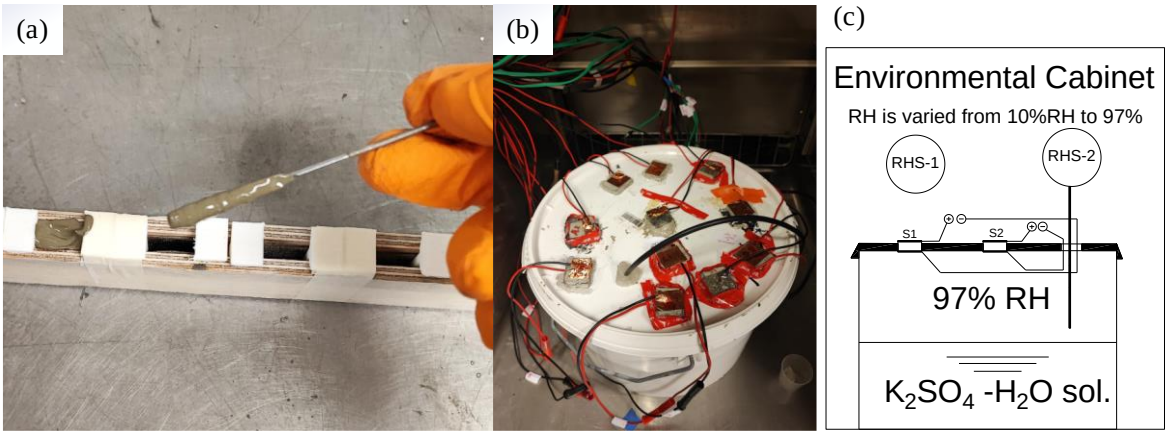

Figure 1. (a) 3DP TPU mold with taped nickel foam sheets during cement paste casting, relative humidity test setup showing (b) sample placement and (c) schematic diagram of the test setup, relative humidity sensor (RHS), and samples represented by S.

3. EXPERIMENTAL SETUP AND CHARACTERIZATION

A representative electrode was selected from each group and investigated using Raman Spectroscopy (Renishaw inVia™ Confocal Raman Microscope). The samples were examined using a 523 nm laser and a 20x microscope. Scanning of the samples was made under a focus track with a laser intensity of 1%. Electrode morphology was investigated using a Scanning Electron Microscope (SEM) (Quanta FEG 450) equipped with an ETD and CBS detector. The voltage was set to 10 kV, and the magnification varied up to 10000x. Samples were tested under differential humidity from both sides. A container was filled with K_2SO_4 solution to provide relative humidity (RH) of around 97% RH (Carotenuto & Dell'Isola, 1996). The samples were placed in existing holes, and their sides were tightened with a double tape that is resistant to temperature and moisture. The container was placed inside the environmental cabinet, and coupled temperature and humidity sensors were placed inside and outside the container. The relative humidity of the environmental cabinet varied from 97% RH to 10% RH. The voltage readings were recorded and plotted as a function of the difference between relative humidity values in the container and in the cabinet.

4. RESULTS

Raman spectroscopy results for group A, B, and C electrodes are shown in Figure 2. The results show that group A (NF) is treated well with HCl without any oxide layers, while groups B and C show peaks related to CNTs. It can be shown that the D-band (around 1350 cm^{-1}) is barely noticeable while G-band reaching around 11844 and 27927 (a.u) for dispersed and undispersed CNTs, respectively. The high G/D ratio >90 indicates that these CNTs are pristine with no signs for surface functionalization. NF is not showing any signs of oxidation, which implies that the CNTs are the driving force for hydrovoltaic energy generation.

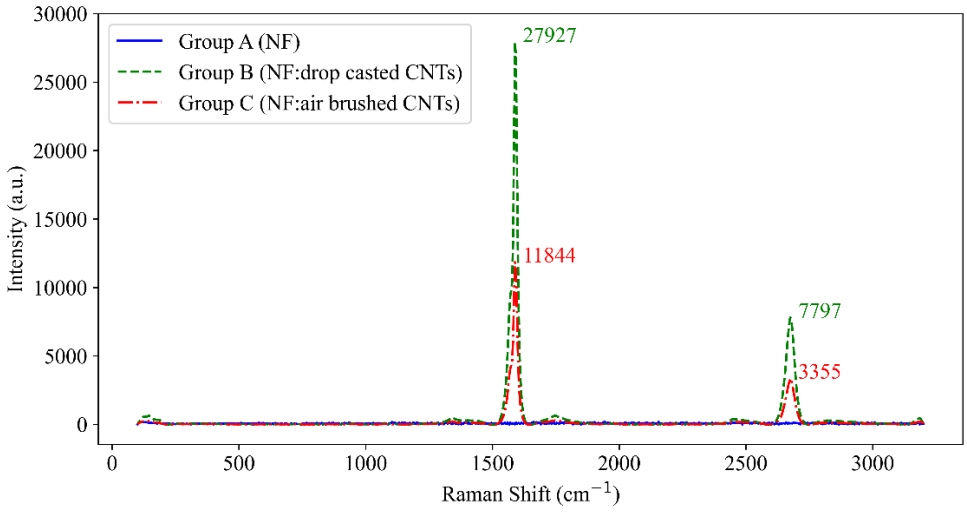

Figure 2. Raman Spectroscopy for bare NF and NF with drop cast and air brushed CNTs

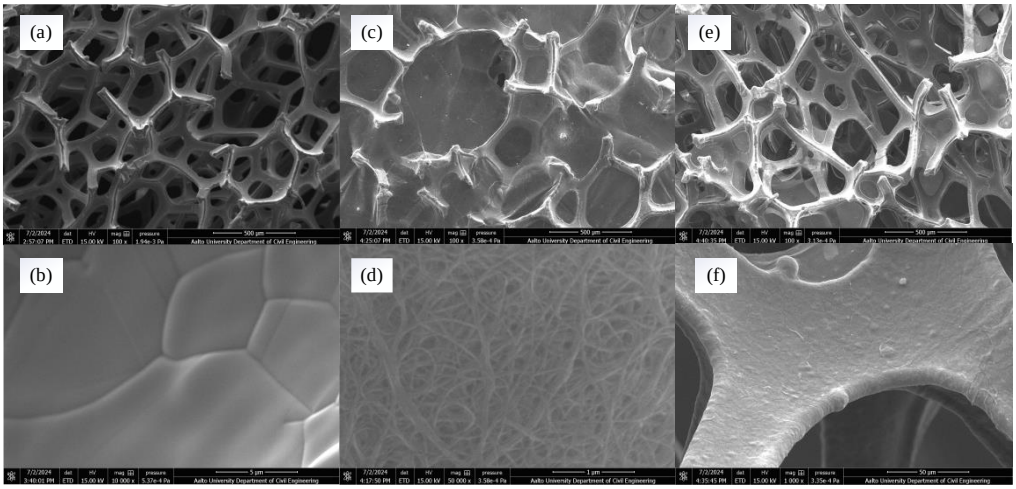

Figure 3. SEM images showing (a,b) bare NF, (c,d) NF with drop cast CNTs, and (e,f) NF with airbrushed CNTs

The morphology of the CNTs was investigated using SEM, as shown in Figure 3 (a-f). The morphology shows that the CNTs tend to form a "spider-network" like network when transferred by drop casting, which blocks the 3D NF pore structure, as shown in Figure 3(c), where the CNTs are interlocked, as shown in Figure 3 (d). In the case of spraying CNTs using an airbrush, the CNTs are mostly settled on the NF stems, as shown in Figure 3(e and f). Bare NF is displayed in Figure 3 (a and b) for comparison, showing no sign of CNTs.

Figure 4 shows that sample A, which represents the bare NF, has an insignificant potential of 2.8 mV, while sample C, which represents the NF with airbrushed CNTs, has a slightly higher potential of 6.4 mV. The drop cast CNTs samples, noted as B, show a potential difference of up to 40.1 mV for a surface area of only 6.25 cm^2. These results show that the CNTs have a significant role in generating the potential difference, while the method of deposition of CNTs has a critical role on hydrovoltaic energy generation.

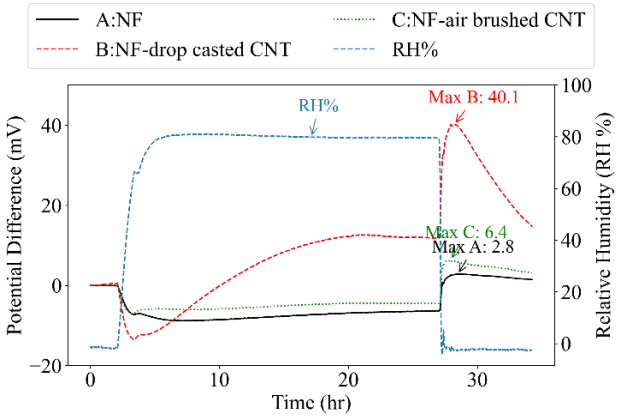

Figure 4. Hydrovoltaic test results at 87% relative humidity difference

5. DISCUSSION

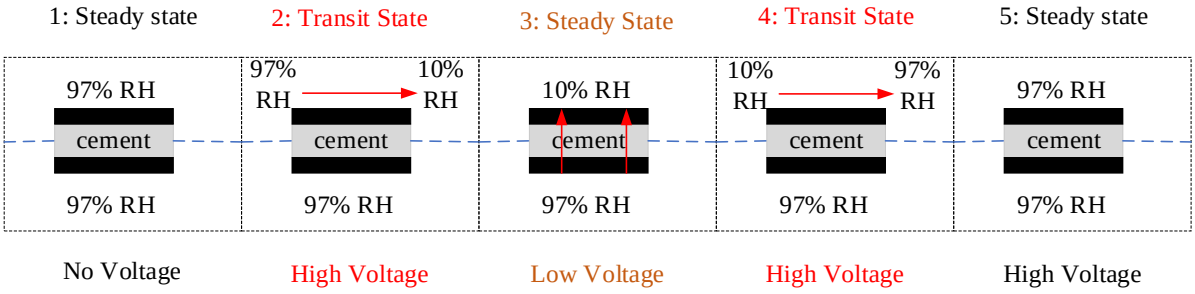

Figure 5. Schematic diagram showing different stages

Figure 5 shows different stages for the hydrovoltaic energy generation. Stage 1 shows a steady state where the same relative humidity (97% RH) is set to both sides, and no voltage is induced as a result of still water molecules. During variation of the ambient of the upper electrode from 97% RH to 10% RH, i.e., in transient state, a pressure gradient is formed between low and high humidity regions, which forces the water molecules to evaporate from the surface of the CNTs, causing an increase in local electrons at the upper electrode. The electrons interact with water molecules and oxygen and produce OH^-, which migrate to the lower electrode inducing a voltage difference between the upper and lower electrode (Yu et al., 2023). The results in Figure 4 show that CNTs transferred by drop casting tend to have a more extensive network of interconnected channels for water molecules, inducing a higher hydrovoltaic potential than air-brushed CNTs. The water molecules remain still when the environmental cabinet is steady at 10% RH in stage 3. Thus, no voltage is created from the motion of the water across the width of a single electrode. However, due to the diffusion of water vapor and liquid water l from one side to the other, low voltage is formed due to the moving of water molecules within the CNT nanochannels across the thickness of the electrode. Similarly to the stage 2, the stage 4 shows the moisture change by an increase in the humidity chamber from 10% to 97% RH. Thus, more moisture comes in contact with the CNTs, and a high voltage is induced. Finally, stage 5 shows the steady state where the water is no longer in motion and no voltage is induced.

6. CONCLUSION

This study presents a novel idea for generating electricity from the internal humidity difference of a building material. Hydrovoltaic energy generation of cement paste samples enclosed by two electrodes composed of NF sheets and CNTs is presented by investigating also the role of the porous NF sheet and its deposition by CNTs. The results can be summarized as:

1. Method of deposition of CNTs has a significant effect on the hydrovoltaic energy generated, as a uniform distribution of the CNTs on the walls of porous NF produced by airbrushing results in a lower contact between moisture and CNTs than the drop-casting method in which CNTs block the pores of the foam.
2. Bare NF sheet induces the least potential of 2.8 mV, followed by 6.4 mV received with air-brushed CNTs, and finally, NF sheet with drop-cast CNTs gave a potential of 40.1 mV at a relative humidity difference of around 87% RH.
3. Hydrovoltaic energy is mainly generated by the separation of water molecules from the surface of CNTs driven by moisture gradient between the electrodes and at their surfaces, which occurs along with a change in the surrounding relative humidity.

Based on conclusions, hydrovoltaic energy generation shows a promising path towards generating electricity in buildings from the variation of the relative humidity. Future recommendations include full-scale implantation of the hydrovoltaic energy on roof and wall façades.

SUMMARY
This study investigates the impact of methodological assumptions in building performance modelling to select façade design strategy based on the expected Greenhouse Gass Emissions (GHG). A parametric simulation framework was employed to examine the effects of varying COP (Coefficient of Performance) and SEER (Seasonal Energy Efficiency Ratio) calculations, embodied emissions considerations, future climate scenarios, and decarbonization pathways on façade optimization decisions. The framework was applied to case studies in Turin, Italy, and Eindhoven, Netherlands, revealing significant geographical variations in emissions reduction potential. The study shows substantial reductions in combined operational and envelope-related embodied GHG emissions when considering variable COP with progressive decarbonization pathways - up to 61.8% in Italy and 50.3% in the Netherlands. Key findings indicate that while absolute emission values exhibit substantial variation across methodologies, the relative ranking of façade design strategies remains predominantly consistent, particularly for wall configurations with performance variations typically limited to 2-4%. This observation suggests that simplified approaches, despite overestimating absolute emissions, can offer reliable guidance for comparing façade design alternatives during early-stage decision-making.
Keywords: Thermal Resilience, Lifecycle Assessment, Building Envelope, Parametric Simulation-based Framework, Dynamic Carbon Assessment.

1. INTRODUCTION

Climate change creates challenges for buildings: they must adapt to extreme weather while maintaining comfort and reducing emissions. Building resilience - the ability to maintain performance under changing conditions while minimizing environmental impact - has become crucial for the building sector (Attia et al. 2021). The building façade, acting as the barrier between inside and outside, shapes thermal performance and impacts energy use, comfort, and emissions (Soudian & Berardi 2025). The connection between resilience and emissions is key as buildings must adapt to extreme weather while reducing their climate impact. Research shows façade design strongly influences future building resilience. Tettey et al. (Tettey et al. 2017) found that orientation, Window-to-Wall Ratio, and glazing significantly affect future energy performance. Karimpour et al. (Karimpour et al. 2015) showed Mediterranean buildings will shift from balanced heating-cooling to mainly cooling needs by 2070. Building resilience involves more than weather patterns - it includes interactions between building systems, energy grids, and environment. Therefore, understanding how building envelope design affects resilience requires evaluating both immediate performance and long-term environmental impacts, making emissions assessment crucial for resilient design strategies. Previous research demonstrated the importance of future weather data for assessing building resilience (Heiranipour et al. 2025). However, this approach often overlooks other climate-influenced factors affecting emissions, like grid decarbonization and

building system efficiencies. This might therefore ignore the complex interdependencies between different aspects of performance, leading to strategies that may not be robust under evolving climate scenarios (Rouws et al. 2024). On the other side future operational GHG emissions could be reduced by higher penetration of renewable energy generation in the electrical grid, while embodied carbon emissions could become more significant, thus influencing building envelope related design choices.

Considering the above, this study focuses on the following research questions: *to what extent do simplifications in methodological assumptions related to building system and building-to-grid interaction —such as variability in COP (Coefficient of Performance) and SEER (Seasonal Energy Efficiency Ratio), consideration of embodied emission and of decarbonization pathways — may impact on façade design strategy selection for building heat resiliency?* These methodological considerations - such as varying HVAC performance and grid decarbonization pathways - are fundamental for developing façade design guidelines that remain effective under future climate and energy scenarios. To address this, a parametric simulation-based framework was improved with the aim of testing these assumptions systematically. By comparing the effects of these factors on façade strategy rankings across different climates, this study aims to determine whether these methodological variations critically influence decision-making or if a simplified approach could still yield reliable results. Subsequent sections present the methodology, analyse results, and discuss implications for sustainable façade design, concluding with recommendations for developing climate-resilient, low-carbon buildings.

2.METHODOLOGY

The building resilience evaluation framework previously developed (Heiranipour et al. 2025) has been enhanced to be able to consider the following three key methodological variants: (i) future climate evolution scenarios (already featured), (ii) heating-cooling system performance modelling approach (constant versus climate-dependent COP/SEER), and (iii) future potential decarbonization pathways for national electricity mix (Scenarios 1, 2, and 3). While the original framework assessed multiple Key Performance Indicators (KPIs), for sake of simplicity this study focuses only on GHG emissions during operation (Op) and envelope-related embodied emissions (Env.Emb), expressed as t_CO2_eq.

This paper methodology explores interactions between façade design strategies, HVAC system efficiency, and GHG emission scenarios over a 30-year building lifetime. Two current and future weather datasets have been produced considering Turin (Italy) and Eindhoven (the Netherlands), based on the dynamical downscaling methodology (Machard et al. 2024) considering RCP 8.5 scenario. The dynamic Coefficient of Performance (COP) and Seasonal Energy Efficiency Ratio (SEER) are based on Eq. (1). and Eq. (2)., validated for air-to-water systems against both manufacturer specifications and experimental data (Bordignon et al. 2024).

$$COP = 0.6261 + 0.0528 * (Tair + 273.15) - 0.0391 * (T\ load, out\ heating + 273.15) \quad (1)$$

$$SEER = 12.7264 - 0.0404 * (Tair + 273.15) + 0.158 * (Tload, out\ cooling + 273.15) \quad (2)$$

- T_{air} is the outdoor air temperature in degrees Celsius.
- $T_{load,out\ heating}$ and $T_{load,out\ cooling}$ are the temperatures of the water used for heating and cooling, respectively, in degrees Celsius (for cooling set on 7°C and for heating set on 40 °C).

The GHG emissions calculation considers both operational and envelope-related embodied carbon over a 30-year building life (2025-2055). The operational ones are calculated based on energy calculations of two 15-years intervals: 2025-2040 using current EPW results and 2040-2055 for mid-future EPW results (Figure 1). Moreover, a static baseline scenario was established using current weather data for the entire building lifetime, maintaining constant emission factors and fixed HVAC system efficiencies. This approach represents conventional practice that does not account for climate change effects, providing a reference point for comparing more sophisticated methodological variants. Different emissions factors definition methods are used to convert electrical delivered energy use to GHG emissions. As a benchmark, a constant emission factor has been implemented using the current location-specific factors from the Covenant of Mayors for Climate and Energy (Bastos et al. 2024). Afterwards, three different decarbonization scenarios have been established: Scenario 1 implements an aggressive linear reduction pathway aiming for carbon neutrality by 2050 (International Energy Agency 2024); Scenario 2 follows the European Environment Agency's projections with a two-step approach, initially aiming for a reduction to 82% of 2023 levels by 2030, followed by a linear decline to zero emissions ("Climate Pledges Explorer – Data Tools," n.d.); Scenario 3 is derived from historical emission reduction trends (2002-2023) documented in the Energy Performance of Buildings Directive (EPBD) reports ("Directive (EU) 2024/1275 of the European Parliament and of the Council" 2024). A combination of these operational and envelope-related embodied emissions has been then obtained summing the two-contribution expressed as tCO2-eq per 30-year. For the embodied carbon assessment, the calculation focuses exclusively on the envelope materials for stages A1-A3, and it is based on the EcoInvent 3.9 database and building archetype quantities, with calculations performed using openLCA 2.2 software and the EF3.1 impact assessment method.

The building model uses Grasshopper 1.0.0007 within Rhino 7 (SR31) coupled to Ladybug Tools 1.8.0, with thermal energy assessments conducted using EnergyPlus under dynamic yearly conditions. The case study is a single-family house archetype representative of typical European residential construction based on the archetype defined by (Fakhari et al. 2023) while complying with local regulations. The HVAC system accounts for 8-15% of total building embodied emissions. For this case study the HVAC system contributes 9.516 tCO2eq in total embodied emissions (0.183 tCO2eq/m²) (Kiamili et al. 2020). The load-bearing structure represents 20-30% of total embodied emissions, with contributions varying significantly based on construction method (Khan et al. 2022): a reinforced concrete structure is responsible for 46.8 tCO2eq (0.450 tCO2eq/m²), whereas a steel structure would result in 83.2 tCO2eq (0.800 tCO2eq/m²). A timber structure results in 46.0 tCO2eq (0.442 tCO2eq/m²) and 89.9 tCO2eq (0.864 tCO2eq/m²) if a prefabricated modular system is used. However, in this research, both embodied emissions related to HVAC and building structure are intentionally excluded to emphasize the envelope design strategies (which together would account for approximately 55-100 tCO2eq).

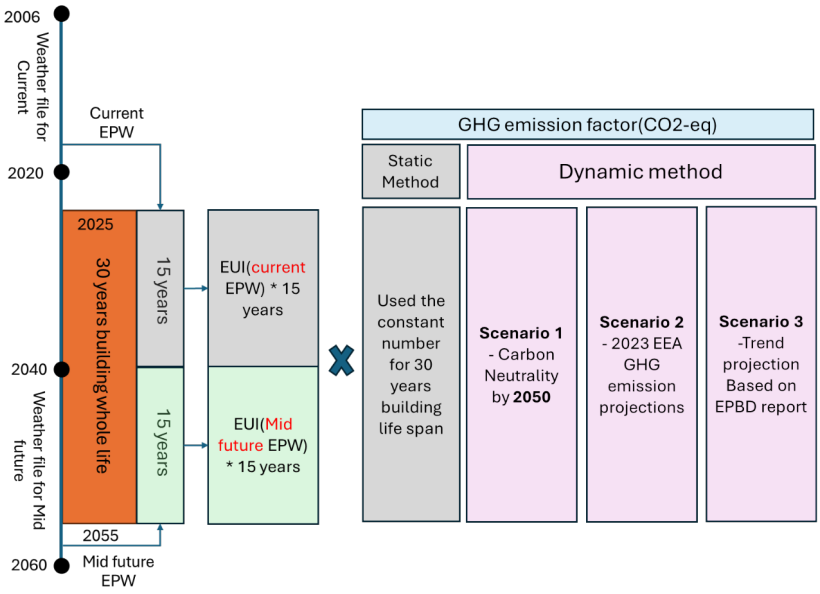

Figure 1. Framework of total GHG emission of whole life of building with emission scenarios.

Table 1. Building simulation characteristic

Building parameters		Values	Ref
Geometry parameter	Number of storeys	2	(Fakhari et al. 2023)
	Building width/depth (m)	8*6.5	
	Area per storey (m^2)	52	
	Glazing ratio (%)	[Parametric]	
Internal heat gain	No. of occupants(N/m^2)- schedule	0.07- Residential	(ISO 2016)
	Metabolic rate (Met)	1.2	
	Lighting density (W/m^2)- schedule	7- Residential	
	Equipment load (W/m^2)- schedule	3.125- Residential	
Thermal characterizes	Ground floor thermal transmittance (W/m^2K)	0.517	(Fakhari et al. 2023)
	External roof thermal transmittance (W/m^2K)	0.193	
	Wall thermal transmittance (W/m^2K)	0.330	
	Window thermal transmittance (W/m^2K), SHGC, Tvis	1.70, 0.55, 0.70	
Infiltration and ventilation parameters	Infiltration rate (m^3/s per m^2 facade)	0.005	(Fundamentals 2017)
	Mechanical ventilation rate (ACH)	0. 35	
HVAC characterizes	Heating setpoint (°C)	20	
	Cooling setpoint (°C)	26	
	HVAC system	Ideal air load	

Table 2. Facade design strategies considered (first row is the benchmark, compliant with local regulation).

WWR	Wall number	Type of wall	Thermal characteristics for different façade designs
40 %	Wall_3	Plaster (2cm),Insulation (15cm), Brick (25cm), Gypsum (1cm)	(U=0.23 W/m^2K) (Y=0.021 W/m^2K)
20 %	Wall_1	Plaster (2cm),Brick (25cm), Gypsum (1cm)	(U=1.63 W/m^2K) (Y=0.498 W/m^2K)

60%	Wall_2	Plaster (2cm),Insulation (5cm), Brick (25cm), Gypsum (1cm)	(U=0.55 W/m^{2}K) (Y=0.061 W/m^{2}K)
	Wall_4	Plaster (2cm),Insulation (25cm), Brick (25cm), Gypsum (1cm)	(U=0.15 W/m^{2}K) (Y=0.012 W/m^{2}K)

To assess methodological impacts, two exemplary building envelope parameters were selected based on previous findings (Heiranipour et al. 2025): the WWR and opaque wall configurations in terms of insulation thickness. These parameters were chosen as they significantly influence both the building's energy balance and the trade-offs between heating, cooling, and lighting energy use, hence controlling the overall dynamic heat transfer (Table 2). In this study, all possible combinations of WWR with each insulation thickness configuration were examined to comprehensively evaluate the interaction effects between these design parameters.

3. RESULTS

The analysis of the baseline energy distribution reveals that grid decarbonization scenarios and HVAC performance models impact the calculation of GHG emissions related to different façade strategies differently based on the location. In the Italian context, for the benchmark case (WWR=40%, insulation thickness=15cm) with constant COP and no future climate consideration, a more balanced energy profile was obtained, with heating accounting for 49.5%, cooling 11.3% and equipment and lighting 39.2%. In contrast, the Netherlands shows a heating dominated profile with heating accounting for 63.2%, cooling negligible at 0.20% and equipment and lighting 36.6%. Considering only future climate scenarios with constant COP, Italy shows a 6.2% decrease in heating emissions and a 18.7% increase in cooling emissions, resulting in a net decrease of 4.2% in total energy use, while the Netherlands shows a 2.3% decrease in heating emissions and a 170% increase in cooling emissions, leading to a net increase of 1.8% in total energy use. Despite the dramatic percentage increase in cooling demand for the Netherlands, its impact on total energy use remains moderate due to the very low baseline cooling energy consumption. The introduction of temperature-dependent COP/SEER calculations, together with the consideration of future climate leads to further significant changes: Italy's heating emissions decrease by an additional 16.1% and cooling emissions by 29.4%, while the Netherlands shows an additional 16.0% reduction in heating emissions and a 32.8% reduction in cooling emissions. Based on Figure 2, average COP values for Italy range from 2.6-3.3, while the Netherlands shows a slightly higher and narrower range of 2.8-3.4, reflecting the difference in winter temperature distributions between the locations. Under future climate scenarios, both locations show improved COP values due to warmer winter conditions. SEER values demonstrate more pronounced geographical variations, with Italy maintaining relatively stable values around 4.8 despite future temperature increases, while the Netherlands shows a significant decrease from current values around 5.2 to future values around 4.6, though this efficiency reduction has limited impact on total emissions due to the Netherlands' predominantly heating-dominated energy profile.

Embodied part (Window)	0.065			

Transitioning from a constant COP with static GHG emissions to temperature-dependent HVAC performance consistently lowers absolute emissions in both locations. Within each WWR category, increasing insulation thickness progressively minimizes these methodological differences. In Italy, Scenario 3 (targeting carbon neutrality by 2042) achieves the most significant reductions, with total emissions decreasing by up to 61.8% when combined with a variable COP. Conversely, in the Netherlands, Scenario 1 (aiming for carbon neutrality by 2050) yields optimal results, reaching a 50.3% reduction. These geographical variations reflect differences in energy demand patterns and grid decarbonization trajectories between the two regions. Notably, the relationship between operational and total emissions (Op+Env) remains consistent across scenarios for each design strategy, maintaining proportional differences regardless of the calculation methodology.

As WWR increases, embodied carbon consistently decreases, with a 16.8% reduction for the same wall configurations. Conversely, within each WWR category, increasing insulation thickness results in a steady 2.6% increase in embodied carbon. The analysis reveals distinct optimal configurations across locations: in Italy, the configuration with 20% WWR and Wall_4 achieves minimum GHG emissions, while 20% WWR with Wall_1 results in the highest emissions. Interestingly, the Netherlands shows a different optimal configuration, with 40% WWR and Wall_4 performing best, though it shares the same worst-performing configuration as Italy. In this research, the transparent facade had lower embodied carbon than the opaque part, as it was modelled as a residential window. For tertiary buildings, curtain walls with the same WWR would have higher embodied carbon. While absolute emission values show substantial variation between different calculation approaches, the relative ranking of façade design strategies remains remarkably consistent, especially for wall configurations where performance variations typically stay within 2-4%. Consequently, simpler methodologies—though potentially overestimating absolute emissions—can still provide reliable insights for comparing façade design strategies in early-stage decision-making.

4.CONCLUSION

This study demonstrates that methodological choices in building performance modelling significantly influence GHG emissions predictions related to different façade design strategies across two geographic regions. In Itay, reductions of up to 61.8% when combining variable COP with advanced decarbonization pathways, while the Netherlands shows more moderate but still significant reductions of up to 50.3%, reflecting its more stable climate conditions. Temperature-dependent HVAC performance modeling reveals climate-specific patterns, with Italy's broader COP distribution reflecting its variable winter temperatures, compared to the Netherlands' narrower range. Our research addresses a critical gap in façade design literature by quantifying how methodological simplifications in HVAC modeling and grid decarbonization impact decision-making. Previous studies overlooked these interdependencies, focusing on weather patterns without considering relationships between envelope performance, system efficiency, and grid emissions. By examining these factors across geographical contexts, we resolve uncertainty about when comprehensive modeling approaches are necessary for early design decisions.

Notably, while these methodological refinements substantially affect absolute emission values, the relative ranking of façade design strategies is constant, with performance variations typically remaining within 2-4%. However, in locations where cooling energy represents a substantial portion of total energy use, the consideration of temperature-dependent SEER becomes crucial for façade design optimization, as cooling efficiency shows greater sensitivity to climate change impacts. The result of this paper suggests that simplified methodological approaches, though overestimating absolute emissions, can provide reliable guidance for comparing façade design alternatives during early-stage decision-making, particularly in temperate climates, while comprehensive frameworks incorporating variable HVAC performance and grid decarbonization remain essential for accurate absolute predictions.

SUMMARY
This research explores how moisture transfer affects the thermal transmittance (U-value) of timber frame walls using experimental and numerical methods. Six wall systems with different insulation materials and finishing layers were analyzed. Results show that moisture flow increases the U-value when aligned with the heat flux, with more significant effects in highly permeable systems. The study also highlights the limitations of the Heat Flow Meter (HFM) method, which inaccurately measures U-values by blocking moisture flow. The findings emphasize the need to account for moisture effects in energy performance assessments and to develop advanced measurement techniques for accurate evaluations.

Keywords: Moisture transfer, Thermal transmittance (U-value), Heat flow meter method (HFM).

1. INTRODUCTION

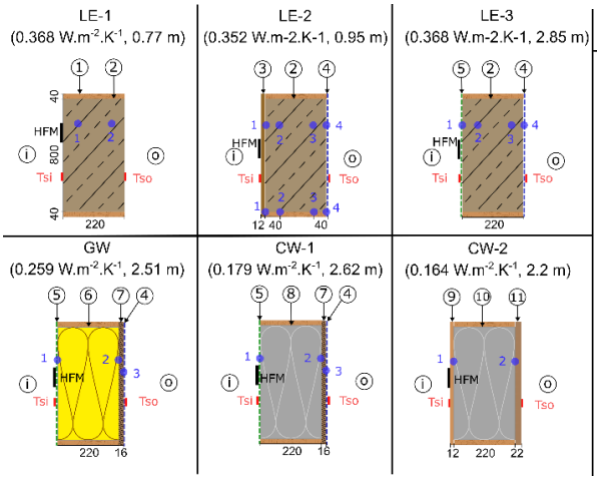
The thermal transmittance coefficient of a wall (or U-value) is a crucial parameter for assessing heat loss and determining a building's energy needs. It can be theoretically evaluated following the methodology outlined in ISO 6946 or measured experimentally through in situ methods such as the Heat Flow Meter (HFM) method (Gaspar et al., 2018; Ficco et al., 2015), the thermometric method (Bienvenido-Huertas et al., 2018), or quantitative infrared thermography (Albatici and Tonelli, 2010; François et al., 2021). Due to its simplicity, the HFM method, described in ISO 9869-1, is the most widely used. This method involves measuring heat flux with heat flux sensors and surface temperatures using two thermocouples. It has been extensively tested on walls made of non-hygroscopic materials. Several factors have been shown to influence the accuracy of this method, including heat flux deflection caused by the heat flux sensor (Cucumo et al., 2018), the emissivity of the sensor relative to the wall's surface (Cesaratto et al., 2011), the positioning of the thermocouple, as well as the size, shape, and orientation of the heat flow meter sensor (Meng et al., 2015), the contact quality between the sensor and the wall (Ficco et al., 2015) and the temperature gradient across the wall (Ficco et al., 2015; Albatici and Tonelli, 2010; Gori and Elwell, 2018; Desogus et al., 2011). All these studies showed that thermal transmittance can be evaluated with an uncertainty ranging between 14 to 30 %. Recent studies have highlighted the emergence of walls more open to moisture transfer, attributed to better moisture management within walls (McClung et al., 2014; Mlakar and Štrancar, 2013; Lstiburek, 2004) or lower indoor relative humidity levels (Mlakar and Štrancar, 2013), while maintaining significant drying potential (Lstiburek, 2004). These new walls often incorporate bio-based concretes (Shea et al., 2012; Evrard and De Herde, 2010; Piot et al. 2017; Lelievre et al., 2014). Coupled heat and moisture transfers occurs such walls, which can influence their thermal transmittance coefficient.

Nevertheless, literature studies concerning the effects of moisture on the in situ thermal transmittance measurements are scarce. Nicolajsen (Nicolajsen, 2005) compared the thermal transmittance of a facade insulated with cellulose wadding to one with rock wool in a real Danish climate. The results showed that moisture content, reaching up to 18% in winter, had no significant impact on measured values. Latif et al. (Latif et al., 2014) compared panels with hemp and rock wool insulation of similar theoretical transmittance under different conditions. They found that thermal transmittance increased with rising moisture content, with a slightly greater increase for hemp-insulated panels. In another study, they compared three panels with identical theoretical U-values under winter conditions (Latif et al., 2018). Results indicated that the bio-based panel had higher U-values than the traditional ones, highlighting the influence of moisture on hygroscopic materials. These studies only consider the rise in U-value resulting from the increase in moisture content. However, the situation is more intricate, as moisture can have additional effects on the measurements like latent heat transfer on the surface. This research focuses therefore on the influence of moisture transfer on the thermal transmittance (U-value) of timber frame walls through a combination of experimental and numerical analyses. Additionally, the study evaluates the accuracy of the Heat Flow Meter (HFM) method in capturing the full effects of moisture transfer.

2. MATERIALS AND METHODS

In the present study, six distinct wood frame walls are studied (see Fig. 1). The frames are 880 mm wide and 970 mm high (corresponding to a surface of 0.85 m^2) and their thickness is 220 mm, which corresponds to the thickness of the insulation layer. The tested walls are:

- LE-1: dried projected light earth without any finishing layer.
- LE-2: dried projected light earth with a rain barrier outside and earthen plaster inside.
- LE-3: dried projected light earth with a rain barrier outside and a vapor retarder inside.
- CW-1: dried projected cellulose with a rain barrier outside and a vapor retarder inside.
- CW-2: blown dry loose fill cellulose with a rigid rain barrier outside and OSB inside.
- GW: glass fiber with a rain barrier outside and with a vapor retarder inside. GW wall is non-hygroscopic, meaning moisture should have no significant influence on it and can be taken as a reference.



Layer	Material	Thickness [mm]
1	Wooden frame	40
2	Light earth	220
3	Earthen plaster	12
4	Rain barrier (Dorken Delta-XX SD = 0.08 m)	
5	Vapor retarder (Isocell SD = 2 m)	
6	Glass fiber cellulose (ISOMOB35R)	220
7	Medium-density fibre board	16
8	Wet projected cellulose	220
9	Oriented strand board	12
10	Dry blown cellulose	220
11	Rigid rain barrier (Pavatex)	22
–	Thermocouples	
•	Thermohygrometers	
—	Heat flow sensor	

Figure 1. Schematic view of the studied walls, their theoretical U-values and Sd values, their composition, and the sensors placement.

The materials' properties are either measured in the lab or taken from the manufacturer. They are presented in Table 1 (sorption isotherms are characterized by GAB parameters). Using these properties, the tested walls have theoretical thermal transmittance ranging from 0.16 to 0.37 $W.m^{-2}.K^{-1}$ and Sd values ranging from 0.77 to 2.85 m.

Table 1. Material's hygrothermal properties.

Materials	ρ [$kg.m^{-3}$]	λ(w) [$W.m^{-1}.K^{-1}$]	μ [-]	Sd [m]	c_p [$J.kg^{-1}.K^{-1}$]	GAB parameter		
						W_m[-]	K [-]	C [-]

The walls are instrumented with temperature and relative humidity sensors (SHT85 sensors with accuracy of ±0.1 °C and ±1.5% rh). These sensors are embedded within light earth at 40 mm from the surfaces, at the interfaces between different materials, and in the indoor and outdoor environments. K-type thermocouples are placed on the interior and exterior surfaces. Thin, square (50 x 50 mm^2), and rigid heat flux meters HFM (C50 Captec sensor) are fixed to the interior surface using double-sided adhesive tape. They are covered with either black tapes or vapor retarders (depending on the finishing layers of each system) so that the sensors emissivity is similar to walls surface ones. Data are recorded at 5-minute intervals. The instrumented walls are installed in a bi-climatic chamber, where temperature and relative humidity is controlled independently.

To further analyse the results, experiments are simulated using 2D heat and moisture transfer model. Materials properties are those presented in Table 1. The total heat transfer coefficient at the surface which includes both radiation and convection in the enclosure ranges between 8 and 10 $W.m^{-2}.K^{-1}$ for indoor surfaces (depending on wall's surface emissivity) and is set to 10 $W.m^{-2}.K^{-1}$ for outdoor surfaces. Convective moisture transfer coefficient is determined by Lewis relation. Measured ambient temperature and relative humidity are used to assess boundary conditions while temperature and relative humidity measured within the material are extrapolated over the wall's thickness to assess initial conditions.

3. RESULTS AND DISCUSSION

3.1. Analysis of experimental results

The applied experimental protocol consists in fixing a temperature gradient while varying the vapor pressure gradient. Here, two tests are performed: almost no vapor pressure gradient (Test 1) and significant vapor pressure gradient flowing from outdoor to indoor, aligning with the direction of heat flow (Test 2). Temperature and vapor pressure variations in the indoor and outdoor chambers are presented in Fig. 2. Conditions in outdoor chamber are controlled with HVAC systems and setting points are correctly regulated. On the other hand, controlling conditions in indoor chamber with HVAC systems has led to large perturbation on surface heat flux measurement. Therefore, indoor conditions are uncontrolled and equal to those of the lab (which

is more realistic). Indoor temperature fluctuates between 20 and 25 ± 2 °C leading to temperature difference between outdoor and indoor ranging between 10 and 15 °C throughout the experiment. Indoor vapor pressure fluctuates around 1500 ± 500 Pa throughout the test: limited vapor pressure difference is noted for Test 1 (< 300 Pa) while large vapor pressure difference between outdoor and indoor is maintained for Test 2 (> 2600 Pa). Both tests last 7 weeks so that hygrothermal steady state can be reached in all walls at the end of each test.

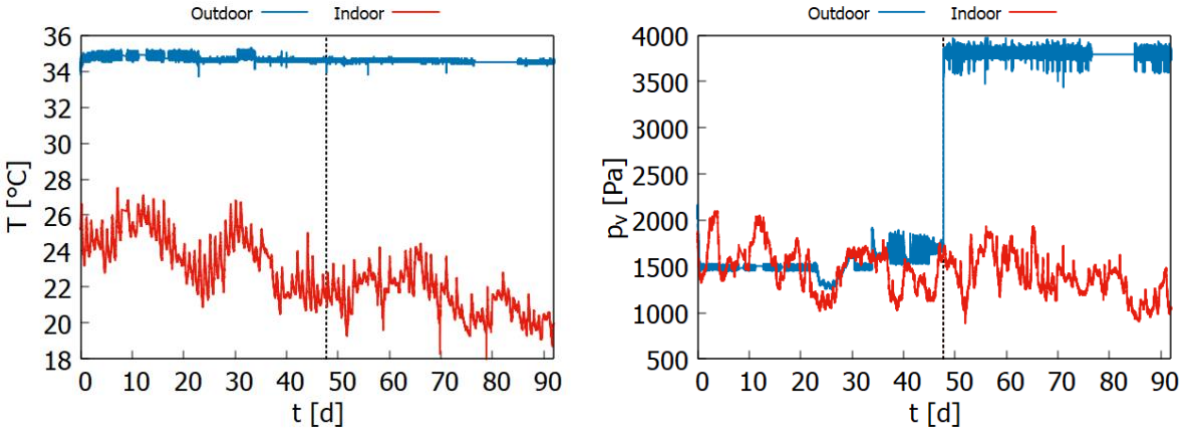

Figure 2. Temporal evolution of the outdoor and indoor temperature and vapor pressures.

Experimental U-values U_{exp} are calculated for all walls using the average method proposed by ISO 9869-1 considering data from the last 5 days of each test:

$$U_{Average} = \frac{\sum_{j=1}^{n} \varphi_j}{\sum_{j=1}^{n} (T_{sej} - T_{sij})} \quad (1)$$

The experimental U-values U_{exp} are plotted in Fig. 3 for light earth walls and in Fig. 4 for walls made with light insulation material. In absence of vapor pressure gradient (Test 1), less than 10% of difference is noted between U_{exp} and the theoretical U-value U_{th} (except for LE-1). These differences are due to assumption when calculating U_{th} (dry thermal conductivity is used, while walls are not dry during Test 1) and to experimental uncertainties. Here, an uncertainty of ± 5.1% is determined using the error propagation method, accounting for 5% uncertainty in the heat flux measurement and 1% uncertainty in temperature measurements (Gloriant et al., 2021). In presence of vapor pressure gradient (Test 2), U_{exp} tend to increase (except for LE-1), slightly for light earth walls (by 7 % and 17 % for LE-2 and LE-3 respectively) and significantly for other walls (almost by 50%).

To explain these increases, hygrothermal simulations are performed considering the physical presence of HFM. The latter is modelled by adding a 50 mm-width moisture-tight layer on the inner side of the wall. Simulated U-values U_{sim} are calculated according to Eq. (1) using simulated surface temperatures below the HFM and heat flux simulated at HFM surface. The results are included in Fig. 3 and Fig. 4. An uncertainty analysis performed for all materials hygrothermal properties has shown logically that thermal conductivity of insulation materials is the most influencing parameter (El Assaad, 2024). Assuming simulation uncertainties of ±10% (due to uncertainty of ±10% in the input thermal conductivity (El Assaad et al., 2024), U_{sim} agree with

U_{exp}, except for two cases. First, U_{exp} present lower values than U_{sim} for LE-1 wall. These errors are attributed to imperfect thermal contact between HFM and light earth wall, which has rugged surface. Second, U_{exp} is much higher than U_{sim} for GW wall for Test 2. In this case, simulation indicates high relative humidity behind the vapor retarder. Nevertheless, simulated are performed with dry thermal conductivity for the GW wall, neglecting therefore its increases at high moisture content and thus lowering U_{sim}.

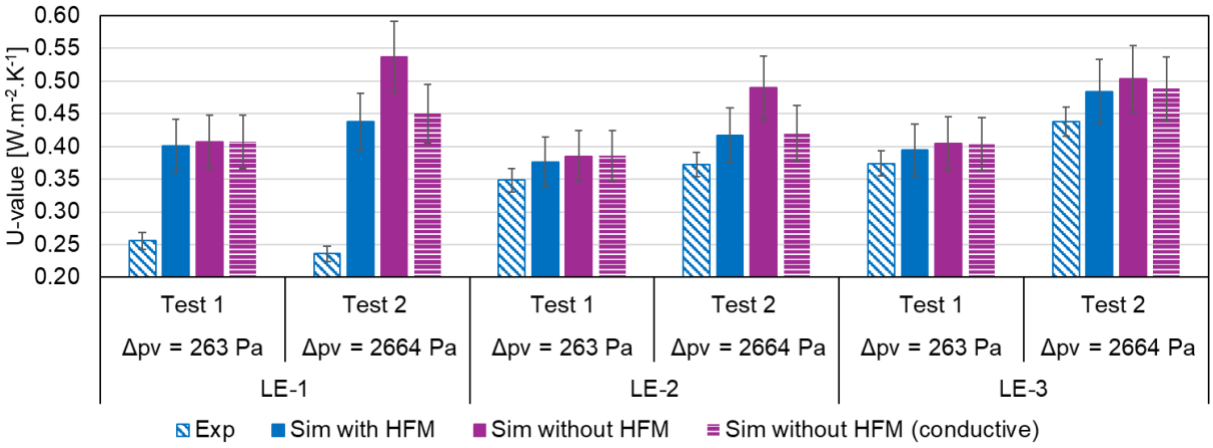

Figure 3. The total U-values simulated under the HFM, the total and conductive U-values without HFS and the experimental values for the light earth systems.

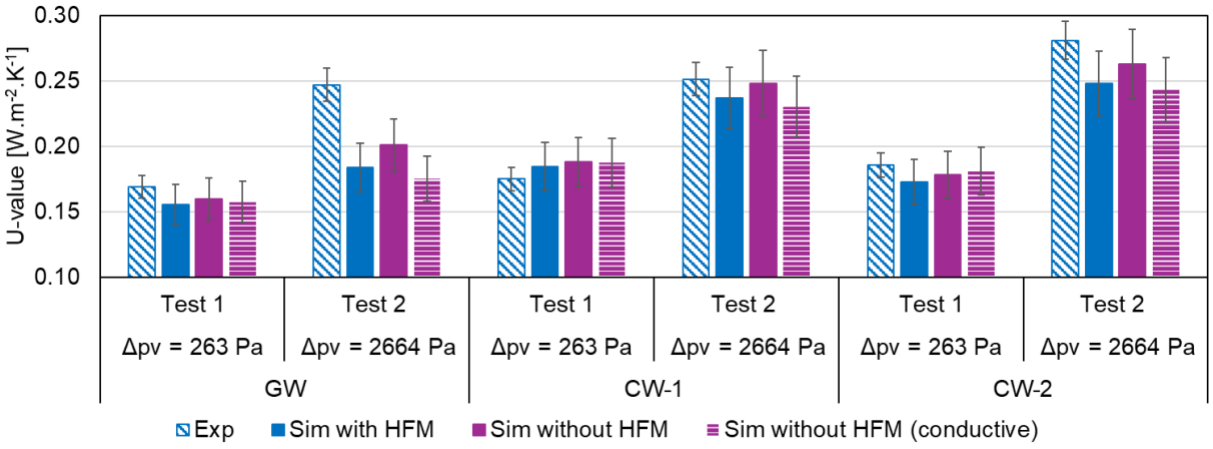

Figure 4. The total U-values simulated under the HFM, the total and conductive U-values without HFS and the experimental values for the conventional systems.

Besides, the simulations of Test 2 show that moisture is blocked behind HFM, which highlights that adding HFM on wall's surface interferes with the wall's hygrothermal behavior. To assess the influence of HFM on U-value evaluation, additional hygrothermal simulations are carried out without HFM. In this case, simulated surface heat flux includes both heat conduction and latent effects of moisture transfer as expressed in Eq. (2):

$$\varphi_{tot} = -\lambda \nabla T + Lv\left(D_v^{\phi} \nabla \phi + D_v^{T} \nabla T\right) \quad (2)$$

To assess the contribution of latent heat transfer to U_{sim}, conductive U-values U_{cond} are calculated using the conductive heat flux described in Eq. (3):

$$\varphi_{cond} = -\lambda \nabla T \quad (3)$$

During Test 1, simulated U-values U_{sim} with and without HFM are logically similar, the differences being lower than 3% (see Table 2). In absence of vapor pressure gradient, moisture flow and thus surface latent heat flux cancel out. During Test 2, U_{sim} without HFM are higher from 3.8% to 18% than U_{sim} with HFM (see Table 2). The more permeable the wall, the higher difference. However, U_{sim} with HFM match well with U_{cond}.

Table 2. Difference between the simulated U-values U_{sim} with and without the presence of HFM.

Wall	Difference [%]		Sd [m]
	Test 1 (Δp_v < 300 Pa)	Test 2 (Δp_v > 2600 Pa)	
LE-1	1.5	18.5	0.77
LE-2	2.3	14.8	0.95
LE-3	2.6	3.8	2.85
GW	2.9	8.5	2.51
CW-1	1.8	4.6	2.62
CW-2	3	5.7	2.2

Finally, when comparing simulations performed without HFM for Test 1 and Test 2, one observes that U_{sim} increase with vapor pressure gradient whatever the wall. For the less permeable walls, this increase is mainly due to the increase of wall's moisture content, which increase the mean thermal conductivity of hygroscopic building insulation material and thus U_{cond}. On the other hand, for the most permeable walls (LE-1 and LE-2), the contribution of surface latent heat flux to the increase in U_{sim} is more significant (up to 18.5 %).

3.2. Extended numerical analysis of the influence of moisture transfer on U-value

This previous finding of the influence of moisture transfer on U-value is extended by running four additional simulations. The simulation conditions are summarized in Table 3. For three cases, heat flows from outdoor to indoor (with a constant temperature difference of 9 °C) and vapor pressure differences between outdoor and indoor vary from negative values (vapor flow opposite to heat flux) to positive values (vapor flow in the same direction as heat flux). For the fourth case, vapor pressure difference is negative, but with the vapor flow is in the same direction as the heat flux (from indoor to outdoor).

Table 3. Indoor and outdoor conditions and vapor pressure difference set for the simulations.

Case	Indoor		Outdoor		Δp_v [Pa]
	T [°C]	Φ [%rh]	T [°C]	Φ [%rh]	
1	21	61	30	29	-300
2			30	36	0
3			30	73	1500
4			10	73	-590

For all walls, U-values U_{sim} are calculated using Eq. (1) once steady-state is reached for each case and compared to U_{sim} calculated for case 2 (i.e. in absence of vapor pressure difference) to evaluate the latent effects on U-value. This latent effect is plotted in Fig. 5 as function of vapor pressure difference between outdoor and indoor multiplied by the sign of heat flux (positive when heat

flows from outside to inside and negative otherwise). The latent effect is positive (i.e. vapor flow increases the U-value) when it aligns with the direction of the heat flux (both in summer and winter conditions) and negative when vapor flows in the opposite direction of the heat flux. A quasi-linear increase is observed whatever the wall, but no correlation is currently found between the slope and the materials or wall properties.

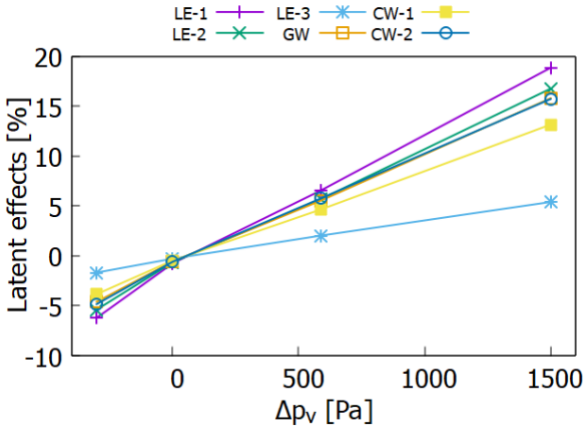

Figure 5. Latent effects due to vapor flow on simulated U-values U_{sim} with respect to the vapor pressure difference multiplied by the sign of heat flux (positive when heat flows from outside to inside and negative otherwise).

4. CONCLUSIONS

This study investigated the influence of moisture transfer on the thermal transmittance (U-value) of insulated timber frame walls, combining experimental and numerical analyses. Six instrumented walls with various designs were tested in a bi-climatic chamber. U-value is measured with HFM by imposing almost constant temperature gradient and by varying vapor pressure gradient. Hygrothermal simulations, including or not the presence of HFM, were carried out to support the experimental data. The key findings from this study are as follows:

- In absence of vapor pressure gradient, measured U-value match with theoretical and simulated U-values considering the experimental and numerical uncertainties and the experimental complexity.
- In the presence of vapor pressure gradient in the direction of temperature gradient (flowing from the outside to the inside), measured and simulated U-value increased up to 50 % due to the moisture accumulation in the less permeable walls and also due to the surface latent heat flow for the more permeable walls. This analysis should be extended to a broader range of materials and configurations to derive a universal equation that accurately defines the contribution of latent effects to the U-value.
- Adding moisture-tight HFM on the indoor surface to measure heat flux inherently blocks moisture transfer at the wall's surface in the presence of vapor pressure gradient. Only conductive contribution to U-value can be therefore measured and errors up to 18% can be made on U-value measurement. Further development of advanced testing methods that can fully capture the latent effects of vapor flow is welcome.

ACKNOWLEDGEMENTS

This work received financial support from ADEME through the Locabati project. Special thanks are extended to the Cellaouate company for providing the cellulose used in this study.

SUMMARY

The optical properties of building envelopes govern the inward and outward energy fluxes of a city; and therefore play a major role in urban overheating due to solar trapping. High reflectance (cool) materials have demonstrated a reduction in surface temperature of roofs with a high sky view factor, but their effects are limited to the upper floors of the buildings. To address the root cause of solar trapping, we must focus our attention on facades and roads, as these are the surfaces that contribute to multireflections in densely populated areas. We will showcase the interrelation between the shortwave optical properties of facades and the leading reflections within the canyon.

We have developed an analytical urban canyon model that integrates a detailed angular shortwave radiation description of materials. We aim to quantify the impact of the optical properties of building facades on solar trapping by analyzing the directionality of their reflections. We track the irradiance reflected toward the road and toward the buildings, as they will affect pedestrian thermal comfort and building cooling needs, respectively. We consider traditional materials (lambertian and specular) to evaluate the current situation, and innovative materials (retroreflective) to envision solar trapping mitigation strategies. Simulations are performed with an hourly time step for a year time period.

To verify the consistency of the model, we present the results for a mediterranean compact midrise neighborhood (H/W=1). During summer, for East-West facade orientations, glazed facades contribute to a 15 % increase of ground peak irradiance (equivalent to 85 W/m^2) compared to typical lambertian facades. The contribution of solar irradiance to thermal stress is evaluated with temperature sol-air indicator. Specular canyons result in a rise of 2°C in peak sol-air temperature. For a typical meteorological year, specular facades increase by 11 % (155) the sol-air degree-hours above 26°C, and increase by 132 % (145) the degree-hours above 40°C compared to lambertian facades. Future studies will focus on measuring the impact on thermal comfort and building energy performance at neighborhood scale.

Keywords: urban canyon model, urban radiative model, solar trapping.

1. INTRODUCTION

Urban overheating is a major problem in densely populated areas, leading to the degradation of thermal comfort and and increase in health problems (Santamouris, 2020). This positive energy balance is primarily driven by a radiative solar trapping phenomenon, resulting from a combination of multiple factors: (1) narrow and deep canyons, which facilitate shortwave multireflections and limit longwave cooling exchanges with the sky, and (2) high-capacity materials that store energy during the day and release it at night. Anthropogenic heat release (urban traffic and other contributions such as air conditioners), and the scarcity of green areas contribute to urban overheating.

High reflectance (cool) materials have proven to be an effective mitigation strategy to cool down surfaces with a high sky view factor (roofs). However, when applied to other urban surfaces (i.e. vertical facades), they increase the multireflections, what consequently penalize neighboring buildings and pedestrian comfort. In recent years, researchers have started to focus their attention toward retroreflective materials. These materials are engineered in such a way that they reflect the incoming shortwave radiation back toward the source and limit the multireflections with surrounding surfaces, hence solar trapping. Retroreflective materials have shown promising results when applied to urban facades both experimentally (Rossi et al., 2015) and numerically (Kyriakodis, Schiavoni, et al., 2023). They have proven to lower ground surface temperature, to improve in pedestrian thermal comfort and to reduce energy consumption.

This article aims to isolate shortwave radiation from other heat transfer mechanisms in order to build a fundamental understanding of how the shortwave directional properties of urban materials—lambertian, specular, and retroreflective—impact irradiance within an urban canyon. To achieve this, we have developed an analytical bidimensional urban canyon model.

2. METHODOLOGY

This section describes an bidimensional urban canyon model that we have developed.

2.1. Shortwave radiation model

This model describes the dynamics of shortwave radiation in an urban canyon. The total solar irradiance on a surface (E) is the result of the combination of the direct (beam) irradiance (E_b), the diffuse irradiance (E_d), as well as the multireflections between the surfaces (E^*), as described in Equation 1 (Duffie and Beckman, 2013).

$$E = E_\mathrm{b} + E_\mathrm{d} + E^* \tag{1}$$

Surface material properties are defined by their angular reflectance $\rho^\mathrm{mat}(\theta)$, which allows to compute the angular reflected irradiance of a material by considering the instantaneous beam irradiance. The novelty of this model is the explicit calculation of the first beam reflection $E_\mathrm{rb}^\mathrm{mat}$ as a function of the angular reflectance of the material (Equation 2). This allows to track the amount and the direction of this reflected radiation (material models explained in 2.1.3). The following reflections are computed following the radiosity model (Gros et al., 2011).

$$E_\mathrm{rb}^\mathrm{mat}(\theta) = \rho^\mathrm{mat}(\theta) \times E_\mathrm{b} \tag{2}$$

The sun position is defined by the solar elevation angle h_{sun} and the solar azimuth ϕ_{sun}. The urban canyon geometry is defined by the building height (H) and the street width (W). Each urban

surface is characterized by the tilt angle χ_{surf} measured with respect to the horizontal plane and an azimuth angle ϕ_{surf} defined clockwise with respect to the North. Solar masks link solar position with surface position, indicating for a given surface whether the surface is being irradiated or not for every time step. As observed in Equation 3, solar masks are defined as boolean Ψ_{surf} that are true if the surface is irradiated.

$$\Psi_{\text{surf}} = \sin h_{\text{sun}} \times (\cos(\phi_{\text{sun}} - \phi_{\text{surf}}) \times \sin \chi_{\text{surf}} + (h_{\text{sun}} > \arctan(H/W)) \times \cos \chi_{\text{surf}}) > 0 \tag{3}$$

For an irradiated surface, the total angle of incidence of the solar irradiance θ_{i} is computed with Equation 4. The angle of incidence is 0° if normal to the surface, and 90° if tangent.

$$\cos \theta_{\text{i}} = \cos h_{\text{sun}} * \cos(\phi_{\text{sun}} - \phi_{\text{surf}}) * \sin \chi_{\text{surf}} + \sin h_{\text{sun}} * \cos \chi_{\text{surf}} \tag{4}$$

The irradiated surface per meter depth of canyon of a vertical building facade ($x_{\text{s}}^{\text{bld}}$) and the street pavement ($x_{\text{s}}^{\text{pav}}$) are computed as a function of solar elevation and the canyon dimensions with Equations 5 and 6 respectively.

$$x_{\text{s}}^{\text{bld}} = \min(|W * \tan h_{\text{sun}}|, H) \tag{5}$$

$$x_{\text{s}}^{\text{pav}} = W - \min\left(\left|\frac{H}{\tan h_{\text{sun}}}\right|, W\right) \tag{6}$$

2.1.1. Reflection of building facades

When considering a vertical building facade, one can compute the total reflected irradiance in W/m (per meter of depth) toward the street and the building, as shown in Equations 7 and 8.

$$x_{\text{s}}^{\text{bld}}(t) * E_{\text{rb}}^{\text{bld}\to\text{pav}}(t) = \int_0^{x_{\text{s}}} \int_{-90}^{\theta_{\text{pav-bld}}} E_{\text{rb}}(\theta, t)\, d\theta\, dx \tag{7}$$

$$x_{\text{s}}^{\text{bld}}(t) * E_{\text{rb}}^{\text{bld}\to\text{bld}}(t) = \int_0^{x_{\text{s}}} \int_{\theta_{\text{pav-bld}}}^{\theta_{\text{bld-sky}}} E_{\text{rb}}(\theta, t)\, d\theta\, dx \tag{8}$$

Where the integration limits can be calculated with Equations 9 and 10. Note that the integration limits are computed at x, that stands for each of the 10 discretized elements of x_{s}.

$$\theta_{\text{pav-bld}}^{\text{bld}} = -90 + \arctan\frac{W}{H - x} \tag{9}$$

$$\theta_{\text{bld-sky}}^{\text{bld}} = 90 - \arctan\frac{W}{x} \tag{10}$$

2.1.2. Reflection on pavement

Similarly, when considering a horizontal pavement, one can compute the total reflected irradiance in W/m (per meter of depth) toward the building on the right with Equation 11.

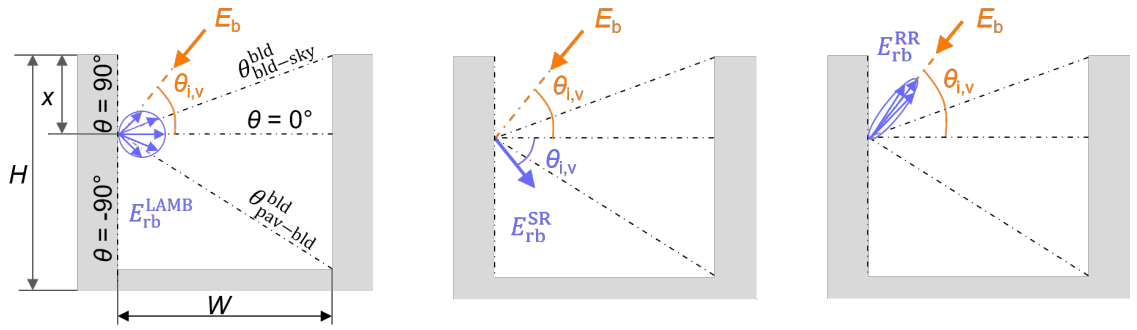
$$x_s(t) * E_{rb}^{\text{pav}\rightarrow\text{bld right}}(t) = \int_0^{x_s} \int_{-90}^{\theta_{\text{bld right}}} E_{rb}(\theta, t)\, d\theta\, dx \tag{11}$$

Equation 12 computes the integration limit of the equation above. Note that the integration limit is computed at x, that stands for each of the 10 discretized elements of x_s.

$$\theta_{\text{bld right-sky}}^{\text{pav}} = \begin{cases} -90 + \arctan\frac{H}{W-x}, & \text{if } \cos(\phi_{\text{sun}} - \phi_{\text{bld left}}) \geq 0 \\ 90 - \arctan\frac{H}{x}, & \text{otherwise} \end{cases} \tag{12}$$

2.1.3. Material models for first direct (beam) reflection

The definition the angular reflection material models is the key of this model. The three material models used in this study can be visualized in Figure 1: lambertian, specular and retroreflective.



(a) Lambertian (LAMB) **(b)** Specular Reflective (SR) **(c)** Diffuse Retroreflective (RR)

Figure 1. Schematic of the beam first reflection for urban canyons with (a) lambertian, (b) specular and (c) retroreflective facades.

Lambertian (LAMB, Figure 1a) model represents matte or rough diffuse surfaces such as concrete or paintings. The reflected irradiance directs toward every point in the space, as described by Equation 13.

$$E_{rb}^{LAMB} = E_b \int \rho^{LAMB} \cos\theta\, d\theta \tag{13}$$

Specular Reflective (SR, Figure 1b) model represents very smooth materials such as glazing. The reflected irradiance presents a form of a point ray in a direction that is symmetrical to the angle of incidence with respect to the facade, as described by Equation 14.

$$E_{rb}^{SR} = E_b \int \rho^{SR} \delta(\theta - \theta_i)\, d\theta \tag{14}$$

Diffuse Retroreflective (RR, Figure 1c) model represents innovative materials that reflect radiation mostly in the direction of incidence. The reflection follow a Lafortune lobe (with concentration factor $n = 15$), as described by Equation 15.

$$E_{rb}^{RR} = E_b \int \rho^{RR} \cos(\theta - \theta_i)^n\, d\theta \tag{15}$$

2.2. Metric for thermal stress

Temperature sol-air ($T_{\text{sol-air}}$) is the chosen indicator to measure the contribution of irradiance to thermal stress. This is a standard equivalent temperature that includes both convective and radiative heat transfer to calculate the temperature of the considered surface using the overall irradiance. It is calculated with Equation 16:

$$T_{\text{sol-air}} = T_{\text{amb}} + \frac{\alpha \times E}{h_{\text{e}}} \tag{16}$$

Where T_{amb} stands for the air temperature from the weather file, α is the material shortwave absorptivity and h_{e} is the equivalent (convective and radiative) heat transfer coefficient. According to the Standard EN ISO 6945 h_{e} is set to 25 W/Km^2.

2.3. Case study

This study analyzes an infinite urban canyon along the axis North-South located in a compact midrise neighborhood (H/W=1) with mediterranean climate (Nice, South of France) for a typical meteorological year. We aim to evaluate the impact of the optical properties of the urban surfaces (facades) on the solar irradiance distribution within the canyon and the pedestrian thermal stress. More specifically, we will compare lambertian reflection representing residential buildings with low window-to-wall ratio; specular reflection, representing glazed facade buildings of financial districts; and retroreflection, representing innovative facades with diffuse retroreflective properties.

To compare these three reflective properties in realistic conditions, typical material properties have been chosen according to Saint-Gobain database. lambertian facades are defined with 30 % albedo. Specular facades present an angular dependent albedo varying between 40 and 90 %, with average value of 50 % and an average absorption of 26 %. Retroreflective materials present an albedo of 60 %. The street presents an albedo of 15 % (Kyriakodis and Santamouris, 2018).

3. RESULTS

This section presents the results of irradiance and temperature sol-air for a North-South urban canyon (H/W=1) with a mediterranean climate.

3.1. Daily solar irradiance

June 23 has been selected as a representative day in summer, the closest to the summer equinox with high sky clearance. Figure 2 shows the total solar irradiance on a West facade and the ground analyzed on an hourly basis for the three materials examined in this study. Irradiance values are normalized by the area of the respective surfaces. Yellow shaded areas represent the solar direct and diffuse irradiance; dark and light pink shaded areas stand for the reflected radiation from the East and West facades respectively; green shaded areas represent the reflected radiation from the ground; and gray areas represents multireflections.

We can observe that the direct and diffuse irradiance components are consistent across all West facades and the ground. Peak irradiance occurs at 17:00 for the West facade and at 13:00 for the ground. The daily direct and diffuse radiant exposure amounts to 1800 Wh/m^2 for the West facade and 2900 Wh/m^2 for the ground.

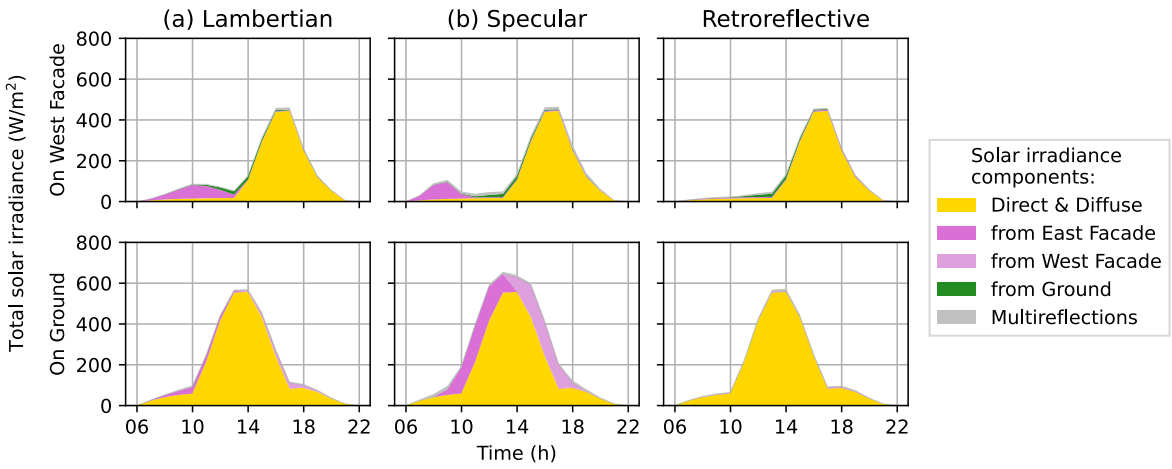


Figure 2. Total shortwave irradiance on West facade (first row) and ground (second row) on June 23 for a H/W=1 urban canyon with (a) lambertian, (b) specular and (c) retroreflective facades.

West facades in both lambertian and specular canyons experience a 230 Wh/m^2 (10 %) increase in radiant exposure compared to retroreflective canyons, primarily due to reflections from the east-facing facades. Specular East facades reflect solar irradiance toward the West facade in the early morning (before 10h), while lambertian east facades reflect irradiance until 13h. Peak irradiance remains equal for the three canyons. The contribution from the ground represents 3 % of the total daily irradiance.

The radiant exposure on the ground of a specular canyon is 970 Wh/m^2 higher than lambertian canyon and 1140 Wh/m^2 higher than a retroreflective canyon. Specular reflection by the East facade increases by 40 % the total daily irradiance on the ground compared to retroreflective canyons. Peak irradiance increases by 85 W/m^2 (15 %) due to specular reflection compared to canyons with lambertian and retroreflective facades.

3.2. Annual solar irradiance on facades

The total solar irradiance on the West facade for a typical meteorological year is presented in Figure 3 in terms of W/m^2 for every hour of the year for a H/W=1 urban canyon with lambertian, specular and retroreflective facades. Total irradiance includes direct, diffuse and reflections from the surrounding surfaces (East facade and Ground). White areas indicate no irradiance, dark intensity indicates higher irradiance.

We can observe that all lambertian, specular and retroreflective facades are irradiated between 13h and 20h, this corresponds to direct and diffuse irradiance, and reflection from the ground. Unlike retroreflective facades, that are only irradiated during these period, lambertian and specular facades are also irradiated between 6h and 13h due to reflections from the East facade. Specular facades present a thinner irradiated region during the morning period. Annual peak irradiance is up to 589 W/m^2 in both lambertian and specular canyons, 1.5 % higher than retroreflective facades. Regarding the daily radiant exposure for the year period, specular canyons increase the annual peak by 9 % compared to retroreflective canyons.

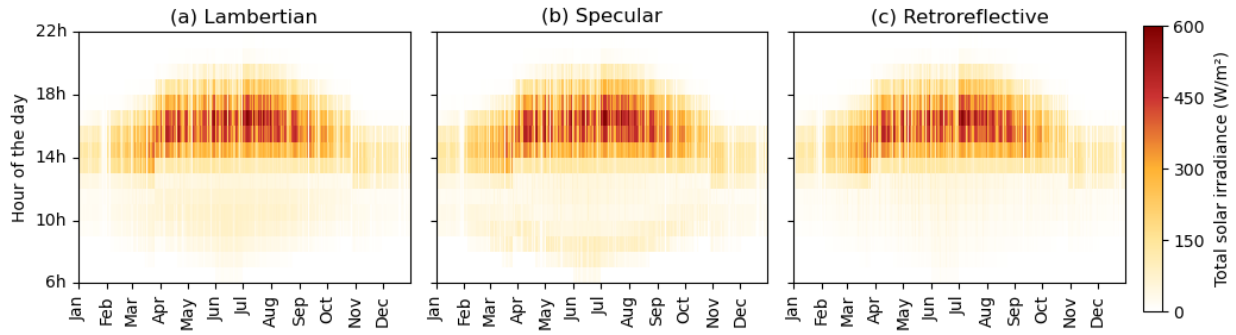

Figure 3. Total shortwave irradiance on West facade (direct, diffuse and reflections) for a H/W=1 urban canyon with (a) lambertian, (b) specular and (c) retroreflective facades.

3.3. Irradiance contribution to thermal stress

The temperature sol-air for the ground for a typical meteorological year is presented in Figure 4 for every hour of the year for canyons with lambertian, specular and retroreflective facades.

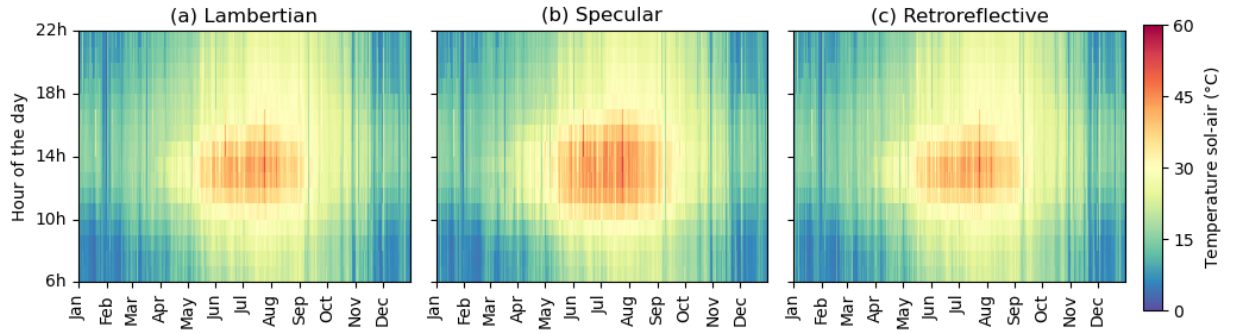

Figure 4. Temperature sol-air on ground for a H/W=1 urban canyon with (a) lambertian, (b) specular and (c) retroreflective facades.

Specular canyons lead to a maximum annual temperature sol-air of 54°C, that is 2°C higher than lambertian and retroreflective canyons. Specular canyons lead to 1555 degree-hours/year of temperature sol-air above 26°C, that is 155 degree-hours (11 %) more than lambertian canyons and 210 degree-hours (16 %) more than retroreflective canyons. Sol-air temperatures above 26°C occur between April and October.

Specular canyons result in 255 degree-hours per year of sol-air temperatures exceeding 40°C, which is 145 degree-hours (132 %) higher than lambertian canyons and 150 degree-hours (143 %) higher than retroreflective canyons. These sol-air temperatures above 40°C are observed between May and August.

4. CONCLUSIONS AND PERSPECTIVES

This study aims to improve our understanding of shortwave irradiance and interreflections between surfaces by examining typical materials—Lambertian, specular, and retroreflective. To achieve this, we developed a bidimensional urban canyon model that accounts for the angular reflectance of these materials. Our findings demonstrate consistent differences between the three models, emphasizing the need for caution when using radiosity algorithms to model all surfaces within a neighborhood, especially in the presence of large specular surfaces.

For an urban canyon with a height-to-width ratio of $H/W = 1$ in a Mediterranean climate (Nice, South of France), specular facades (with angular-dependent albedo ranging from 40 % to 90 %) result in a 15 % increase in peak irradiance on the ground (85 W/m^2) compared to lambertian (30 % albedo) and retroreflective (60 % albedo) canyons. This increase in peak irradiance contributes to a higher thermal stress, measured using the sol-air temperature indicator. Specifically, specular canyons lead to an increase of 225 degree-hours per year (+143 %) above 40°C compared to lambertian canyons. This study highlights the strong correlation between shortwave radiation directionality and thermal stress.

Beyond this first approach to demonstrate the issues of specular materials in dense cities and the potential of innovative retroreflective materials, we will exploit this fast analytical model (1 minute calculation time for an annual analysis) to perform an extensive parametric analysis on aspect ratio, street orientation and geolocation for different materials. Besides we are conducting an experimental validation and intermodel comparisons that will be published soon. Then, we will develop a three-dimensional multiphysics model to asses neighborhood configurations and quantify the impact of urban surfaces on thermal comfort and building energy performance, building upon the promising results presented by Kyriakodis, Schiavoni, et al. (2023).

SUMMARY
To accurately evaluate the performance of deep energy retrofits in future climates, validated building energy models are required. In this study, energy and hygrothermal models representing a pilot deep energy retrofit were created using EnergyPlus 23.1 and DELPHIN 6.1, respectively. Base case models were created using building specifications and conservative assumptions. Using data for both measured energy use and envelope conditions from the building as well as previous models, the initial model variables were manually tuned such that energy use, envelope temperature and moisture were calibrated. Energy models were assessed using established thresholds for Normalized Mean Bias Error (NMBE) and Coefficient of Variation of Root Mean Square Error (CV(RMSE)). Hygrothermal models were assessed visually and with previously proposed thresholds for Mean Absolute Error (MAE) and Pearson Correlation Coefficient (r). Final calibration levels for the energy models and preliminary calibration levels for the hygrothermal models are presented. The models can be used to assess this retrofit type under different future weather scenarios as well as to develop a co-simulated energy-hygrothermal model that streamlines the modelling process.

Keywords: energy modelling, hygrothermal modelling, calibration

1. INTRODUCTION

Building energy and hygrothermal models can be effective tools in assessing the performance of deep energy retrofits, through predictions of energy savings and improvements to occupant comfort as well as evaluating any durability risks in the new envelope. However, confidence in model predictions is limited if the models are not calibrated (Huerto-Cardenas et al. 2020; Dang et al. 2023). This is often achieved by comparing model outputs with measured outputs from the building using established metrics and thresholds. Common outputs include utility usage for energy models, or temperature and moisture measurements in the wall assembly for hygrothermal models. The level of calibration required for energy models is set out in several standards, while no current standard exists for hygrothermal models (Huerto-Cardenas et al. 2020).

The motivation for this study was to develop calibrated energy and hygrothermal models of the same building by applying existing calibration strategies. The calibrated models can then be used to assess the future performance of the design under various environmental conditions. To achieve this, multi-zone energy and one-dimensional hygrothermal models in EnergyPlus 23.1 and DELPHIN 6.1 representing a retrofitted semi-detached residential building were created. Measured utility data was used to calibrate the energy models, with ASHRAE Guideline 14 thresholds serving as the calibration standard (ASHRAE 2014). The hygrothermal models utilized recently proposed metrics and thresholds that have been applied in a guarded hot box calibration

experiment (Huerto-Cardenas et al. 2020; Hilbrecht 2024). To reach calibration, input variables of the models with uncertainty were manually tuned in a stepwise manner.

2. METHODOLOGY

2.1. Case Study Building

The building is a retrofitted community housing unit in Ottawa, Canada, shown in Fig. 1. The east unit (rightmost, Fig. 1) was modelled, with an above grade volume of approximately 6.89m x 7.95m x 5.85m. It was selected for the available data on the project that could be used to calibrate the model. Four years of pre-retrofit electricity usage data (on an hourly basis), and two years of natural gas usage via monthly billing data were available. Post-retrofit, sub-divided usage of the new HVAC, water heating, and plug loads were available at hourly intervals. The cross section of the pre and post retrofit wall assemblies are shown in Fig. 2. Sensors were installed in various layers of the exterior retrofitted envelope to record temperature, moisture content and relative humidity (RDH Building Science 2021, Carver and Dicaire 2021).

Figure 1. Case study building before and after retrofit (Dicaire and Carver 2023).

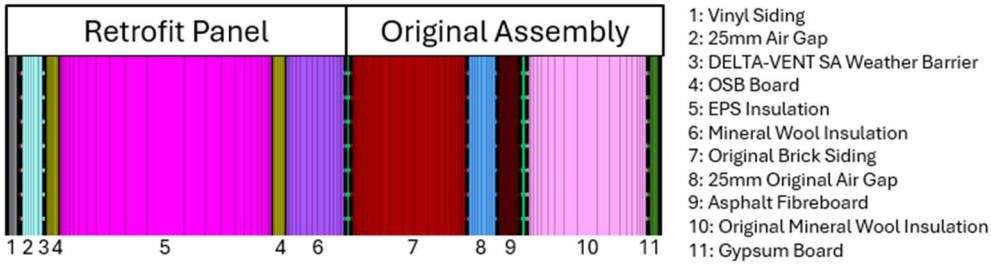

Figure 2. Cross section of pre (right) and post (left) retrofit wall assemblies.

The original building envelope was a brick veneer, wood framed construction built in 1960. It was heated by a central air natural gas furnace with no central cooling; however, most units had installed window-mounted air conditioning units for cooling. Domestic hot water (DHW) was heated by natural gas.

The deep energy retrofit used an exterior, prefabricated panelized construction (layers 1-6 in Fig. 2). A new roof was also installed, coupled with solar PV added to the south facing roof. Cold climate air source heat pumps replaced the furnace and included a backup electrical resistance furnace. The DHW was upgraded to a heat pump water heater, also air source.

2.2. Energy Models

Monthly electrical and natural gas usage in the models were assessed against the measured data using the NMBE and CV(RMSE) as shown in Eq. 1 and Eq. 2 (ASHRAE 2014). Although the measured electrical usage was provided on an hourly basis, it was summed for each month. This was done to reduce variability in plug loads related to occupancy, since the small number of people living in the building would have an outsized effect on total usage. Next, although four years of data was available for the electrical usage, it was apparent that a vacancy and change in occupancy significantly altered the usage in the building during periods of time. Thus, 2017 was used for calibration since it showed consistent occupancy and aligned with the only full calendar year of natural gas data provided.

$$NMBE(\%) = \frac{1}{\bar{m}} \frac{\sum_{i=1}^{n}(m_i - s_i)}{n-p} \times 100 \quad (1)$$

$$CV(RMSE) = \frac{1}{\bar{m}} \sqrt{\frac{\sum_{i=1}^{n}(m_i - s_i)^2}{n-p}} \times 100 \quad (2)$$

Occupancy preferences, weather files, air infiltration and ground heat transfer are some of most significant factors affecting energy model outputs (Beausoleil-Morrison 2020; Mahdavi and Tahmasebi 2019; Chen 2015). Building airtightness was tested pre- and post-retrofit through a blower door test. The infiltration at 50 Pa retrieved from the testing was scaled down to natural air pressures to extract values used by EnergyPlus to calculate a wind dependant infiltration rate. Ground heat transfer was calculated using KIVA, which has been shown to produce reliable results (Kruis and Krarti 2017). To reduce uncertainty in exterior conditions, actual year weather files (AMY) were created using data from Environment and Climate Change Canada and NASA Power databases for the calibration year.

Remaining variables with large uncertainty were occupant influenced. This included water use, thermostat setpoint, and internal heat and moisture gains from occupancy presence and appliance use. The water use schedule was selected from published averaged data (Edwards et al. 2013). Water use quantity was then tuned for natural gas usage until the annual water usage approached estimates from the pre-retrofit energy audit data. Thermostat setpoints were used to further calibrate natural gas consumption, since no information regarding setpoints were available. Occupancy schedules were first set with profiles from Mitra et al. 2020 but were changed to seasonal daily averaged profiles of the usage data. Internal gains magnitude was a summed amount of appliance values taken from the ASHRAE Handbook of Fundamentals (ASHRAE 2023).

For the post-retrofit model, envelope layers were added to reflect the exterior panels installed. Infiltration inputs were updated based on the second blower door test results. HVAC and DHW system models were revised to represent post-retrofit electrification. Since the post-retrofit usage data was sub divided into HVAC, water heating, and plug loads, the electrical usage of each device was output monthly and compared to the measured data.

2.3. Hygrothermal Models

2.3.1 Pre-Retrofit Model

The pre-retrofit hygrothermal model was not calibrated using statistical metrics like Eq. 1 and Eq. 2 since there was no temperature and moisture data for the original wall. Thus, an inter-model comparison was used to assess model calibration (Dang et al. 2023). A base case of the pre-retrofit assembly was created in DELPHIN 6.1, then simulated and compared to previous models of the same construction in WUFI Pro 6 (McNally 2022).

Materials were taken from the closest material in the DELPHIN database, with a focus on similar default values of thermal conductivity and water absorption coefficient, and numerical properties were changed to match the WUFI database materials to be consistent with previous models (McNally 2022; Natural Resources Canada, 2023). Existing moisture functions were automatically scaled by DELPHIN based on the numerical value changes. Air and moisture sources were applied to layers of the assembly using best practices for hygrothermal modeling and ASHRAE Guideline 160 (Wright et al. 2021). This included exterior air infiltration in the original air gap (layer 8, Fig. 2) of $10\frac{1}{h}$, 1% of wind driven rain (WDR) applied to the interior elements of the brick (layer 7, Fig. 2), and 0.01% WDR applied to the exterior elements of the fibreboard (layer 9, Fig. 2). The model was run for four years with the ASHRAE Year Three moisture reference year weather file for Ottawa. The moisture content in the brick and fibreboard were compared to previous WUFI models to see if quantities and trends were the same.

2.3.2. Post Retrofit Model

The post-retrofit model added layers 1-6 in Fig. 2 to the pre-retrofit model and included new sources of air and moisture exchange. A multi-run process was used for calibration that has been previously applied to WUFI models (Lstiburek et al. 2016; McNally 2022).

Pre-retrofit rain sources in layers 7 and 9 were removed since rain no longer penetrated these layers. Air infiltration in layer 8 was removed to reflect the air sealing that occurred. New exterior infiltration was placed in the layer 2 air gap behind the vinyl cladding. An additional infiltration source was placed between layers 6 (mineral wool) and 7 (brick) via a 5 mm air gap. WDR sources of 1% and 0.01% were added just behind layers 1 and 4. The vinyl rain source was facilitated using a thin brick layer, consistent with previously calibrated models (McNally 2022). An interior infiltration source was applied between the original fibreboard and mineral wool layers.

Initial conditions were determined from the end of a one-year simulation using a 2021 AMY weather file and moisture content taken from the end of the construction period calibration process completed in WUFI Pro 6. The calibration period comprised of a one-year simulation using a 2022 AMY weather file. Calibration was achieved using an approach based on previous work by McNally 2022. This was selected for its novel application of tuning infiltration source levels variables via the multi-run methodology in WUFI. Ranges of infiltration rates for each air gap were selected from experimental data by Finch and Straube 2007. Here, DELPHIN's scripting capability allowed for all combinations of each infiltration rate to be simulated quickly, the calibration metrics were calculated for each variant. The best variants selected for further refined runs with narrower gaps between infiltration values. The methodology could later be adapted to work within an optimization framework using calibration statistical metrics.

The inner OSB layer was expected to be an at-risk material and was the primary focus of the

calibration. First, measured and modelled moisture content curves were plotted to see if they showed similar magnitudes and trends over the calibration period. Next Eq. 3 and Eq. 4 were computed to assess model calibration (Huerto-Cardenas et al. 2020). These metrics have been shown to better articulate the accuracy of hygrothermal models, compared to the metrics used for assessing energy models (Huerto-Cardenas et al. 2020).

Model output of the moisture mass density (kg/m^3) in the inner OSB, $MC_{\text{OSB-abs}}$, was converted to a percentage, $MC_{OSB}\,(\%)$, using Eq. 5 for easy comparison to the calibration thresholds. The density of the material, ρ_{OSB} (kg/m^3), was taken from the material data file. Once Eq. 3 and Eq. 4 approached the threshold values, the outer OSB, new batt insulation, and rainscreen layers were examined to verify overall model agreement.

$$MAE = \frac{\sum_{i=1}^{n}|m_i - s_i|}{n} \tag{3}$$

$$r = \frac{\sum_{i=1}^{n}(m_i - \bar{m})\times(s_i - \bar{s})}{\sqrt{\sum_{i=1}^{n}(m_i - \bar{m})^2}\times\sqrt{\sum_{i=1}^{n}(s_i - \bar{s})^2}} \tag{4}$$

$$MC_{OSB}(\%) = \frac{MC_{OSB-a}}{\rho_{OSB}} \times 100\% \tag{5}$$

3. RESULTS

3.1 Energy Models

Calibration was considered complete as soon as model outputs met ASHRAE Guideline 14 thresholds. Table 1 shows the achieved level of calibration in electrical and natural gas energy against the threshold value for select metrics, and Fig. 3 and Fig. 4 provide monthly insight into the month-by-month comparison of the models predicted usage versus the measured actual use.

Table 1. Final values of calibration metrics achieved for energy models.

Metric	ASHRAE Threshold	Pre retrofit electricity	Pre retrofit natural gas	Post retrofit heating and cooling	Post retrofit hot water
NMBE (%)	±5	0.42	-3.18	-4.3	-1.14
CV(RMSE) %	15	14.43	12.88	14.98	8.53

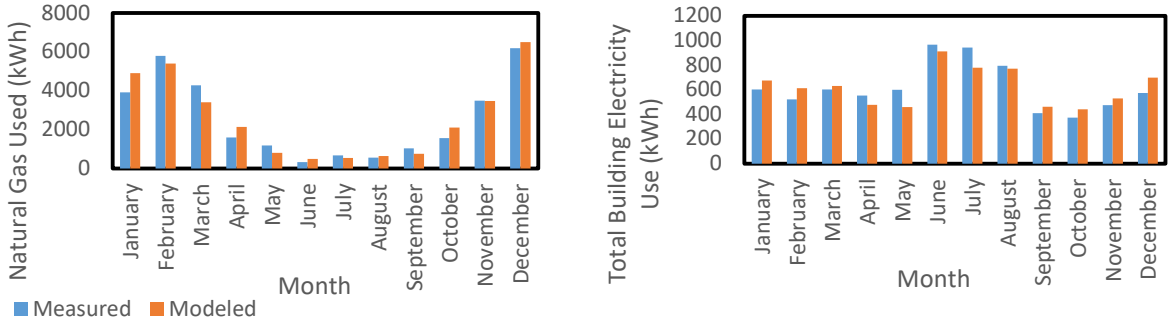

Figure 3. Monthly energy usage of building pre retrofit. Natural gas (left) and electricity (right).

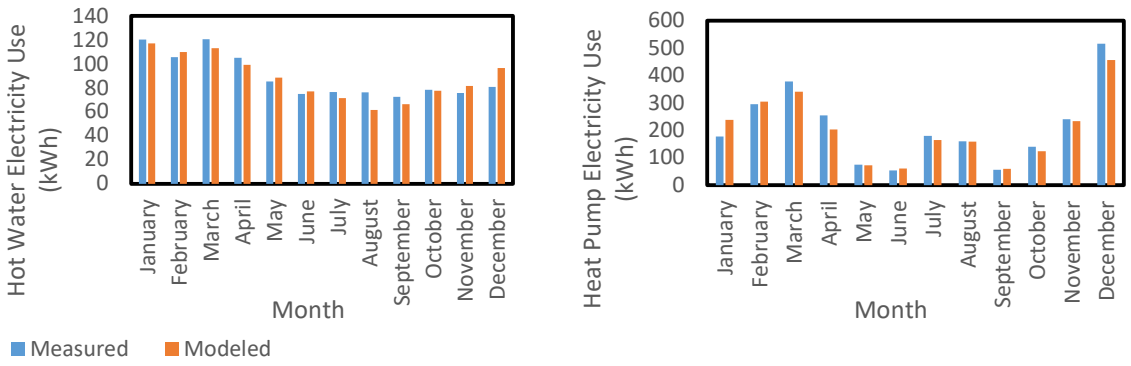

Figure 4. Post retrofit hot water (left) and heat pump (right) electricity usage.

3.2. Hygrothermal Models

The moisture content of the fibreboard and brick layers over the pre-retrofit simulation are shown on Fig. 5. Compared to previous WUFI models, the fibreboard moisture content profile shows similar cyclic behaviour of wetting and drying year on year in magnitude and timing (McNally 2022). The brick moisture content profiles also show similar behaviour through the simulation, but the DELPHIN model predicts lower moisture contents by 20-30kg/m^3. This likely results from limitations in transferring the customized moisture functions of the brick material into DELPHIN. Given the air sealing that occurred as part of the retrofit, if moisture levels in the brick do not increase, this deviation is acceptable as there was no mould risk at the brick interface in either model. While this cannot be considered full calibration, given the lack of in-situ data available pre-retrofit, equivalent results between this model and the previous WUFI model represent a strong likelihood of model conditions and behaviour in the envelope that matched the original building.

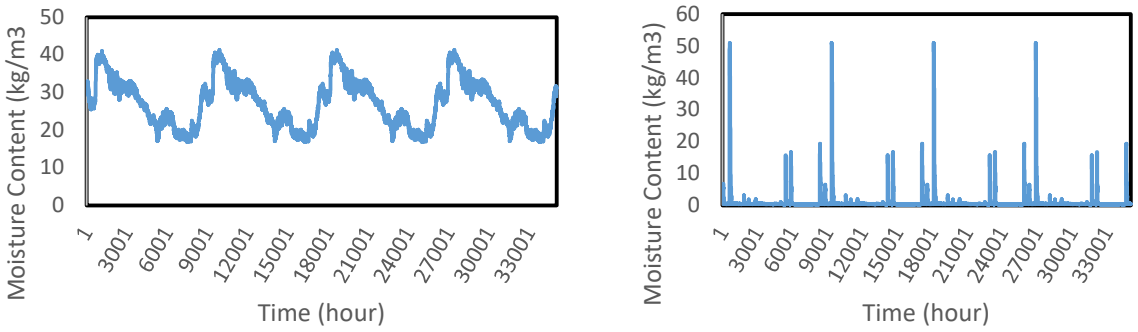

Figure 5. Year on year moisture content in fibreboard (left) and brick (right) layers pre retrofit.

Table 2 summarizes the calibration level in each layer of the post-retrofit assembly. Only the lower threshold was reached for MAE, while all layers met the single threshold for R-value with differing degrees of success. Note, the model with the lowest MAE for the inner OSB was not selected as the best case due to poorer performance among other layers. The model outputs are compared to

the measured levels in Fig. 6. Despite the satisfactory level of performance of Table 2 metrics, the difference in trends of the moisture content in OSB layers suggests the level of calibration can be improved upon. Thus, these results are presented as a preliminary level of calibration. It is estimated that uncertainty in material properties is a possible cause, since both the DELPHIN and WUFI libraries contain multiple OSB material files. Although the infiltration rates are constant, which does not reflect changing conditions in the wall, previous work has shown static infiltration rates can result in good calibration. Here, a static infiltration rate in the air gap placed next to the Squishy insulation layer resulted in an excellent result.

Table 2. Model details and calibration level achieved for calibrated model.

Metric	Proposed LV 1 Threshold	Proposed LV 2 Threshold	Inner OSB Moisture Content (%)	Outer OSB Moisture Content (%)	Squishy Insulation RH (%)	Rainscreen RH (%)
MAE	< 5%	< 10%	6.34	5.89	5.07	10.94
r	> 0.5	N/A	0.80	0.78	0.69	0.53

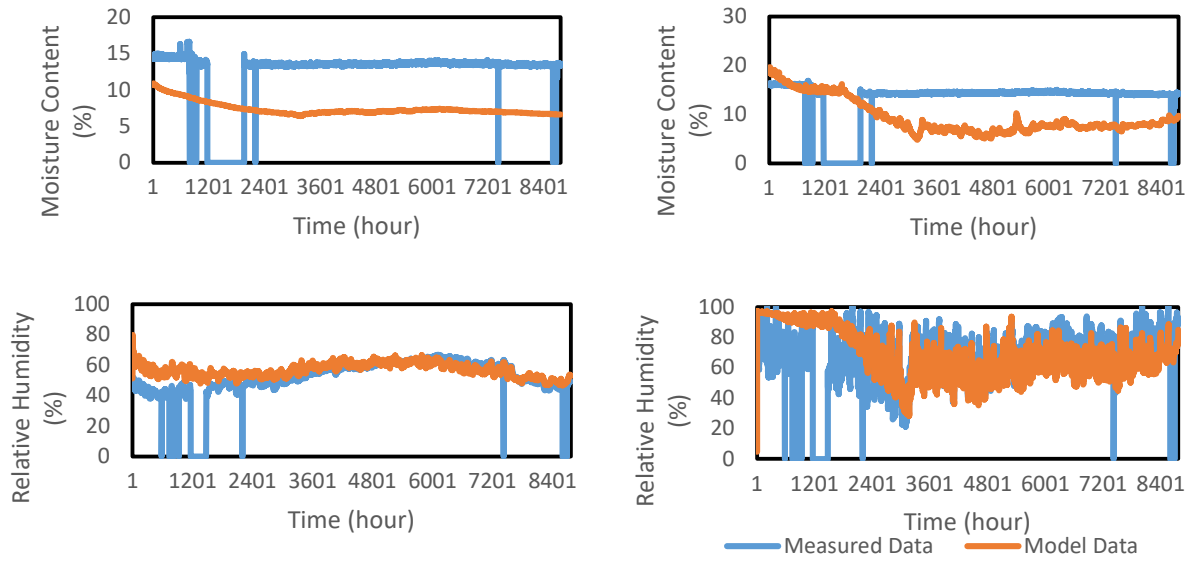

Fig 6. Moisture content and relative humidity of inner (top left), outer (top right) OSB layers, mineral wool (bottom left) and rainscreen (bottom right).

4. CONCLUSIONS AND FUTURE WORK

This study outlined the calibration process for energy and hygrothermal models of a pilot project undertaken in Ottawa, Canada. Both energy models met established thresholds by varying building variables with greatest uncertainty, while the hygrothermal models applied proposed thresholds and a recently developed calibration methodology with moderate success.

Improvement to hygrothermal model calibration will be attempted using different OSB material options in the DELPHIN database. Given the uncertainty of material properties from different sources and locations, and the potential for different amounts of infiltration in the assembly due to

poor assembly or lack of maintenance, future hygrothermal calibration may benefit from increased use of stochastic modelling techniques. This way, uncertainty in the calibration can be quantified. Finally, all models will be simulated under future weather conditions to assess whether climate change reduces the effectiveness or durability of the retrofit.

SUMMARY
Improving the building envelope's thermal insulation can lead to significant thermal load reduction and save energy. Prefabricated insulated panels are often applied to the exterior surfaces of the existing building facade in a deep building energy retrofit. However, few studies have been done to assess the hygrothermal performance of the retrofitted assembly in an occupied building. Considering the airtightness level of the panel-to-panel seams, the presence of an air gap between the existing façade and the new insulation panels can lead to increased heat loss through exfiltration, risk of moisture condensation and significant reduction in the effective thermal resistance of the building envelope if the air leakage and vapor transport are not controlled properly in the wall assembly. There is a need to quantify air and airflow conditions in these air gaps and how they impact the overall panel performance under different climatic conditions in order to better define requirements for retrofitting material system design and building operation. This paper presents a post-retrofit hygrothermal analysis to evaluate the performance of a retrofit assembly consisting of insulated Expanded Polystyrene insulation foam panels. The new panel system was installed at a dormitory building at Syracuse University's campus. The existing external enclosure includes pre-cast concrete and wood-framed wall assemblies. Measurements included heat flux, surface temperature, relative humidity, and air temperature and humidity on both the interior side of the existing assembly and exterior of the new insulated panels, as well as the air temperature and relative humidity inside the air cavity. The study investigates the hygrothermal performance of the entire assembly using data collected from September to December 2024. Results show that the mean effective R-value of the whole assembly after retrofit was 6.02 $m^2 \cdot K/W$, representing 5.44 times increase over the pre-retrofit condition on average. The air cavity data analysis revealed an average temperature difference of 4.01°C (summer) and 9.47°C (winter) for the top and base sections for the concrete wall, and 3.17°C (summer) and 9.76°C (winter) for the top and base sections for the wood-framed wall, indicating a significant vertical temperature gradient due to little to no air mixing inside the wall cavity. The local hygrothermal analysis showed that the new insulation material absorbed less moisture at low temperature winter days indicating vapor diffusion capability of the retrofitting panel but under warm temperature summer condition, the panels adsorbed more moisture from the outside air at the night and released them into the indoor space during the day. These findings contribute to the understanding of the hygrothermal dynamics in retrofit panel systems and provide valuable insights for optimizing future building envelope retrofits, improving performance across varying climatic conditions.

Keywords: Hygrothermal performance, External wall insulation system, Building envelope.

1. INTRODUCTION

In the United States, buildings account for more than 70% of total electricity consumption and they are a major source of carbon emissions (IEA, 2018). Older residential buildings, particularly those constructed before 1950, dedicate 54% of their energy usage to space conditioning, in

contrast to 43% for homes built between 2000 and 2009 (EIA, 2009). With ambitious climate goals to reduce greenhouse gas emissions, the United States has aligned on the vision to reach a net-zero-energy building stock by 2050 (Biega & Krarti, 2024). Achieving this goal will necessitate significant advancements in energy efficiency for both new constructions and existing buildings. In particular, the retrofit effort will require a blend of strategies, including the broader adoption of energy efficient electrification technologies, the development of grid-interactive communities, as well as building envelope upgrades. Improving the building envelope's thermal insulation can lead to remarkable energy savings in existing buildings. One of the most promising technologies for building envelope energy retrofitting is prefabricated panelized exterior insulated envelope systems (Mirzabeigi et al., 2023). While prefabricated insulated wall assemblies are widely available for new construction, the market offers very few options specifically designed for retrofit applications. Exterior insulated retrofit panels can be applied on the exterior envelope of existing buildings to considerably improve insulation and airtightness while also offering potential aesthetic improvements. These improvements are essential for achieving better-performing residential buildings. Given the pivotal role of the building envelope in retrofit strategies, evaluating their hygrothermal performance is essential for understanding pre-retrofit conditions and validating improvements made through retrofitting (Recart & Sturts Dossick, 2022). The term hygrothermal refers to the movement of heat and moisture through buildings. However, there are few studies that have assessed their hygrothermal performance in an occupied building (Choi et al., 2023). Considering the airtightness level of the panel-to-panel seams, the presence of an air gap between the existing assembly and the new insulation represents hygrothermal advantages and disadvantages (Recart et al., 2023). Therefore, there is a need to quantify air gap conditions and the overall panel performance under different climatic conditions (Byrne et al., 2016). This paper presents a post-retrofit hygrothermal analysis to evaluate the performance of an integrated energy efficiency retrofit assembly with exterior insulated insulation foam panels.

2. DESCRIPTION OF THE CASE STUDY

The case study is a two-story multifamily townhouse-style building, that consists of 8 units and is located on Syracuse University's South Campus. It was originally constructed in 1972-1973. The exterior walls consist of pre-cast concrete and wood-framed walls. The pre-cast walls have 1-inch closed-cell extruded polystyrene foam for a wall area of 175.98 m^2. The 2 by 4 wood-framed walls have 3.5 inches of fiberglass batt insulation for a wall area of 205.46 m^2. Fig. 1 shows the exterior view of the pre- and post-retrofit condition of the building and monitoring locations on the architectural plans.

The project's whole-building retrofit approach includes highly insulated prefabricated exterior building envelope panels for improved thermal performance and airtightness at the walls, roof, and foundation, and high-efficiency integrated mechanical pod solution with real-time performance monitoring for heating, cooling, ventilation, and domestic hot water. In particular, the building envelope panels are prefabricated, reinforced, insulated Expanded Polystyrene (EPS) foam exterior panel system with air-sealing at seams and penetrations for mechanicals, windows, doors, foundation, and sealant and backer rod for continuous seal for air and moisture barrier. The system provides varying thicknesses (6"-7-1/2") for integration with existing wall construction. Fig. 2 shows the panel composition with typical vertical and horizontal connection sections.

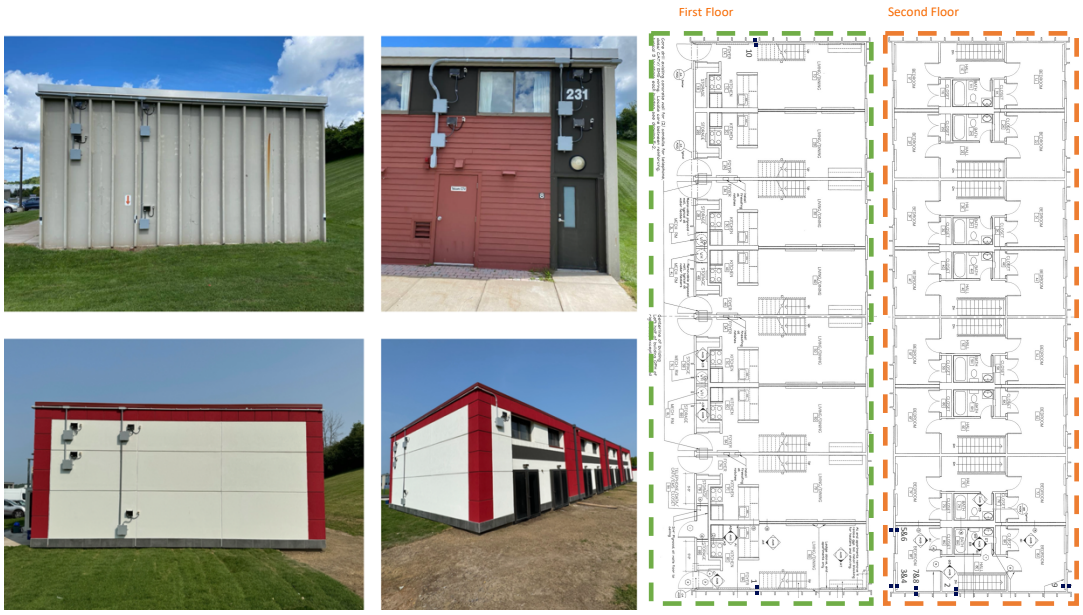

Figure 1. Exterior views of the pre- and post-retrofit condition of the case study building (left) and monitoring locations on the architectural plans (right).

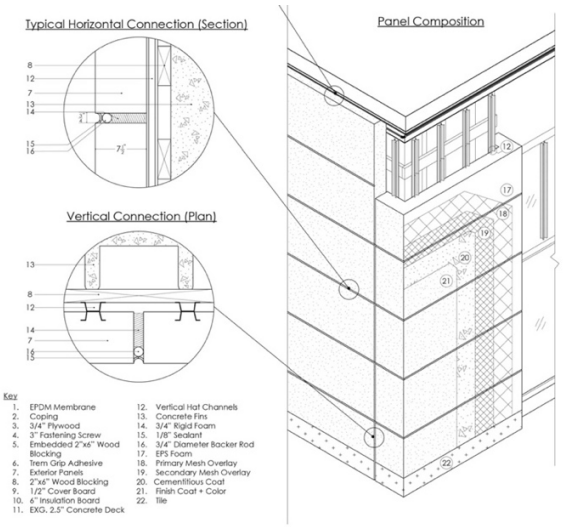

Figure 2. Panel composition with typical vertical and horizontal connection sections.

3. METHODS

This section is divided into: (1) the description of the sensing method, which combines the integration of in-house developed interior and exterior sensor packages and the wireless LoRa sensors for measuring temperature and humidity inside the air gap; and (2) the explanation about the framework the approach for quantification of the R-value of the post-retrofit whole assembly.

3.1. Sensing Method

For each monitoring location shown in Fig. 1, there are three measurement spots including interior surface of the existing wall, inside the air gap, and exterior surface of the newly added insulation panel. For the interior and exterior wall measurements, we developed custom sensor packages

(Mirzabeigi et al., 2025). The full description of the experimental setup and data collection method is provided in Mirzabeigi et al., (2025). Each monitoring location (interior and exterior) is equipped with an Arduino micro-controller, Wi-Fi radio, analog-to-digital converter, power module, and sensor module. Two sensor modules are a mated pair through the Bluetooth radio configuration. There is also one central sensor gateway that is responsible for monitoring and controlling the package communication, in addition to pushing data to the database for storing purposes. The sensor module consists of a heat flux thermocouple pile (with Sensitivity of 1 μV/(W/m^2)), type T thermocouples (±1°C or ±0.75%), surface Relative Humidity (RH) (± 3.5%), and a BME 688 environmental sensor (for monitoring local air temperature (±1°C) and RH ((± 3.5%)). Interior packages were powered by wall outlets. For measuring the air temperature and humidity, LHT65N Dragino sensors (±0.3 °C with 0.1°C resolution for temperature measurement and ±3% RH with 0.5% RH resolution) are utilized that are connected to a central gateway for sending the data to the cloud for storing purposes. In addition to measuring interior surface, inside air gap, and exterior surface of those ten monitoring locations (used for pre- and post-retrofit), more sensors were utilized to characterize the air gap conditions at four height levels. Fig. 3 highlights the location of these sensors on two vertical sections of pre-cast concrete and wood-framed walls on the south and west elevation of the building.

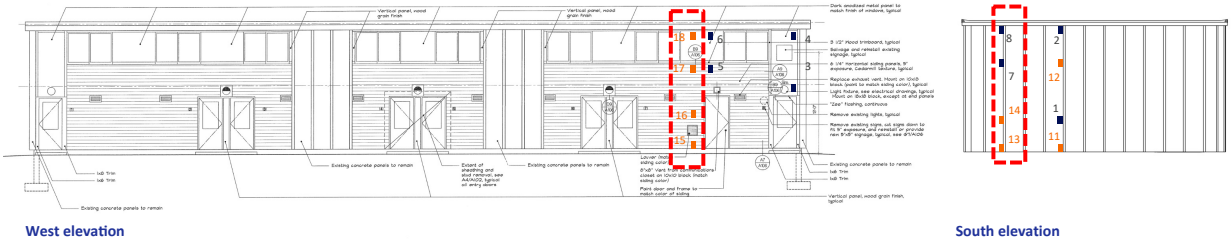

Figure 3. Location of air gap sensors for two vertical sections of pre-cast concrete and wood-framed walls on the west and south elevation of the case study building.

3.2. R-value Calculation Method

The calculation of R-value is in accordance with the ASTM C1155-95 - Standard Test Method for Determining Thermal Resistance of Building Envelope Components from the In-Situ Data (ASTM, 2021). The effective thermal resistance will be calculated from measured in-situ temperature difference among interior and exterior surface temperatures and interior heat flux data by using summation technique over time. The estimation of the effective thermal resistance is calculated by using summation technique (see Eq. (1)).

$$R_e = \frac{\sum_{k=1}^{M} \Delta T_k}{\sum_{k=1}^{M} q_k} \tag{1}$$

In this equation, R_e is thermal resistance ($m^2 \cdot K/W$); M is number of values of ΔT and q in the source data; ΔT is difference in temperature between interior and exterior surface (K); k is counter for summation of time-series data, and q is heat flux (W/m^2). To determine the time to compute the estimate thermal resistance, the convergence factor (CR_n) is calculate from Eq. (1), with n time units. At selected time, CR_n remains below 0.1 for at least 3 periods of length n to evaluate if the calculated thermal resistance of the building component is acceptable or not

$$CR_n = \frac{R_e(t) - R_e(t-n)}{R_e(t)} \quad (2)$$

4. RESULTS AND DISCUSSION

A detailed analysis of the post-retrofit performance of the integrated exterior building envelope retrofitting system was performed, incorporating field-measured data collected from the case study. The hygrothermal performance of the system was assessed by measuring key parameters such as interior and exterior surface temperature, RH and heat flux and air temperature and RH inside the air gap across various locations for both pre- and post-retrofit conditions. The analysis is focused on the post-retrofit performance of the whole assembly with the insulated panel system.

4.1. Temperature and Humidity Conditions in the Air Gap

For the air gap, a detailed analysis was performed for two vertical sections of pre-cast concrete (location 7, 8, 13, and 14) and wood-framed walls (location 15, 16, 17, and 18) of the building. A detailed analysis of the temperature, absolute humidity and RH for the pre-cast concrete wall for summer (September 1 - 7) and winter (December 1-7) was provided in Fig. 4. The analysis reveals that the air gap behaves differently at various elevations, with the top section generally exhibiting higher temperatures and lower RH values compared to the base section. In warm conditions, daytime temperature differences between the top and base of the concrete wall averaged 4.01 °C, and nighttime differences averaged 3.73 °C. For the wood-framed wall, these differences were smaller, with daytime values of 3.17 °C and nighttime values of 3.15 °C. By contrast, in cold conditions, daytime temperature differences increased to 9.47°C for the concrete wall and 9.76 °C for the wood-framed wall. Nighttime differences were slightly higher at 9.80 °C for the concrete wall and 10.05 °C for the wood-framed wall, reflecting stronger vertical gradients during colder conditions. This stratification, especially under colder conditions, suggests the presence of natural convection within the cavity. However, as air velocity was not directly measured in this study, this remains a hypothesis that should be validated in future investigations. Additionally, thermal bridging at panel joints and penetrations may have influenced localized heat flow and further analysis is needed to quantify that effect. Future acknowledged modeling work will incorporate these variables to assess their long-term impact on hygrothermal performance. Outdoor air shows consistently lower absolute humidity values overall. The concrete top layer generally shows higher temperatures and absolute humidity, but lower relative humidity compared to other layers, indicating it absorbs and retains more heat and moisture. In summer, absolute humidity differences between the top and base sections were 1.01 g/m³ during the day and 1.12 g/m³ at night for the concrete wall, while the wood-framed wall exhibited values of 0.87 g/m³ and 1.12 g/m³, respectively. In winter, these differences were smaller, with values of 0.96 g/m³ (day) and 0.99 g/m³ (night) for the concrete wall, and 0.41 g/m³ for both day and night for the wood-framed wall. The Concrete base layer remains cooler and more humid, likely due to due to air behavior, the proximity to the ground and the insulating effect of the building's foundation.

Day and night dynamics provide further insights into the hygrothermal performance of the system. During warm summer nights, cooler external air led to moisture adsorption by the insulation material, as seen in rising absolute humidity values inside the air gap. During the day, solar radiation and increased cavity temperatures facilitated desorption, releasing moisture into the cavity air. By contrast, in winter, lower ambient temperatures and reduced vapor pressures resulted in reduced moisture exchange, with moisture gradients remaining relatively stable throughout the day. This temperature and moisture retention pattern, particularly in the concrete walls, supports the hypothesis that the air cavity plays a significant role in the overall hygrothermal performance of the system. The air cavity, a critical feature of the retrofitted system, showed notable temperature and humidity gradients across different sections. An interesting observation was made

regarding the moisture dynamics inside the air cavity. The moisture retention properties of the insulation material varied with temperature. At lower temperatures, the new insulation material absorbed less moisture, likely due to the reduced moisture vapor in the air. However, at higher temperatures, the material released more moisture into the cavity air, highlighting the material's dynamic interaction with the hygrothermal environment.

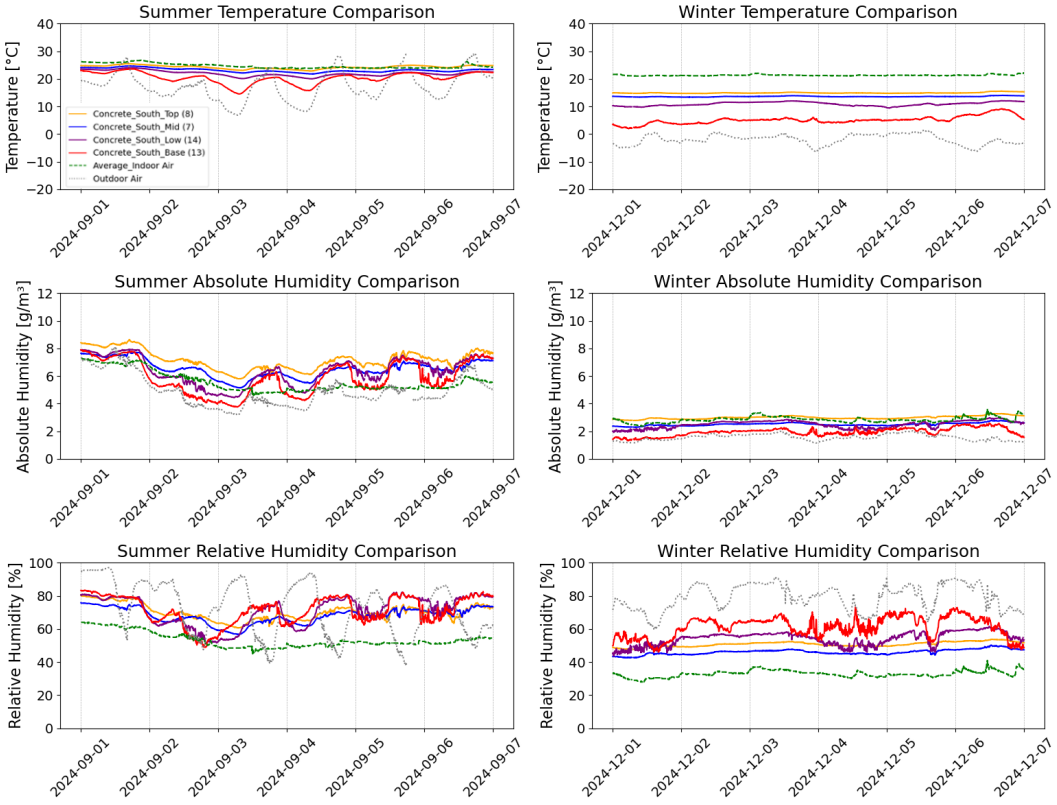

Figure 4. Temperature, absolute humidity and RH for air gap.

4.2. Hygrothermal Performance and R-value Assessment

The analysis of the hygrothermal performance focused on two period of September 1 - 19 (Fig. 5) and November 1 - 15 (Fig. 6) for the selected monitoring locations (representing various orientation and construction materials). Surface temperature, as shown in Figure 5, reveal a clear impact of solar radiation on the wall assembly. During peak solar exposure periods, interior surface temperatures of the whole assembly increase too. This effect is particularly pronounced on the southwest and west walls, where solar radiation is highest. When the intensity of solar irradiation is reduced the observed difference between southwest and north is not very significant. Overall, internal surface temperatures remain more constant, illustrating the walls' impact on temperature stabilization. However, this stability is also influenced by the building's indoor space conditioning system, which regulates interior temperatures. The interaction between the wall assembly's thermal resistance and the space conditioning system contributes to the observed stabilization of internal surface temperatures. Additionally, indoor RH trend showed relatively stable values compared to the fluctuating outdoor RH. While outdoor RH exhibited considerable daily variation due to temperature changes and weather conditions, the indoor RH remained more consistent.

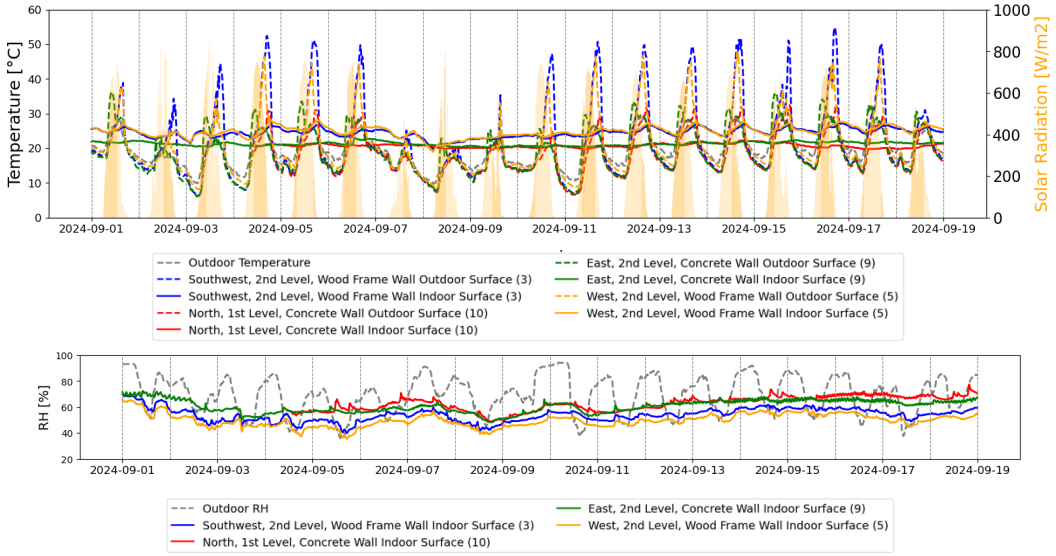

Figure 5. Surface temperature variations (top) Indoor humidity variation (bottom) and of selected walls.

Fig. 6 shows the interior surface temperatures are relatively constant compared to the exterior temperatures. There is a considerable temperature drop between the exterior and interior side of the insulation panel (air gap layer) for all locations (relative difference between air gap and outdoor vs. air gap and indoor), showcasing the retrofit panel effectiveness. When it is colder this difference is more pronounced (better insulation and more airtight compared to pre-retrofit).

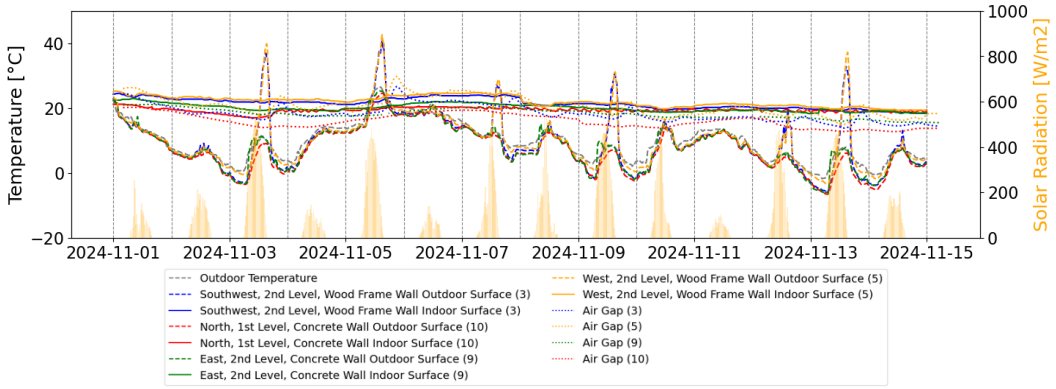

Figure 6. Temperature variations across the assembly for the selected locations.

R-value assessments were performed in accordance with the methodology for determining the thermal resistance of building envelope components based on in-situ measurements. It should be noted that for the design values, the summation of existing wall, air gap and newly insulation layer was considered (conduction only). Table 1 provides a detailed breakdown of the R-value calculations for both concrete and wood-framed walls. These calculated values show the retrofit's role in significantly enhancing the thermal barrier properties of the building's envelope, ultimately leading to reduced heat transfer and improved energy efficiency. Measured R-values align with design specifications. These values fall within the broader performance range of exterior retrofitting systems, which reported thermal resistances from 2-6.67 $m^2 \cdot K/W$ for systems with thicknesses between 7-64 cm (Mirzabeigi et al., 2023). This confirms that the retrofit solution applied here performs near the upper end of the spectrum in terms of R-value.

Table 1. Summary of R-values.

Post-retrofit R-value Assessment	Wood Frame Design	Wood Frame Measured	Deviation between R-values	Concrete Design	Concrete Measured	Deviation between R-values
Mean R-value(m^2·K/W)	6.52	6.30	3.4%	5.86	5.69	2.9%
Standard Deviation	-	1.10	-	-	1.14	-
Coefficient of Variation	-	17.4%	-	-	19.9%	-

5. CONCLUSION

This study presents a detailed post-retrofit hygrothermal assessment of an integrated exterior building envelope retrofitting system, focusing on the impact of insulation foam panels with an air cavity. The results highlight considerable improvements in thermal performance and heat loss reduction, with the whole retrofitted system achieving an average effective R-value of 6.08 m^2·K/W. In warm conditions, the air cavity mitigated heat gain and facilitated moisture redistribution through adsorption and desorption cycles driven by solar radiation and temperature gradients. The insulation absorbed less moisture during cold conditions, indicating its vapor diffusion capability, while in warm conditions, it exhibited higher moisture dynamics, absorbing moisture from external air at night and releasing it during the day. The analysis of temperature and humidity variations within the air gap revealed insights for further considerations and used in hygrothermal model development for a more detailed analysis. Furthermore, the R-value assessments confirmed the role of the new insulation in enhancing the building's thermal resistance, leading to reduced energy consumption. These findings underscore the potential of prefabricated exterior insulation systems for improving the energy efficiency of existing buildings in cold climates, offering valuable insights for future retrofit strategies.

SUMMARY
Developing building archetypes is a crucial preliminary step in bottom-up Urban Building Energy Modelling (UBEM), where buildings with shared characteristics are grouped together. Selecting the most important set of features is vital for accurate energy performance analysis, as it directly impacts energy usage predictions and model accuracy. However, existing engineering-based and statistical feature selection methods often oversimplify complex interactions or face challenges with multicollinearity. Additionally, conventional data-driven approaches such as wrapper and embedded methods are often prone to bias and lack robustness and reliability.
This study introduces a novel ensemble-based methodology to select important features for developing residential building archetypes that are both reliable and robust while maintaining computational efficiency. A multistage ensemble data-driven feature selection technique, along with a single embedded feature selection method, is compared for four different scenarios from four perspectives: selection accuracy, stability and robustness, performance, and reliability.
The results indicate that ensemble feature selection outperforms embedded methods in terms of selection accuracy, robustness, and reliability. Regarding classification accuracy, the ensemble method surpasses embedded only for minimal and balanced models (5 and 10 features), achieving 74% and 87% compared to 72% and 77%, respectively. However, as the number of selected features increases (for the detailed model with 20 features and for the high-complex model with 30 features), embedded performs better, with classification accuracies of 92% and 93%, compared to 89% and 89.1% for the ensemble method. In the ensemble method, the high-complex model achieved superior reliability and robustness scores of 1, along with PSFI and PIFS values of 0.33 and 0.38, respectively. By focusing on important variables and eliminating irrelevant information, this approach helps stakeholders better understand energy consumption factors and identify effective retrofit measures.

Keywords: Archetypes, Urban Building Energy Modelling (UBEM), Data-Driven Approach, Feature Selection.

1. INTRODUCTION AND LITERATURE REVIEW

Energy analysis and evaluation of residential buildings on large scales can be achieved by Urban Building Energy Modelling (UBEM) (Kong et al. 2023). Nonetheless, simulating numerous buildings at the urban scale quickly becomes computationally expensive. This challenge in urban-scale building energy simulations is often addressed using various clustering and grouping techniques (Dahlström et al. 2024). Instead of collecting data and characterizing each individual building, a subset of representative buildings (archetypes) is created for upscaling.
Identifying the most important set of features for archetype development can be done based on

three approaches: engineering, data-driven, and hybrid. In the engineering approach, features are selected based on the existing literature. A review of the existing UBEMs shows that the choice of feature configuration is made based on the engineering method (Johari et al. 2022; Ferrando et al. 2022). Despite the popularity of this method, it has some disadvantages. First, choosing features is arbitrary and there are some discrepancies in the selected features. Second, this method is unsuitable for high-dimensional datasets such as building stock datasets.

In the data-driven approach, statistics or machine learning algorithms aid in finding key features. This approach is well-suited for high-dimensional datasets, as they often contain irrelevant and redundant features. Based on the search strategy for finding the key features in this method, the feature selection is classified into filter-based, wrapper-based, embedded-based, and ensemble-based techniques (Barbieri et al., 2024). The filter method, also referred to as the correlation-based method, is the most common approach for feature selection. The second method, wrapper-based, identifies the optimal feature subset by generating various possible subsets and comparing their prediction or classification performance. Compared to the filter method, this method typically provides better prediction accuracy, but this comes with the drawback of higher computational costs (Eskandari et al., 2024). The third method, the embedded-based method, integrates feature selection into the training process, and this is the key distinction of the embedded method compared to the filter and wrapper methods (Moslemi, 2023). Finally, the ensemble method involves combining multiple models, rather than relying on a single model, to identify and select important features resulting in greater stability compared to other methods (Pes, 2020). Despite the advantages of the ensemble method, it has rarely been used to select key features that influence building energy ratings, which can ultimately aid in archetype development.

Identifying and selecting important features for archetype development significantly impacts the quality and accuracy of the resulting archetypes. In most existing UBEM studies, engineering-based feature selection remains the dominant approach. However, this method is inherently biased—if past studies have overlooked a feature, it is likely to be excluded again. Moreover, superior advantages of ensemble feature selection such as the ability to increase stability and robustness, improve interpretability, and decrease risk of overfitting have not been tested on the available dataset for archetype development.

The aim of this research is to evaluate the effectiveness of a novel ensemble-based feature selection method for archetype development from multiple perspectives, including selection accuracy, reliability, stability and robustness, and performance. The proposed method is compared against embedded methods using the aforementioned criteria.

This paper is organized as follows: Section 2 details the methodology developed, including a description of the steps taken to extract key features. Section 3 presents and discusses the results of the Irish case study. Finally, Section 4 concludes with a summary of challenges and suggestions for future work.

2. METHODOLOGY

The development of residential building archetypes involves four key steps, as illustrated in Fig. 1. The first step is data collection from the existing building stock dataset. This is followed by the pre-processing step, which uses data-driven techniques to enhance the quality of the building stock data. The third step, feature selection, identifies the critical features that influence the energy rating of existing buildings. This rating encompasses space heating, ventilation, water heating and lighting under standardized operating conditions.

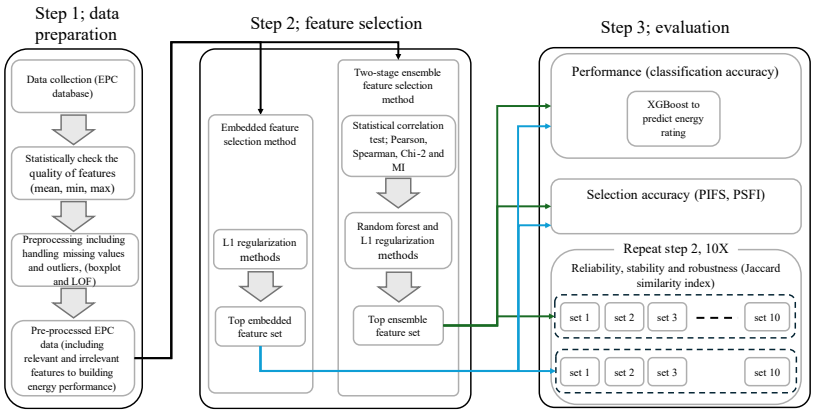

Figure 1. Overarching methodology for ensemble-based machine learning feature selection method.

2.1 Data collection and preparation

Energy Performance Certificate (EPC) databases are a valuable resource as they provide detailed data on building features, including U-values, heating systems, and construction types, which are essential for defining building archetypes. This data source supports data-driven feature selection, as it includes normalized annual energy consumption and energy rating for each building, serving as a valuable target variable for identifying the most impactful features.

Building stock dataset pre-processing takes place after data collection and includes an initial statistical analysis, data pre-processing, and outlier detection. The initial sub-step consists of a preliminary statistical analysis of the building stock dataset. Then, data pre-processing addresses the identified inconsistencies with the following steps: data cleaning for addressing missing or zero values, data reduction for eliminating irrelevant attributes, and finally data discretization for converting attributes format. In the third sub-step, methods such as the Local Outlier Factor (LOF), further improve data quality by removing outliers.

2.2 Feature selection

The focus of this research is on feature selection where a novel two-stage ensemble-based machine learning method is implemented to select the most impactful features of the energy rating of buildings in the EPC database. The contribution of each feature to predictive accuracy of the model is the key criteria for selection. This study compares the proposed methodology with the embedded data-driven feature selection method. Figure 2 shows the schematic of the proposed methodology. In this research, four filter-based feature selections are used. For numerical variables, Spearman and Pearson, and for categorical data, Chi-square (Chi-2) and mutual information (MI) are selected. This combination can capture a wider spectrum of linear, monotonic, and non-linear relationships, ensuring more robust feature relevance detection. Moreover, it can reduce the risk of overlooking important factors, leading to improved model performance and generalization.

Filter- and embedded-based methods are combined via intersection and union to form two aggregated subsets. The primary reasons for selecting these four Filter-based methods are: 1) They offer a reasonable combination of different FS categories, 2) They are among the most widely used FS methods in literature (Ali et al., 2020; Eskandari et al., 2024; Zhang et al., 2023). The resulting subsets of these four methods are then intersected to form the first aggregated subset. Following this stage, two well-known embedded-based feature selection techniques namely LASSO (Least

Absolute Shrinkage and Selector Operator) Regression or L1 Regularization, and Random Forests which is a Tree-Based method are implemented to create the second aggregated subset using union.

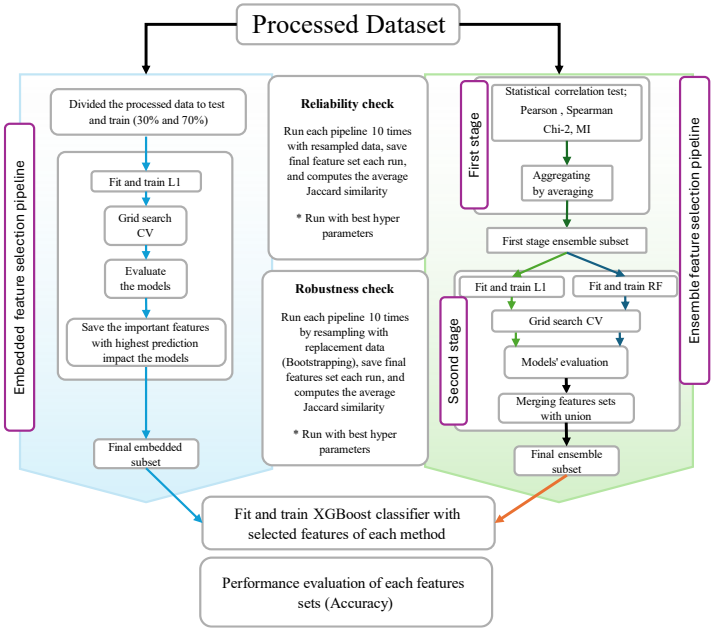

Figure 2. A schematic of the methodology used for feature selection and evaluation of the selected features

Alongside this ensemble-based feature selection pipeline, an embedded method is used to identify the most important features of the EPC database. For this standalone feature selection pipeline, L1 regularization is applied, as its results were deemed acceptable in a study conducted by Neale et al. (Neale et al., 2022). Additionally, this method has better computational costs than the wrapper method (Barbieri et al., 2024).

2.3 Evaluation

To evaluate the impact of feature selection on archetype development, four scenarios are considered. The minimal model (Top 5) includes only the most essential features, while the balanced model (Top 10) expands the selected features. The detailed model (Top 20) and high-complex model (Top 30) further incorporate additional features, increasing depth and complexity for a more refined analysis. For both methods, these scenarios are evaluated based on four criteria: reliability, classification performance, stability and robustness, and feature selection accuracy. Feature selection accuracy is assessed using two metrics: the Percentage of Informative Features Selected (PIFS) and the Percentage of Selected Features that are Informative (PSFI). Performance is measured by classification accuracy, while stability and robustness are evaluated using the Jaccard similarity index.

3. RESULTS AND DISCUSSION

The cleaned EPC dataset of Ireland was downloaded from (Raushan, 2023). This dataset provides detailed information on 701,898 residential buildings in Ireland. Despite being cleaned, the dataset still contains outliers and zero values. Data cleaning was performed by imputing missing values with simple mean imputation and applying the LOF method. Additionally, features with more than

99% missing values or those irrelevant to energy consumption, such as assessment dates and building IDs, were removed from the dataset. In the next step, focusing on Dublin City, because it has the highest proportion of the cleaned EPC dataset, and filtering for houses with existing energy ratings reduced the dataset to 16,940 houses with 165 features.

To evaluate selection accuracy and identify the most important features for building energy performance, it is first necessary to determine the key parameters for archetype development. Since not all features in the EPC dataset are relevant (Neale et al., 2022), a list of common features shared between the EPC dataset and previous literature (Ali et al., 2020, 2024; Egan et al., 2018; Neale et al., 2022) is compiled. Following this, selected features for different final subset sizes in both methods are presented in Figure 3.

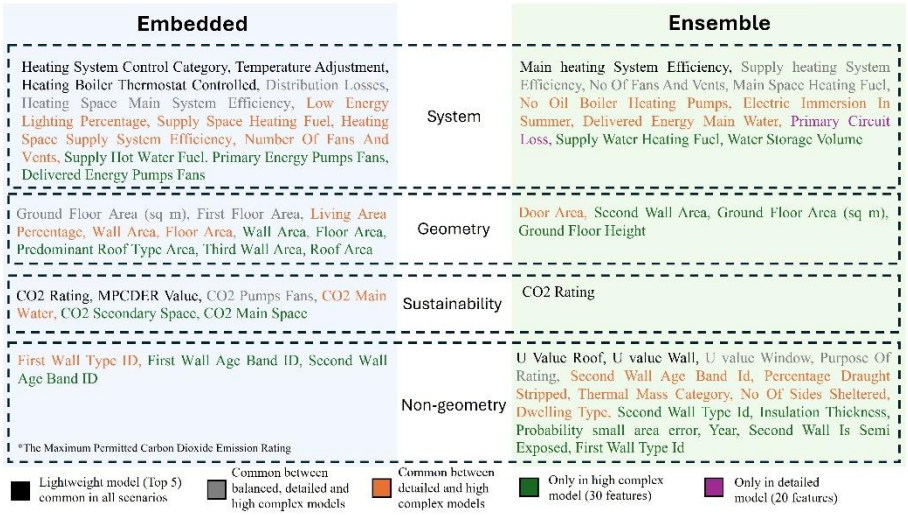

Figure 3. Selected features by embedded and ensemble methods, for various final subset size

The comparison between embedded and ensemble feature selection methods highlights differences in variable prioritization. System-related features remain important in data-driven approaches, even though they receive less attention in traditional engineering models. Key parameters such as heating system efficiency, supply heating fuel, and ventilation consistently appear, demonstrating their strong influence on energy performance. While ensemble methods apply correlation thresholds, their "or" condition for Pearson and Spearman correlations allows redundant features like CO2 rating to persist. Additionally, ensemble methods tend to capture more system-related and geometric dependencies as model complexity increases, whereas embedded methods focus more on primary efficiency indicators. This broader feature selection may enhance predictive performance but also raises the risk of overfitting.

Feature selection accuracy of embedded and ensemble methods is compared in Figure 4. The results indicate a clear advantage of the ensemble method over the embedded method in terms of both PSFI and PIFS. For instance, when selecting the top 5 important features, the ensemble method achieves a PSFI of 80% and a PIFS of 15%, compared to 0% PSFI and PIFS for the embedded approach, demonstrating its superior capability to identify and prioritize significant features even with a small feature set. As the number of selected features increases, PIFS values rise for both methods; however, the ensemble method consistently outperforms the embedded method. This suggests that the ensemble approach not only captures a larger proportion of truly informative features but also selects features more precisely, likely due to its ability to aggregate information from multiple models, reduce variability, and better handle correlated features.

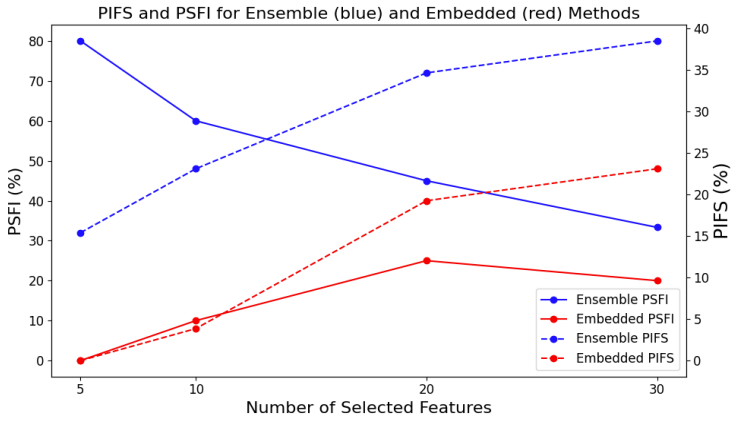

Figure 4. Comparison of selection accuracy based on PIFS and PSFI for ensemble and embedded methods with respect to the number of final feature subsets.

The classification accuracy results (Figure 5) highlight key trade-offs between feature selection methods across different model complexities. At lower feature counts, the ensemble method outperforms the embedded method, making it a strong choice for minimal and balanced models, where selecting the most dominant predictors is crucial. However, as the feature count increases, the embedded method surpasses the ensemble approach at 20 and 30 features, suggesting that it better captures higher-order feature interactions in detail and high-complex model scenarios. The ensemble method's reliance on correlation-based filtering may explain its stagnation beyond 20 features, as redundant but individually significant features can limit further accuracy improvements. In contrast, the embedded method benefits from dynamic selection, optimizing performance as more features are introduced. These results indicate that ensemble selection is ideal for constrained models requiring efficiency and stability, while embedded methods are better suited for complex, feature-rich environments.

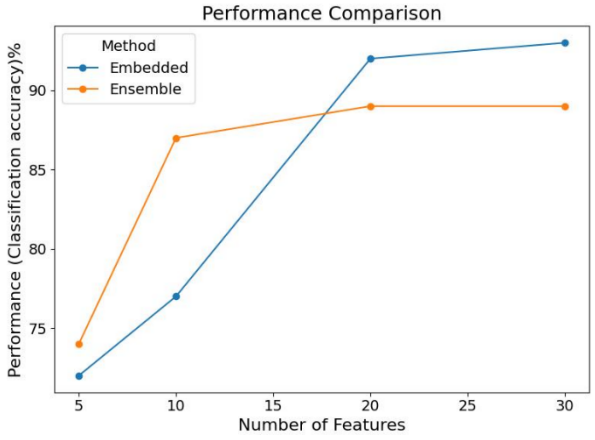

Figure 5. Classification accuracy of the XGBoost model using final sets of ensemble and embedded methods

The Jaccard similarity index measures the reliability of feature selection by assessing the consistency of selected sets over 10 runs. The ensemble method demonstrates high reliability, achieving a perfect similarity score of 1 for minimal, detailed, and high-complex models, and 0.93 for the balanced model. A noticeable drop in similarity at the 10-feature set suggests increased sensitivity to data variations, particularly in the embedded method, which appears more dependent

on algorithmic factors. This instability may result from interchangeable features with similar predictive power. However, as the number of selected features increases to 20 and 30, selection stabilizes, reducing inconsistency and reinforcing the reliability of ensemble methods.
The ensemble method also outperforms embedded methods in robustness, making it a more reliable choice for models that need to generalize across different data variations. The embedded method's instability at 10 features highlights the need for additional validation when selecting a balanced model. A decline in robustness at 20 features suggests the introduction of less dominant features, increasing variability. However, by 30 features, selection stabilizes again, emphasizing the importance of carefully evaluating mid-sized feature sets for robustness, particularly when using ensemble methods.

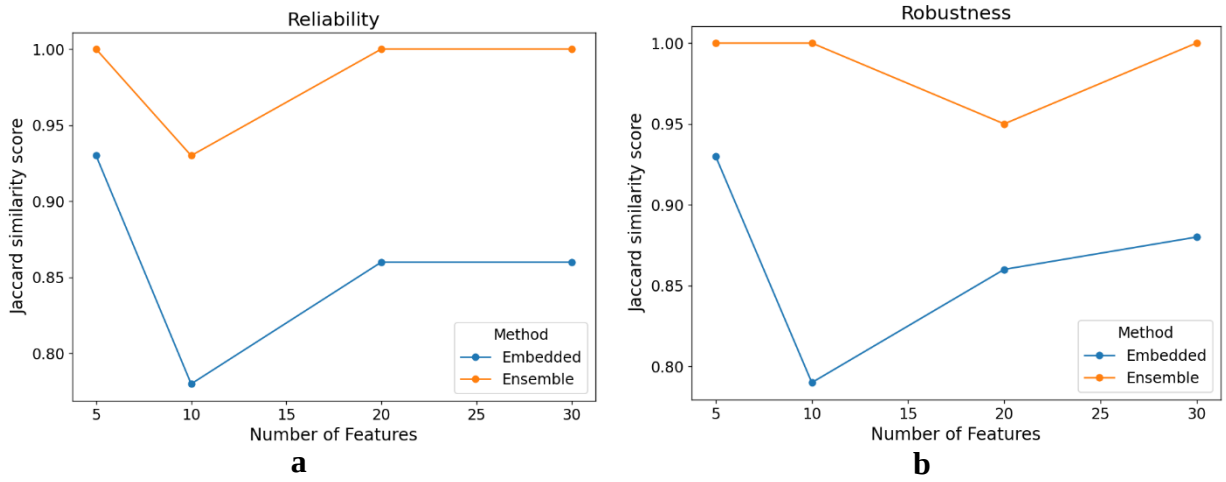

Figure 6. Average Jaccard similarity score for 10 runs for ensemble and embedded methods, a) bootstrapping without replacement for reliability. b) bootstrapping with a replacement for stability and robustness.

4. CONCLUSION

This study presents an innovative ensemble-based approach for selecting key features to develop reliable and robust residential building archetypes. The study compares a multistage ensemble data-driven feature selection technique with a single embedded method across four dimensions: selection accuracy, stability and robustness, performance, and reliability. This research demonstrates that an ensemble-based methodology for developing residential building archetypes provides a robust and reliable feature set.
The study reveals that ensemble feature selection outperforms the embedded approach in all evaluated aspects except classification accuracy. The number of selected features impacts various evaluation criteria, including selection and classification accuracy, reliability, and robustness. Furthermore, for the ensemble method, the high-complex model with 30 features performed better in reliability and robustness with scores of 1, PSFI and PIFS values of 0.33 and 0.38, respectively. However, the classification accuracy of this model was equal to the detailed model with 20 feature subsets with 89% accuracy. In conclusion, ensemble-based feature selection demonstrates strong potential for selecting reliable and robust features that are important in energy rating. This characteristic can aid archetype development by enhancing model consistency, reproducibility, and trustworthiness. This approach not only helps domain expert confidence but also supports practical and interpretable models.
This study highlights several opportunities for future research, particularly in optimizing feature

selection methods. For instance, wrapper feature selection was not employed due to its high computational costs, an issue that future work should address. Additionally, execution time should be incorporated as a critical evaluation criterion when comparing feature selection techniques.

SUMMARY
This study investigated the influence of design parameters on the efficiency of hybrid natural ventilation facilitated by monitor roofs (with and without rain shelters) using computational fluid dynamics (CFD). The design parameters of monitor roofs include the width S, height H, and eave overhang E. In consideration of engineering practices, the parameter ranges were set as follows: S=1.2, 1.8, 2.4, and 3 m; H=0.3, 0.6, 0.9, and 1.2 m; and E=0, 0.3, and 0.6 m. The set wind speed (0.01–3 m/s) refers to the wind speed at a height of 10 m. The results show that for a larger monitor roof (width =3 m, height =1.2 m), the presence of outdoor wind combined with thermal buoyancy increased the ventilation rate to 1.5-3.5 times that found when only buoyancy was present. After rain shelter installation, a rain protection effect was achieved, and the ventilation rate increased because of flow structure conformity, with an overall average effectiveness of 1.02.

Keywords: ventilation, monitor roof, rain shelter, roof, building.

1. INTRODUCTION

Natural ventilation involves the use of natural forces, such as wind and/or thermal buoyancy, to introduce fresh air into indoor spaces without the use of mechanical energy. These natural forces usually affect the natural ventilation performance. Notably, natural forces can be isolated, opposed, or mutually reinforcing, and occasionally, they can act synergistically. As a common means of building ventilation, monitor roofs (or a ridge vent of a smaller size) with or without rain shelter have been employed to introduce indoor airflow via thermal buoyancy and/or wind.

Taiwan is located in a tropical area. Various types of monitor roofs are often installed at the roof ridges of buildings (as shown by the red dotted line in Fig. 1(a)) to increase the effectiveness of indoor ventilation in the spaces below, and their ability to induce ventilation is widely recognized. However, people have different evaluations of their ability to induce natural ventilation. What is the ventilation rate? Are there any appropriate design parameters? To date, these details have not been unveiled in the literature. The available data on design details are relatively limited, and only our previous studies focused on such topics (Chen et al., 2022)(Lin et al., 2023)(Win et al., 2024). Moreover, to prevent rainwater from entering the building via the monitor roof, a rain shelter can be installed (hereafter referred to as the modified monitor roof), as shown by the blue dotted line area in Fig. 1(b). How design parameters affect the efficiency of hybrid natural ventilation caused by monitor roofs is an issue that needs to be clarified. Thus those issues have become the motivation for this study.

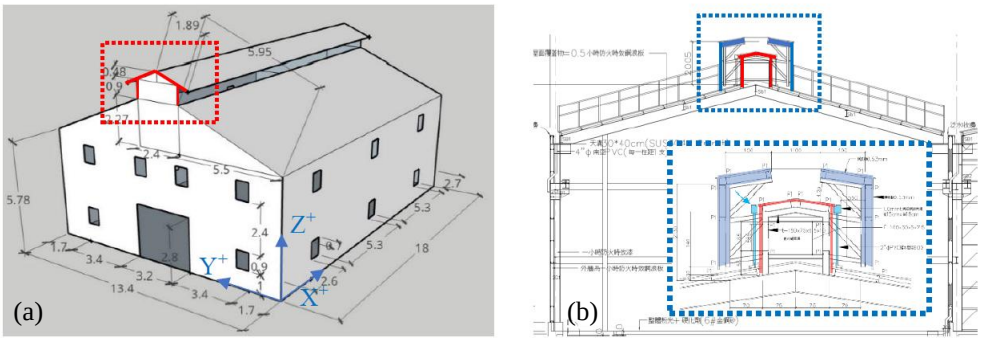

Figure 1. The illustration of a monitor roof (red line) and the addition of a rain shelter (blue line) (Win et al., 2024).

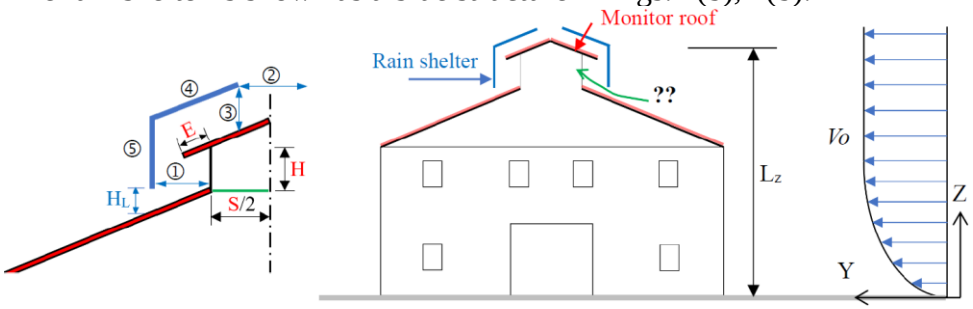
2. RESEARCH METHOD

The considered monitor roof design parameters are the width (S), height (H), and eave overhang (E), as shown in Fig. 2(a). The length range of each parameter is as follows: S, 1.2–3 m; H, 0.3–1.2 m; and E, 0–0.6 m; these ranges were derived from engineering practice and confirmed in our previous study (Chen et al., 2022). In the second part of this study, a common monitor roof with the rain shelter was investigated, and its dimensions are as follows: S = 1.2 m, H = 1.2 m, E = 0 and 0.3 m. The rain shelter is shown as a blue structure in Figs. 1(b), 2(b).



(b) Design parameters of the modified monitor roof

(a) Modified monitor roof, pitched roof and the space below

Figure 2. Physical model used in this study (not to scale; unit: m).

The design procedure for the rain shelter is as follows: the distance between the vertical plates of the rain shelter and that of the existing monitor roof (① in Fig. 2(d)), 1 m in this study) is determined; the width of the horizontal outlet of the rain shelter (②, 1 m) is obtained; the distance between the top of the rain shelter and the upper roof panel of the existing monitor roof (③, 0.7 m) is measured; the inclination angle of the roof panel of the rain shelter is matched to that of the monitor roof; the length of the roof panel (④) is determined; the length of the vertical panel of the rain shelter (i.e., the side flow opening H_L (= 0.4 m, 0.6 m)) is obtained; and the length of eave overhang is calculated (E = 0 and 0.3 m).

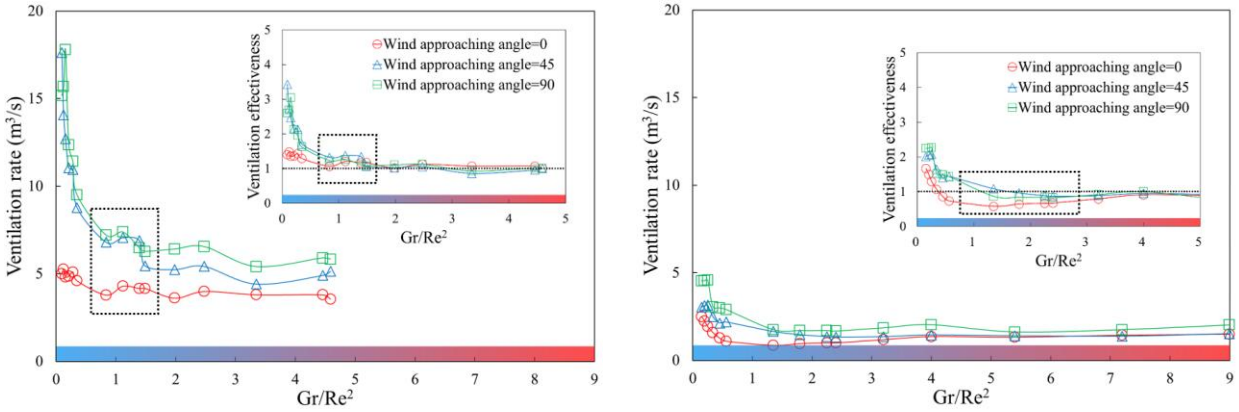
Finite-volume CFD code PHOENICS was used to simulate fluid flow and heat transfer. The detailed information of the used numerical methods and parameter settings are detailed in (Win et al., 2024). The governing equations solved by PHOENICS include a three-dimensional incompressible Navier–Stokes equation, a time-independent convection diffusion equation and the

LVEL turbulence model. Their formulations can be found in the PHOENICS manual. Iterative calculations were conducted until all field variables in the problem satisfied the specified relative convergence value of 10^{-3}.

3. RESULTS AND DISCUSSION

3.1 Ventilation performace of the monitor roofs (without rain shelter)

Figure 3(a) shows when the outdoor wind is very weak (Gr/Re^2>1.5), the ventilation airflow is dominated by the buoyant effect (via solar heating), and the ventilation rate does not change dramatically with a change in Gr/Re^2 for a fixed direction of the incoming wind. As the outdoor wind speed increases, Gr/Re^2 decreases accordingly. When Gr/Re^2=0.84-1.5, the ventilation rate first increases and then decreases, as shown in the dashed-line box. When Gr/Re^2<0.84, the trend of the ventilation rate at various incoming wind directions is different. When the incoming wind direction is 0°, the ventilation rate slightly increases as Gr/Re^2 decreases; however, when the incoming wind direction is 45° or 90°, the ventilation rate increases significantly as Gr/Re^2 decreases, suggesting that outdoor wind under these conditions can effectively increase the ventilation rate.



(a) S =3 m, H =1.2 m, E =0.3 m (b) S =1.2 m, H =0.3 m, E =0.3 m

Figure 3 Effect of Gr/Re^2 on the hybrid ventilation rate of the monitor roof under different incoming wind directions

Figure 3(b) shows when the width and height of the monitor roof decrease (S=1.2 m, H=0.3 m, and E=0.3 m), the ventilation efficiency caused by thermal buoyancy and outdoor wind is lower than that of the larger monitor roof (S=3, H=1.2, E=0.3). When the incoming wind direction is 45° or 90° and Gr/Re^2=1.4-3.2, the ventilation rate first decreases and then increases. In this Gr/Re^2 range, the presence of outdoor wind has a negative effect on the ventilation efficiency. At an incoming wind direction of 0°, the ventilation rate first decreases and then increases over Gr/Re^2=0.45-3.2, indicating a larger range of Gr/Re^2 over which the outdoor wind negatively impacts the ventilation rate. Thus, Gr/Re^2=1 is not suitable as a criterion for when the outdoor wind starts to impact the ventilation rate.

3.2 Ventilation performance of the monitor roofs with rain shelter

In general, after rain shelter (H_L = 0.4 m) installation on the monitor roof, the average effectiveness reached 1.02. Figure 4 shows that a rain protection effect could be achieved, and the ventilation

rate increased by 2% because of flow structure conformity. As shown by the green dotted line area, when there is no wind or when a low wind speed occurs (0.01 m/s), the driving force of the ventilation airflow is the thermal buoyancy force generated by the heated roof slab. Moreover, for both the monitor roof and the modified monitor roof, their geometric shapes allow the thermal buoyancy airflow to first move upward and then exit the roof. Therefore, both the monitor roof and the modified monitor roof provided similar ventilation performance levels, and the effectiveness approached 1.

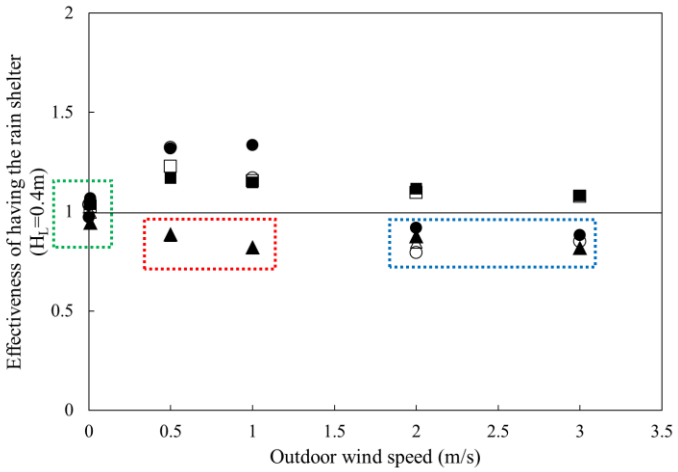


Figure 4. Physical Relationships between the effectiveness of the rain shelter (HL = 0.4 m) and the outdoor wind speed, wind direction, and presence of eaves.

When the wind speed increased to 0.5–1 m/s, due to the flow structure, the ventilation performance of the modified monitor roof was better than that of the monitor roof under wind angles of 0° and 45°. Under a wind angle of 90°, owing to the large area of the gable, the airflow was obstructed. The opening of the modified monitor roof is located in the wake area downstream of the gable, so it cannot efficiently guide the indoor airflow outward, and the ventilation effectiveness is lower than that of the monitor roof, yielding an effectiveness less than 1, as shown by the red dotted area.

4. CONCLUSION

For a larger monitor roof (width =3 m, height =1.2 m), the presence of outdoor wind combined with thermal buoyancy increased the ventilation rate to 1.5-3.5 times that found when only buoyancy was present. For a smaller monitor roof (width =1.2 m, height =0.3 m), Gr/Re^2=0.45-3.2 was the transition range over which the presence of outdoor wind decreased the ventilation rate below that found when only buoyancy was present. After installing a rain shelter (side flow opening H_L = 0.4 m) on the monitor roof, rain protection was achieved, and the ventilation rate increased owing to flow structure conformity, with an overall average effectiveness of 1.02.

Adaptive Insulation System with thermochemical Actuation for thermally activated Building Structures (TABS)

Jonina Felbinger [1], Marc Linder [1]

[1]*German Aerospace Center, Institute of Engineering Thermodynamics, Stuttgart, Germany, jonina.felbinger@dlr.de*

SUMMARY
A novel adaptive insulation system, actuated by thermochemical gas pressure control, was developed and successfully demonstrated in laboratory experiments. The system consists of an open-pored vacuum insulation panel coupled with a metal hydride reactor to precisely and reversibly adjust the thermal conductivity by varying the internal gas pressure. Experiments demonstrated that the insulation system allows for effective control of the heat transport, and thus, activating massive building components such as screed or concrete as thermal energy storage. This makes it possible to charge building masses to higher temperatures, utilizing existing storage capacity and offering options for minimally invasive retrofitting and flexible energy management in existing buildings.

Keywords: Variable conductance envelope, Thermochemical reactions, Thermal energy storage, Building retrofit

1. INTRODUCTION

According to the 2020 Global Status Report of the United Nations Environment Programme (United Nations, 2020), the building and buildings construction sector collectively contribute to more than one-third of global final energy consumption and nearly 40% of the total direct and indirect CO2 emissions. There is clearly a significant potential for innovative and resource-efficient thermal management for buildings. Traditional insulation materials offer low – but constant – values of thermal conductivity and thus play a significant but only passive role for the heat flows in buildings. However, if insulating materials are variable in their thermal transmittance, heat flows can be adapted to fluctuating internal (heating/cooling comfort, number of people and electronic devices, etc.) and external (seasons, weather, day/night cycles, etc.) conditions, and further, building components could be made active components of the energy system.

Firstly, adaptive building envelopes are capable of contributing to significant energy savings, according to a referred study in a comment (Henry,2020) in Nature Energy, which declares variable conductance buildings envelopes to be one of the five grand challenges for thermal energy decarbonization. This would allow solar heat to be gained temporally and partially in winter and transitional seasons as needed. Most importantly, variable conductance building envelopes can reduce the energy consumption of air-conditioning in non-residential buildings by taking advantage of the passive cooling effect by night during hot summer periods.

Another scenario for controllable insulation in buildings is the utilization of existing high-capacity building components as thermal energy storage and thereby transforming buildings into active players for load shifting and grid flexibility. Provided the heat flux through an insulation layer can be controlled in terms of time and amplitude, thus thermally activated building components (TABS), charged by excess energy, are able to contribute to space heating/cooling and peak shaving. Figure 1 depicts schematically the implementation potential of controllable

insulation systems in buildings.
This contribution presents the development, experimental investigation, and application perspectives of a thermally controllable insulation system with gas-solid reactions as actuation mechanism for the heat switch, developed at the German Aerospace Center (DLR).

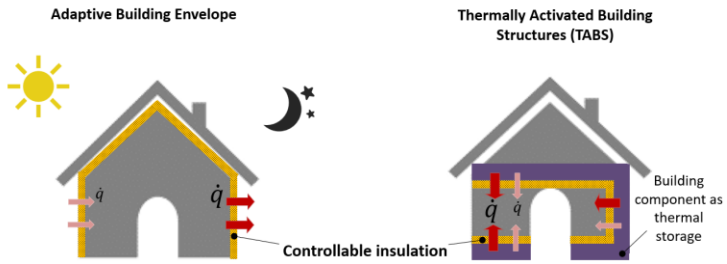

Figure 1. Schematic visualization of application scenarios of controllable insulation systems in buildings.

2. METHODS

2.1. Concept

The working principle of the controllable insulation layer is to adjust the gas pressure in open-pored insulation panels to control thermal conductivity along an S-shaped curve (Knudsen effect). This can be achieved by using thermochemical materials by precisely setting the temperature of the reaction material and thus the gas pressure can be adjusted reversibly along the equilibrium line. By coupling the thermochemical reaction with an open-pored panel, an insulation system with adjustable thermal conductance is realized. Figure 2 gives a schematic overview.

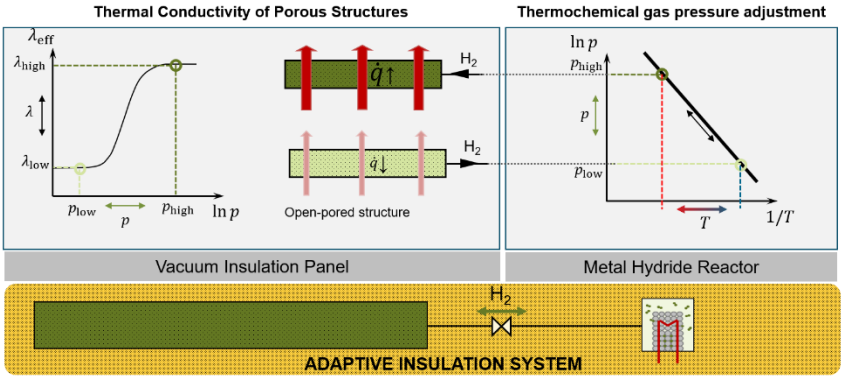

Figure 2. Representation of the concept and fundamentals of the controllable thermal insulation system, with the Knudsen effect (left) and the Van't Hoff equilibrium plot of thermochemical materials (right).

The two core components of the adaptive insulation system are the enveloped open-pored vacuum insulation panel and the metal hydride reactor for the hydrogen gas pressure adjustment in the panel. These units are physically linked, meaning that the temperature setting of the metal hydride is directly related to the gas pressure and, as a result, to the thermal conductivity of the insulation panel.

2.2. Experimental Setup

A prototype vacuum insulation panel was developed using open-pored core materials and

enclosed in multi-layer laminates. For gas pressure regulation, metal hydride materials were studied (Felbinger,2023; Felbinger,2024), and an additively manufactured reactor was designed and its operational behavior characterized. Figure 3b-c) shows such a custom-made vacuum insulation panel with a 30 cm edge length, as well as a developed metal hydride reactor for gas pressure control. To experimentally verify the function of the lab-scale 30x30x2 cm controllable insulation system – with fibre mat as core material -, a dedicated test bench was constructed. This setup enables both the actuation of the reactor and the measurement of gas pressure on the reactor side, as well as the assessment of the resulting thermal performance on the panel side. The test bench is illustrated in Figure 3c). Gas pressure is intended to be varied between approximately 1 and 1000 mbar. The system is equipped with multiple temperature sensors, pressure transducers, a heat flux meter, and an infrared camera to monitor the insulation system's response under controlled laboratory conditions. In a second approach, a laboratory setup was built, combining the controllable insulation with an electrically charged massive concrete screed layer, to investigate a TABS floor heating application. Here, the heat flux into the room during charging and discharging are managed by the adaptive insulation, demonstrating the system's potential for building integration. Figure Figure 3d) shows the experimental layer structure. The 30x30x6 cm screed layer is heated by an electrical heating mat (120 W/m²), while the adaptive insulation minimizes heat flow into the room in its 'OFF' state. After 6 hours, the heating mat is switched off and the adaptive insulation is turned 'ON' to increase space heating, continuing until the thermal storage layer is fully discharged.

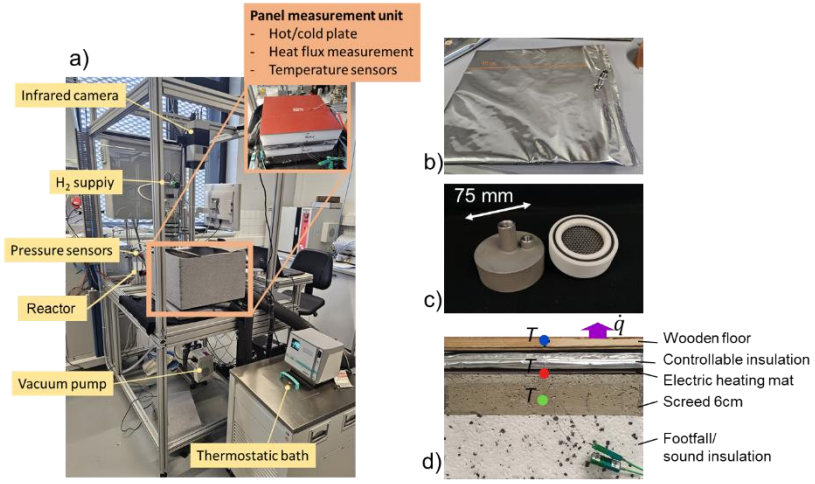

Figure 3. Experimental setup for investigating adaptive insulation system (a), custom-made insulation panel with gas connection (b) and metal hydride reactor (c).

3. RESULTS

3.1. Proof of Function

The proof of function experiments demonstrated that the thermal conductivity of the insulation system can be modulated in a reversible and precisely controlled manner. As a first step, the gas pressure-dependent thermal conductivity of the porous insulation element was measured. Figure 4a) illustrates the characteristic S-shaped curve of the fibre-core insulation panel, achieved by varying the hydrogen gas pressure. The results show that, when the gas pressure is changed from 1 (or less via vacuum pump) to 1000 mbar, a switching ratio (SR) (defined as the ratio of maximum to minimum thermal conductivity) of approximately 15 is obtained.

3.2. Application for Thermally Activated Building Components

The initial experimental investigations of the targeted activation of building structures, using adaptive insulation, have yielded promising results. Figure 4b) illustrates the results of the described experiment. During the first 6 hours, the charging phase takes place, with the storage mass heated by an electric mat. To minimize heat losses during this period, the adaptive insulation is set to its insulating state, meaning the gas pressure is kept as low as possible. As a result, the heat flux into the room (violet line) remains below 15 W/m², and the floor surface temperature (blue line) does not exceed 25 °C, even though the charging phase leads to an average screed temperature (green line) of 48 °C. At the 6-hour mark, marking the end of the charging period, the insulation system is switched to the 'ON' state by increasing the gas pressure (as shown by the grey line). This results in a sudden increase in heat flow into the room and a gradual discharge of the storage layer for the next 18 h. The discharge process proceeds in an uncontrolled manner; the gas pressure—and thus the thermal conductivity of the insulation layer by factor 10—was increased only once. The experiment successfully demonstrated that thermal activation of massive building components using controllable insulation is feasible. By regulating the heat flow into the room, it becomes possible to charge building masses to higher temperatures, which significantly increases the storage density.

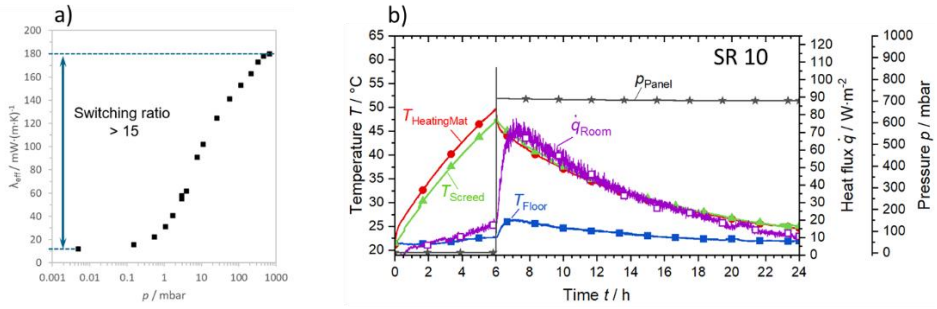

Figure 4. Experimental results of gas pressure-dependent thermal conductivity for insulation system (a), thermal activation of massive components by applying adaptive insulation (b).

4. CONCLUSIONS

A proof of concept for adaptive insulation actuated by thermochemical gas pressure control has been demonstrated, showing its potential for use in building component activation. The approach of using insulation with controllable heat flux enables the electrification of existing buildings through minimally invasive retrofitting, such as with electric heating mats. The – already existing - high thermal storage capacity of screed or concrete allows buildings to contribute to the energy grid and increases operational flexibility. Further research, particularly on advanced control strategies, will be necessary in the future.

Campus-wide indoor environmental quality (IEQ) assessment for MVAC optimization

Tsang Tsz Wun [1], Mui Kwok Wai [1], Wong Ling Tim [1], Liu Bian [1]

[1]*Department of Building Environment and Energy Engineering, The Hong Kong Polytechnic University, Hong Kong, China, hayley.tsang@polyu.edu.hk*

SUMMARY
In this study, both passive and active approaches were adopted to evaluate indoor environmental quality (IEQ) on a university campus, ultimately aiming to optimize MVAC energy consumption. An IoT-based IEQ sensor grid was deployed in air-conditioned spaces throughout the campus, monitoring a total of 10 IEQ indicators, representing thermal comfort, indoor air quality (IAQ), aural comfort, and visual comfort. In selected classrooms, 383 feedback from occupants regarding the thermal, aural, and visual environments, air quality, and overall IEQ was collected. Findings indicated a misalignment between the provided IEQ and occupants' expectations, highlighting issues such as over-cooling and stuffiness. Approximately 20% of occupants were dissatisfied with the perceived thermal conditions and air quality. Based on the thermal response and the Humanized Adaptive Baseline Information Technology (HABIT) algorithm developed earlier, the control parameters for optimal set-point temperature were defined. This paper presents a practical solution to achieve occupant-centric set-point temperature control.

Keywords: occupant-centric, energy optimization, indoor environmental quality

1. INTRODUCTION

Indoor environmental quality (IEQ) is a critical factor significantly impacting the health, well-being, and productivity of building occupants, as well as influencing energy consumption in buildings (Zhang et al., 2023). Among the four key aspects of IEQ—thermal comfort, indoor air quality (IAQ), visual comfort, and acoustic comfort—dissatisfaction predominantly arises from complaints regarding thermal conditions (Wong et al., 2008a). This often indicates a misalignment between building design, operation, and occupant expectations. Notably, overcooling of buildings accounts for an average of 17% of thermal sensation votes in warm climates, corresponding to about 12% of cooling energy wasted in buildings (Alnuaimi et al., 2022).

While building operation predominantly relies on established IEQ or thermal comfort models to assess occupant preferences and determine optimal environmental settings, these models often overlook the importance of integrating occupant perceptions of the environment into building control. Understanding occupant preferences for environmental conditions typically requires collecting feedback through field surveys. When combined with the implementation of set-point control policies to achieve healthy indoor environments and meet occupant expectations at a set-point temperature range of 20 to 25.5°C, annual carbon dioxide (CO_2) emissions from Mechanical Ventilation and Air Conditioning (MVAC) energy consumption could be reduced by 2% to 9% (Wong et al., 2008b). Other research has also suggested that minor adjustments in thermal settings can yield substantial energy savings; for example, increasing the set-point temperature by 1°C can result in an average energy saving of approximately 6% (Yamtraipat et al., 2005; Zhang et al.,

2017).

Although field surveys provide valuable insights into occupant preferences for establishing operational strategies, achieving smart building control automation that accommodates occupant needs requires facility management to adopt both passive and active engagement approaches. Passive engagement involves constant monitoring of environmental parameters through the implementation of a sensing network. This network allows for the monitoring of temporal and spatial variations in environmental conditions resulting from human activities and external factors. When conditions fall below standards, swift responses can be made to restore IEQ. Active engagement, on the other hand, adopts a human-centric approach that allows occupants to "actively" participate in the decision-making process to determine optimal environmental conditions. Where technically feasible, this dual approach leverages both occupant comfort sensation data and corresponding physical environmental condition data to enable (almost) real-time control of the MVAC system, prioritizing the provision of a satisfying and preferred perceived environment.

This study demonstrates the use of such dual approaches for set-point temperature optimization. An IoT-based IEQ sensor grid was deployed in nine air-conditioned classrooms and lecture theatres to monitor crucial surrogate indicators. Feedback from occupants regarding thermal, aural, and visual environments, air quality, and overall IEQ was collected. Based on the subjective and objective measurement results, the Humanized Adaptive Baseline Information Technology (HABIT) framework was adopted to determine the optimal indoor set-point temperature. This study highlights the significance of embracing an occupant-centric approach for environmental comfort and enhancing energy efficiency, paving the way for a new era of building control practices.

2. METHODOLOGY

2.1. Field measurement

2.1.1. Physical measurement of IEQ parameters

The physical measurement is part of a larger campaign conducted across the entire campus to establish a comprehensive continuous environmental monitoring network for evaluating Indoor IEQ performance. For this purpose, an IoT-based IEQ sensing device was developed to measure indoor air temperature, radiant temperature, relative humidity, air velocity, CO_2 levels, particulate matter (PM_{10} and $PM_{2.5}$) levels, total volatile organic compounds (TVOC), horizontal illuminance levels, and sound pressure levels. These parameters serve as representative surrogate indicators for thermal comfort, IAQ, as well as aural and visual comfort.

With a rapid response time and a sampling interval of 10 seconds, minute-average data is transmitted wirelessly via a Wi-Fi network and stored on a backend cloud server maintained by the University. By implementing multiple sensors simultaneously at various locations, the sensing network captures instantaneous environmental variations induced by human activities. This setup also offers spatial characterization and temporal insights into the environment, aiding in the identification of discomfort sources and mitigation strategies. Figure 1 shows the measurements conducted in one of the investigated classrooms.

(a) (b)

Figure 1. (a) A typical air-conditioned classroom investigated during the measurement campaign; and (b) the IoT-based indoor environmental quality (IEQ) sensor deployed for IEQ assessment.

2.1.2. Subjective responses on perceived IEQ

Surveys assessing perceived IEQ aspects and overall IEQ were conducted in nine selected classrooms and lecture theatres. The target participants of the survey were students, who are the primary users of the campus buildings. The survey collected demographic information and subjective assessments of perceived IEQ. Specifically, the 7-point ASHRAE thermal sensation was employed to evaluate perceived thermal comfort (ASHRAE, 2013), while a 5-point scale was used for assessing perceived IAQ. A scoring system was adopted for visual, aural, and overall comfort, and a dichotomous question was included to assess occupant satisfaction with the environment.

2.2. Humanized Adaptive Baseline Information Technology (HABIT) framework

The Humanized Adaptive Baseline Information Technology (HABIT) framework was proposed to determine the optimal indoor set-point temperature based on the best available information regarding thermal demand (Wong et al., 2006). Figure 2 is the schematic representation of the workflow of the HABIT framework.

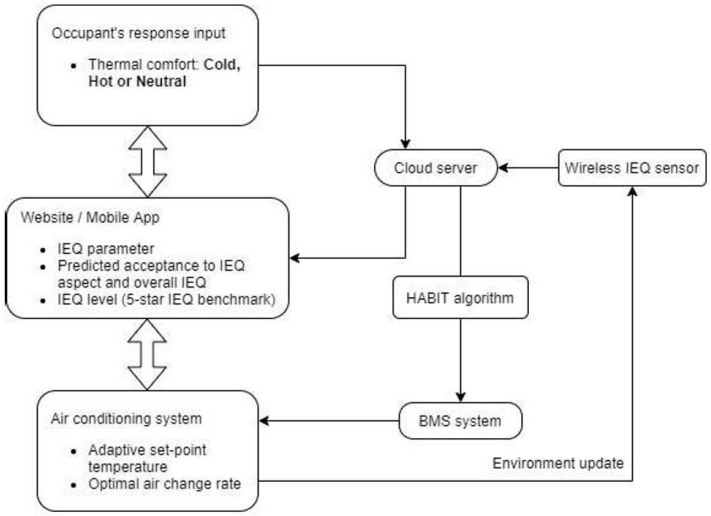

Figure 2. Proposed MVAC system feedback control using the Humanized Adaptive Baseline Information Technology (HABIT) system

The HABIT algorithm can be expressed by Eq. (1), where $T_{a,0}$ (°C) is the set-point temperature at the minimum predicted percentage dissatisfaction D, which is determined by the expected values of an acceptable thermal comfort temperature from occupants within a controllable range of temperatures T_1 (°C) and T_2 (°C).

$$T_{a,0} = \langle \widehat{T_a} \rangle = \langle \int_{T_1}^{T_2} f(T_a) dT_a \rangle ; \frac{\partial D}{\partial T_a} = 0 \quad (1)$$

While students are not permitted to adjust the set-point temperature via the control panel, they are encouraged to provide feedback on their thermal comfort through an online survey. With occupant feedback indicating 'Hot' ($T=T^+$) or 'Cold' ($T=T^-$) regarding the thermal environment at temperature T (°C), the step function ξ(T) shown in Eq. (2) is utilized to update the set-point temperature for occupant satisfaction ξ in the environment, at a selected control constant $0.5 \leq \lambda < 0.5$ and a temperature control range of k=5–10°C.

$$\xi(T) = \begin{cases} 1-\lambda ; & T<T^+; T>T^- \\ \lambda ; & T \geq T^+; T \leq T^- \end{cases} \quad (2)$$

Based on prior knowledge of the temperature distribution that satisfied the majority at the minimum predicted percentage dissatisfied (PPD), i.e., prior mean $\upsilon = 23.2$ and prior standard deviation $\tau = 3.7$, as adopted in design guidelines, a Bayesian approach is used to update this prior understanding with the given complaints, as shown in Eq. (3). The posterior distribution of the set-point temperature T_s can be approximated by a normal distribution with mean θ and variance σ^2, $(\theta|T) \sim N(\upsilon, \tau^2)$. Thermal comfort can thus be maintained by adjusting the set-point temperature when complaints arise due to a set-point temperature falling outside the comfort zone for the target occupants.

$$(\theta|T_s, \sigma^2, \upsilon, \tau^2) \sim N(\theta_1, \tau_1^2); \begin{cases} \theta_1 = \frac{\sigma^2 \upsilon + \tau^2 T_s}{\sigma^2 + \tau^2} \\ \tau_1^2 = \frac{\sigma^2 \tau^2}{\sigma^2 + \tau^2} \end{cases} \quad (3)$$

After determining the neutral temperature based on survey feedback, a simulation was conducted to demonstrate how the HABIT algorithm would adjust the set-point temperature in response to simulated complaints generated by the Monte Carlo sampling technique. Additionally, the settings of parameters such as the control constant λ and temperature control range k were assessed.

3. RESULTS AND DISSCUSSION

3.1. Field measurement results

3.1.1. Environmental conditions

Physical IEQ measurements indicated that environmental control in the measured classrooms and lecture theatres was consistent and stable. As shown in Table 1, thermal parameters were maintained within a narrow range of acceptable levels, in accordance with established guidelines. IAQ parameters also remained within acceptable levels according to the exposure standards set by the IAQ Certification Scheme, except for TVOC, which exhibited elevated average levels. While the horizontal illuminance levels could be considered low for teaching and learning environments, it is believed that the positioning of the IEQ devices requires adjustment to ensure appropriate measurement protocols for visual comfort. Given that the aural environment is regarded as the

most critical aspect for learning activities, the measured sound pressure levels were deemed acceptable (Lee et al., 2012).

Table 1. Environmental conditions in measured classrooms and lecture theatres.

	Operative temperature (°C)	Air velocity (m/s)	Relative humidity (%)	CO_2 (ppm)	TVOC (ppb)	PM_{10} ($\mu g/m^3$)	$PM_{2.5}$ ($\mu g/m^3$)	Horizontal illuminance level (lux)	Sound pressure level (dBA)
Mean	22.4	0.1	62.0	704	564	18.4	14.4	50	46.5
Min	21.5	0.0	36.1	404	0	0.4	0.1	9	23.7
Max	23.5	0.3	89.3	1054	1288	65.2	62.6	145	59.8
Std	0.5	0.1	12.1	131	354	11.4	9.7	22	11.2

3.1.2. Subjective responses and satisfaction

A total of 383 survey responses were collected from students attending classes in the nine selected classrooms and lecture theatres. Among the participants, the gender distribution was balanced, with 93% falling within the age range of 16 to 30. Significant differences in thermal sensation votes between genders were observed ($p = 0.007 < 0.05$, chi-square); however, no such differences were found among different age groups ($p = 0.472 > 0.05$, chi-square). 79.6% reported satisfaction with the perceived thermal environment, with thermal sensation votes skewed towards the cooler side. Votes within the range of $-1 \leq TSV \leq +1$ accounted for 68.7% of the total responses, which was lower than the overall thermal satisfaction rating. This suggests that some respondents may still feel satisfied with the thermal environment even when they experience a sub-optimal or extreme thermal sensation. This finding aligns with a review by Mui et al. (2020), which indicates that thermal preferences may cover a broader range of acceptance than predicted by the traditional PMV-PPD model, possibly due to thermal tolerance and adaptation. Figure 3 illustrates the average percentage and thermal satisfaction corresponding to thermal sensation votes.

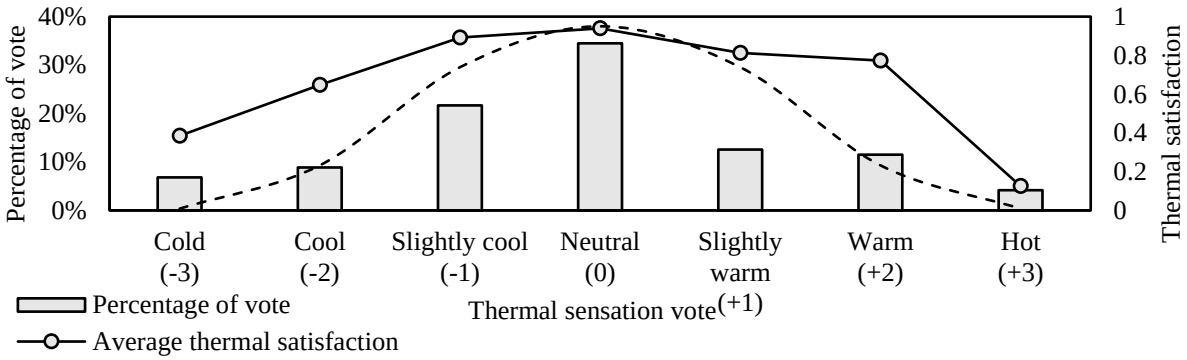

Figure 3. Average percentage of vote and average thermal satisfaction at various thermal sensation votes.

With a narrow range of observable operative temperatures from 21.5°C to 23.5°C, as shown in Figure 4, a linear relationship ($R^2 = 0.38$) was identified between thermal sensation votes and operative temperature, with the neutral temperature found to be 23.4°C. Although no significant trend was observed between operative temperature and thermal satisfaction, the highest level of satisfaction occurred at the warmer end of the thermal conditions (i.e., at 23.25°C).

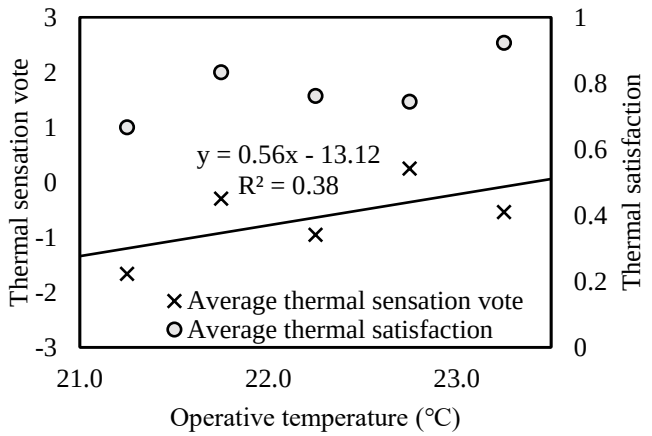

Figure 4. Average thermal sensation vote and average thermal satisfaction at observable operative temperature range.

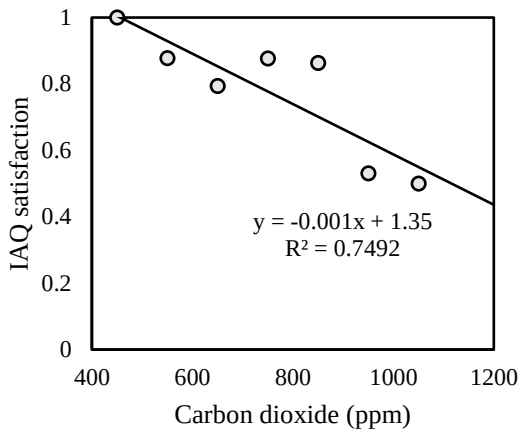

Figure 5. Average IAQ satisfaction at observable range of carbon dioxide levels.

Similar to thermal comfort, up to 81.2% of respondents expressed dissatisfaction with the IAQ. Despite a neutral rating towards IAQ, 18.5% of respondents reported dissatisfaction, indicating that students expect higher than acceptable IAQ levels. No significant association was found between IAQ satisfaction and gender ($p = 0.839 > 0.05$, chi-square) or age group ($p = 0.326 > 0.05$, chi-square). While CO_2 concentrations were maintained below 1000 ppm most of the time, a correlation between IAQ satisfaction and CO_2 concentration was found, as shown in Figure 5. Although it falls outside the scope of this study, this observation of correlation suggests the potential for using subjective evaluations to assess IAQ performance or for ventilation control purposes. No significant correlation was observed between IAQ satisfaction and PM10, PM2.5, or TVOC levels. For visual, aural, and overall IEQ comfort, satisfaction levels reached 88.5%, 90.9%, and 89.5%, respectively, indicating a high standard of perceived environmental quality.

3.2. Optimal set-point temperature determination by the HABIT algorithm

Based on the thermal preferences identified from the field survey, control parameters for optimizing the set-point temperature using the HABIT framework were tested. Utilizing the Monte Carlo sampling technique, both cold and hot complaints were generated from the surveyed distribution of temperature that could lead to thermal complaints. These complaint temperatures served as the initial set-point temperatures to evaluate the progression of the set-point temperature within control ranges of 20–25°C and 18–28°C, i.e., k=5 or k=10°C, after rounds of complaints.

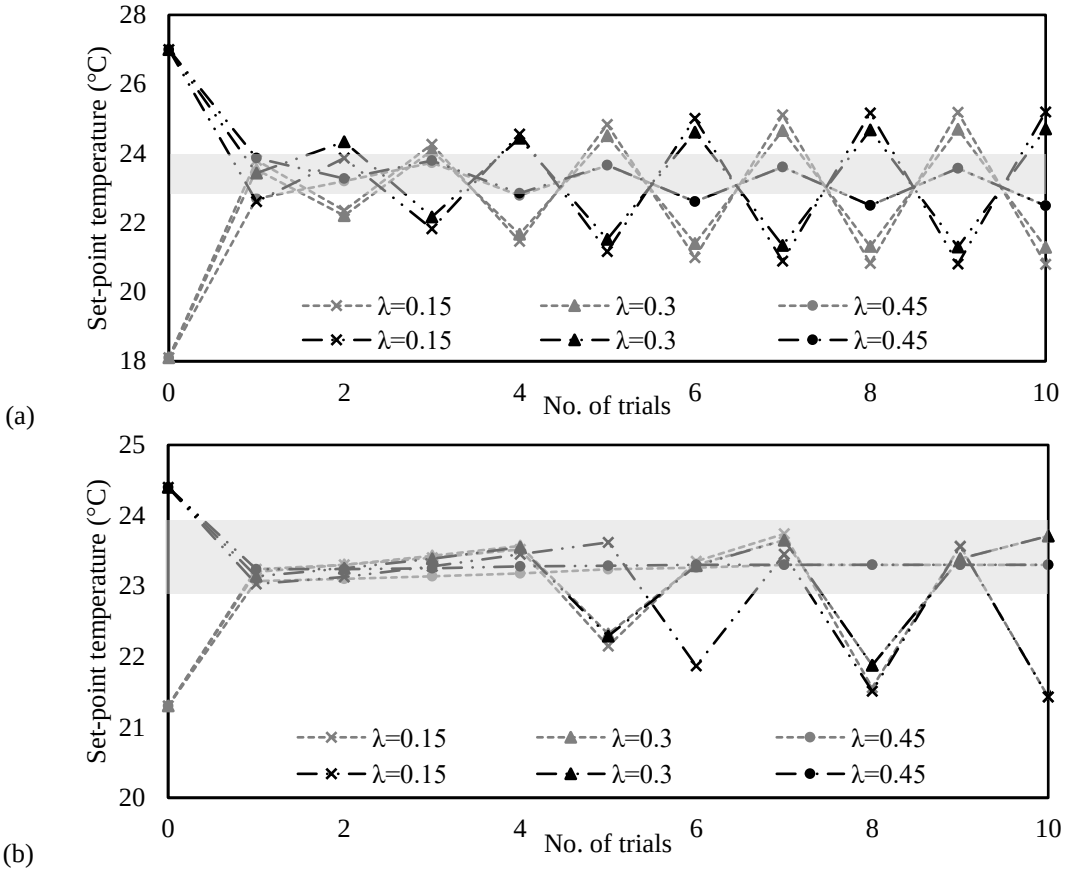

Figure 6. (a) Set-point temperature adjustment using the HABIT algorithm after trials of thermal complaints with (a) k=5℃; and (b) k=10℃. The ideal temperature range of 22.9–23.9°C, derived from the field survey, is highlighted in grey.

Ideally, the set-point temperature would approach the expected neutral temperature of 23.4°C, as indicated by the surveyed. Practically, a temperature range of ±1°C is acceptable. As shown in Figure 6, a small λ, which defines the magnitude of the step change when a complaint is received, resulted in significant fluctuations in the set-point temperature as the optimization process progressed. In some cases, particularly with k=5℃, the set-point temperature not only fell outside the ideal temperature zone but also failed to converge. In contrast, a larger k=10°C mitigated the convergence issue; however, a smaller λ still led to fluctuations in the set-point temperature of up to 4.4℃. Overall, a λ=0.45 is recommended to ensure the stability of the optimization process.

4. CONCLUSION

Indoor environmental quality (IEQ) plays a critical role in influencing the health, comfort, and productivity of building occupants, while also impacting the energy efficiency of buildings. A field study was conducted on campus to measure objective IEQ conditions in air-conditioned classrooms and lecture theatres and gather responses from building occupants. The results indicated occupants were generally satisfied with the perceived environmental conditions. Consistent with findings from previous studies, a broader range of thermal satisfaction was observed compared to the PMV-PPD model. A neutral temperature of 23.4℃ was identified, at which the highest satisfaction level was reported. A negative correlation was found between indoor air quality (IAQ) satisfaction and carbon dioxide (CO_2) concentration, suggesting that satisfaction

could potentially be used as an indicator of IAQ performance. Additionally, high satisfaction levels were noted for lighting, acoustic conditions, and overall IEQ.

Based on the collected data, a dual passive-active approach was adopted, leveraging both occupant thermal sensation data and corresponding physical environmental condition data to determine the optimal indoor set-point temperature within the Humanized Adaptive Baseline Information Technology (HABIT) framework.

Using a Bayesian approach to update the distribution of thermal satisfaction across a fixed range of set-points temperature controls, with observations of thermal complaints, the calculations suggest that, with appropriate implementation of control parameters, the set-point temperature adjusted by the HABIT framework aligns closely with the expected neutral temperature derived from on-site measurements. A small control constant (λ) and temperature control range (k) may lead to significant fluctuations in the set-point temperature, causing it to fall outside the ideal temperature zone and fail to converge. To ensure stability in the calculation process, a control constant λ of 0.45 and temperature control range k of 10℃ are recommended.

This study assessed the efficiency of the HABIT framework based on field study results and simulated complains regarding the thermal condition. Besides, it defined the optimal control parameter for the HABIT algorithm implementation, providing valuable insights into its application for on-site operation in actual building systems with occupant-centric set-point temperature control.

SUMMARY
This study presents a framework for optimizing HVAC scheduling and setpoint selection through occupancy forecasting. Designed as a generalizable algorithm with adjustable parameters, it adapts to various occupancy patterns. The novelty lies in integrating Kernel Density Estimation (KDE), Random Forest (RF), and Cumulative Relative Frequency (CRF) to predict arrival and departure times, defining three operation modes: occupied, unoccupied, and standby. By leveraging historical and real-time data, the method enhances HVAC control for energy conservation. The framework is evaluated against schedule-based operations in a Montreal case study and validated with an additional case in Vienna. Results highlight the proposed method's effectiveness in predicting arrivals and detecting early departures, reducing standby hours by initiating and shutting down the system later or earlier than the schedule-based operation mode.

Keywords: Occupant-centric control, Energy efficiency, Machine learning, HVAC.

1. INTRODUCTION

Energy demand has reached unprecedented levels, raising growing concerns about environmental sustainability. Buildings play a pivotal role in this debate, accounting for approximately 40% of global energy consumption and one-third of greenhouse gas emissions (Lucon et al., 2023). Heating, Ventilation, and Air Conditioning (HVAC) systems are crucial for maintaining thermal comfort but can consume over 50% of a building's total energy use (World Energy Outlook, 2022). Therefore, optimizing HVAC control sequences presents a key opportunity to reduce energy consumption and support low-carbon transitions.

Advances in smart building technologies, driven by declining sensor and data costs, enhance building performance and enable advanced control strategies (Kim et al., 2023). The Internet of Things (IoT) utilizes sensors to collect real-time data on parameters such as temperature, humidity, carbon dioxide (CO_2) levels, motion (via Passive Infrared - PIR sensors), and Bluetooth or Wi-Fi connections (Van Thillo et al., 2022). Subsequently, control methods can leverage this information to optimize HVAC operations by dynamically adjusting setpoints and ventilation rates based on the number of occupants or eliminating energy use in unoccupied spaces (Qiang et al., 2023). Finally, incorporating occupant behaviour insights into HVAC scheduling can improve thermal comfort, reduce energy use and lower carbon emissions.

1.1 Literature review

Occupant-centric control (OCC) is an indoor climate management approach that integrates occupant-related data, such as presence and comfort preferences, into HVAC system operations (Burak Gunay et al., 2021; O'Brien et al., 2020; Xie et al., 2020). A typical OCC framework consists of three key components: 1) Sensing, where sensors capture occupant-related data; 2) Learning, which identifies patterns, preferences, and behaviors from the data; and 3) Integrating, where these insights inform HVAC control strategies to enhance efficiency (O'Brien et al., 2020). Occupant data modeling is an approach that captures, analyzes, and predicts occupant behavior, preferences, and interactions within built environments. By leveraging data from various sources, these models provide valuable insights for optimizing building operations. For instance, Hobson et al. (2019) developed an Artificial Neural Network (ANN) for occupancy counting system using sensor fusion (Wi-Fi, CO_2 sensors, motion detectors, and electricity load meters) with 83% accuracy. Similarly, Mutis et al. (2020) proposed a vision-based ANN system to estimate occupant numbers and activities with 85% accuracy. Sheikh Khan et al., (2021) used desk-mounted PIR sensors in office spaces, achieving 87.5% accuracy to estimate occupant presence. These occupant data models enable the development of predictive control strategies that enhance energy efficiency while maintaining occupant comfort. Taheri & Razban (2021) used a Multilayer Perceptron algorithm to model CO_2 concentrations and optimize ventilation rates, reducing HVAC fan energy use by 50%. Choi et al. (2021) applied vision-based occupancy counting with a Support Vector Machine (SVM), achieving an 11% reduction in annual HVAC energy for small offices. Wang et al. (2022) used a vision-based camera with an ANN for occupant prediction, potentially lowering HVAC energy demand by 40%. Li et al. (2020) developed an HVAC control approach that adjusts indoor temperatures based on occupancy, saving up to 60% of cooling energy during unoccupied hours. Yang & Becerik-Gerber (2014b, 2014a) explored ANN-based start/stop schedules for office HVAC systems, reducing energy use by 10% through occupancy-driven scheduling.

1.2. Problem statement and main contribution

Although numerous studies acknowledge the importance of occupancy-based control, very few focused on developing generalizable algorithms that integrate occupancy pattern predictions with control sequences for HVAC systems. This study presents a framework for optimizing HVAC scheduling and setpoint selection through occupancy forecasting. Designed as a generalizable algorithm with adjustable parameters, it adapts to various occupancy patterns. The novelty lies in integrating Kernel Density Estimation (KDE), Random Forest (RF), and Cumulative Relative Frequency (CRF) to predict arrival and departure times, defining three operation modes: occupied, unoccupied, and standby. By leveraging historical and real-time data, the method enhances HVAC control for energy conservation. The framework is evaluated against schedule-based operations in a Montreal case study and validated with an additional case in Vienna.

2. METHODOLOGY

2.1. Data description and preprocessing steps

The dataset used in this study is collected from an office located in Montreal, Canada. The office space with approximately 200 m^2 is divided into four main zones: an open-concept office, two small shared offices, and a meeting room (see Figure 1). The dataset consists of motion sensor data gathered from PIR devices installed in each zone, spanning 15 months from January 2022 to March 2023.

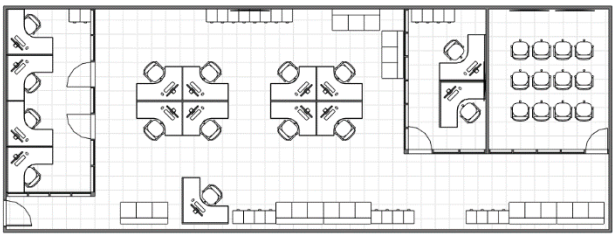

Figure 1. Case study floor plan.

PIR sensors detect movement in 15-minute intervals, providing a binary occupancy status but may miss immobile occupants. To refine occupancy data, zero-motion periods during the first and last daily occupancy events are analyzed. A percentile-based threshold identifies false non-occupancy intervals, which are then corrected to reflect actual occupancy. Furthermore, to facilitate comprehensive data analysis, various statistical methods are applied. Specifically, the analysis included calculating the density distributions of arrivals, and departures.

2.2. Modelling procedure

A total of three techniques are considered—KDE, RF, and CRF—to develop a robust modeling procedure. In this study, KDE is applied to identify dense periods when arrivals and departures are most likely to occur by filtering outliers. Furthermore, this study develops a RF model that predicts daily arrival times leveraging features such as hour, minute, and day of the week. Finally, CRF is applied to estimate the earliest and latest typical arrival and departure times.

2.3. The proposed method

The proposed method defines three distinct HVAC operation modes—occupied, unoccupied, and standby—each with a specific temperature range. By leveraging historical and real-time data, the method enhances HVAC control to promote energy conservation and operational efficiency. Figure 2 presents the flowchart illustrating the proposed method in detail. The KDE method filters the data that will be used by the RF algorithm and the CRF approach, leading to the models being referred to as the KDE-RF model and the KDE-CRF model, respectively.

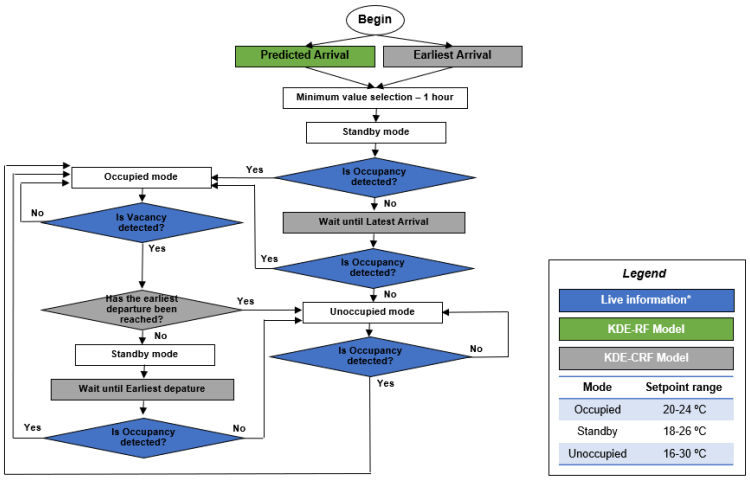

Figure 2. The flowchart of the proposed method.

The proposed method begins by selecting the minimum value from either the KDE-RF model or the KDE-CRF model to initiate standby mode 1 hour prior. This strategy, known as pre-heating or pre-cooling, is designed to prevent discomfort upon occupants' arrival. If occupancy is detected during this period, the system transitions to occupied mode. Otherwise, it remains in standby mode until the latest predicted arrival time, after which it switches to unoccupied mode if no occupancy is detected. Once in occupied mode, the system monitors for vacancy. If a vacancy is detected, it checks whether the earliest departure time has been reached. If so, the system transitions to unoccupied mode; otherwise, it reverts to standby mode, waiting for either the detection of occupancy or the earliest departure time. The framework assumes daily occupancy of the commercial space, meaning it does not account for the ability to predict whether the office space will be occupied or unoccupied on the following day.

2.4. Main algorithm settings

The proposed method is a generalizable algorithm and incorporates seven key parameters: forecasted time range, day selection, training window, dense period threshold, CRF grouping, and arrival/departure percentiles. These parameters define arrival and departure intervals, operating days (weekdays, weekends, or both), modeling period, and common arrival/departure times while filtering outliers. CRF grouping analyzes arrivals and departures by weekday or overall, and percentiles determine the earliest/latest arrivals and earliest departures based on data distribution. Finally, to identify the optimal algorithm settings, a loop is implemented in the proposed method to analyze the output across different thresholds for the latest arrivals and earliest departures, based on the number of weeks.

2.5. Performance evaluation criteria

To evaluate the proposed method, three metrics are established. Table 1 provides an overview of these metrics, including their descriptions and the criteria used for assessment.

Table 1. Evaluation metrics for the proposed method.

Index	Metric	Description	Criteria
1	Arrival accuracy	Measures the accuracy of predicted arrival times.	• Deviation: ±15min and ±30min • Remove days with no occupancy • Remove outliers (KDE)
2	Late arrival frequency	Tracks how often actual arrivals occur after the latest predicted time.	• Deviation: +15min • Remove days with no occupancy • Remove outliers (KDE)
3	Early departure frequency	Measures how often departures occur before the earliest predicted time.	• Deviation: -15min • Remove days with no occupancy • Remove outliers (KDE)

2.6. Comparison of operation modes

To estimate potential energy savings, the proposed method is benchmarked with two operation modes: the current operational system and an idealized optimal operating scenario. The current operational system operates on a predefined schedule. Standby mode begins daily at 6:00 AM to accommodate arrivals, transitioning to occupied mode upon detecting occupancy. For departures, the system remains in standby mode until 5:30 PM or five minutes after the last motion is detected. In contrast, the optimal operating scenario, though idealized and somewhat unrealistic, assumes that standby mode starts exactly one hour before actual arrivals, unoccupied mode begins immediately after the last actual departure, and vacancy days are predicted with perfect accuracy.

While this optimal scenario is unlikely to be fully achievable in practice, it serves as a valuable benchmark for assessing the energy savings potential of the proposed method.

Furthermore, to calculate energy savings, four metrics are established: total savings, arrival savings and departure savings. Total savings metric measures total standby hours saved when using the proposed method, and arrival and departure savings metrics calculates standby hours saved at the start or end of the day, when using the proposed method, respectively.

2.7. Validation of proposed method

To validate the proposed method, a dataset from a university office in Vienna, Austria, is used. The 200 m² space includes six zones: a kitchen, a meeting room, two open-concept offices, and a single office. Motion sensor data was collected from January to December 2013. All previously described steps are replicated for validation.

3. RESULTS

3.1. Data analysis

Figure 3 presents the analysis of arrivals and departures, highlighting distributions using the KDE approach, and weekday-based distributions using the CRF method.

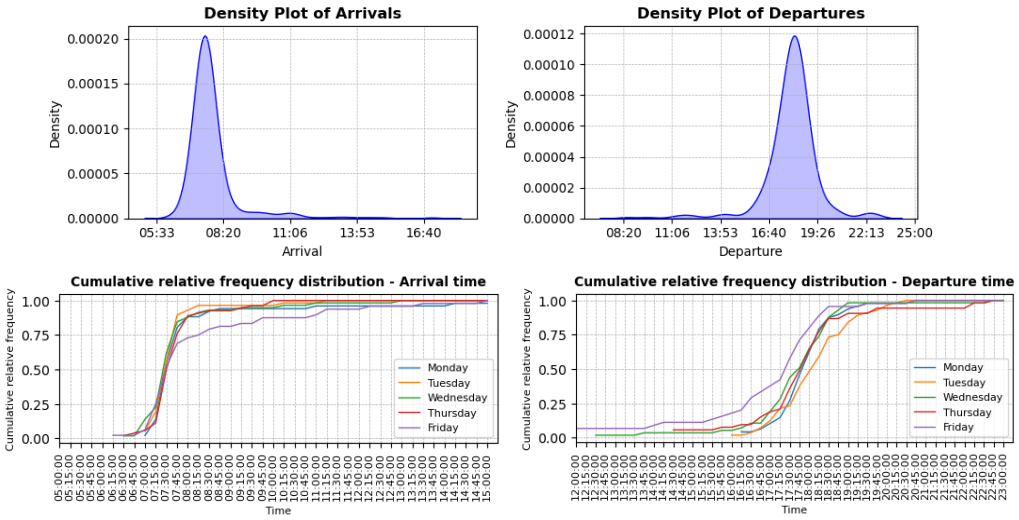

Figure 3. Overview of the dataset.

Figure 3(a) shows that arrivals are concentrated within a narrow time interval, with a sharp peak around 7:00 and 8:00 AM and a few scattered occurrences outside this range. Figure 3(b) presents the CRF curve with arrival distributions remaining consistent across most weekdays, except on Fridays. In contrast, departure events exhibit greater variability, spanning up to five hours compared to the two-hour arrival window. Additionally, departure distributions vary significantly across weekdays, highlighting their more dynamic nature.

3.2. Performance evaluation results

To illustrate the dynamics of the proposed method, Figure 4(a) presents the predicted (blue dots), latest arrivals (red dots), and actual arrivals (green dots), while Figure 4(b) displays the earliest departures (blue dots) and actual departures (red dots).

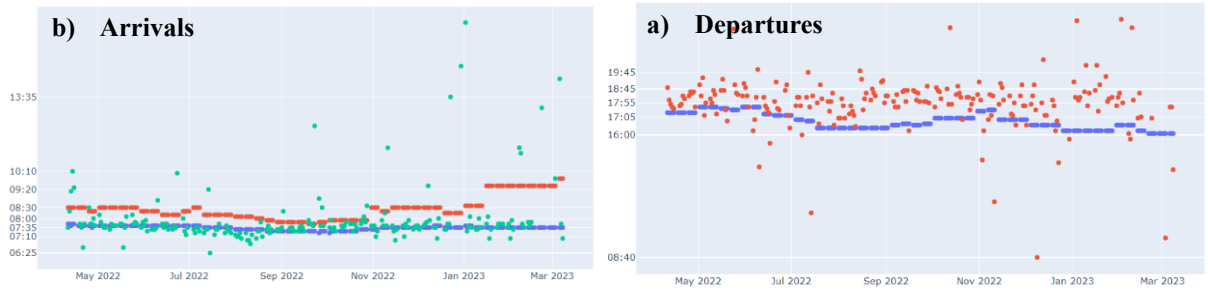

Figure 4. Performance evaluation results: a) Arrivals and b) Departures.

Figure 4 provides valuable insights into arrival and departure patterns over 12 weeks of training. The arrival accuracy shows strong performance, with 98% predicted arrivals falling within ±30 minutes of the actual time and 78% within ±15 minutes, demonstrating the model's reliability. The late arrival frequency of 10%, determined at the 98th percentile, indicating a few occasional discrepancies. For departures, the model shows an early departure frequency of 12%, based on the 10th percentile, highlighting some inconsistencies in early departure events. These results underscore the method's strengths in arrival predictions and identifying early departure events.

3.3 Comparison of operation modes

To estimate potential energy savings, the proposed method is compared with two operation modes. To illustrate the dynamics of each operation mode, Figure 5(a) shows the start times for the optimal operating scenario (blue dots), the current operational system (red dots), and the proposed method (green dots), while Figure 5(b) presents their respective end times.

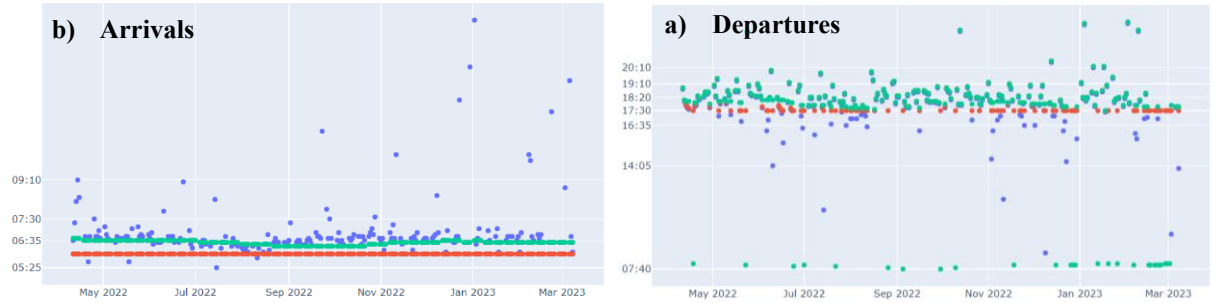

Figure 5. Comparison of operations modes: a) Arrivals and b) Departures.

Figure 5(a) demonstrates that the points corresponding to the proposed method closely overlap with those of the optimal operating scenario for most instances, indicating an efficient and accurate starting time for the HVAC system. In contrast, a noticeable shift is observed between the dots representing the current operating system and those of the other two modes, attributed to the conservative assumptions of building operators. This difference highlights the energy-saving potential achievable when incorporating occupant data into HVAC operation. Similarly, Figure 5(b) reveals instances where the proposed method ends operation early in the day, aligning with

the latest arrival time. On vacant days, the system remains in standby mode until the latest arrival time, and if no occupancy is detected, it transitions to the unoccupied mode. Additionally, the proposed method effectively captures most early departures, allowing the system to switch to unoccupied mode before the default time of 5:30 PM. These results demonstrate how promising the proposed method is for promoting energy efficiency and enhancing HVAC operations. When evaluating total savings, the proposed method reduces standby hours by 57%, equivalent to 299 hours. Of these, 230 hours are saved during arrivals, and 69 hours during departures. However, it is crucial to compare these results with the optimal operating scenario, which, while unrealistic, provides a valuable benchmark for assessing the energy-saving potential of the proposed method. The optimal operating scenario achieves savings of 336 hours during arrivals and 170 hours during departures. Consequently, the proposed method achieves 68% of the savings for arrivals and 41% for departures compared to the optimal operating scenario.

3.4. Algorithm validation

To validate the proposed method, a dataset from a university office in Vienna, Austria, is used, replicating all described steps. Occupants typically arrive between 7:45 and 09:15 AM and depart between 18:00 and 20:45 PM. Moreover, when evaluating the method within this new dataset, arrival predictions achieve 85% accuracy with a 30-minute deviation, late arrivals occur 12% of the time, with an average delay of 95 minutes, and early departures occur 7% of the time, with an average lead time of 38 minutes. Finally, when evaluating total savings, the proposed method reduces standby hours by 47%, equivalent to 472 hours. Furthermore, the optimal operating scenario achieves savings of 553 hours during arrivals and 147 hours during departures. Consequently, the proposed method achieves 71% of the savings for arrivals and 63% for departures compared to the optimal operating scenario. These validation results prove the potential of the proposed method as a generalizable algorithm for promoting energy efficiency and enhancing HVAC operations.

4. CONCLUSION

This investigation proposed a framework to address the stochastic nature of occupancy by analyzing and integrating it into the control sequences of HVAC systems. The framework is designed as a generalizable algorithm with adjustable parameters, enabling it to adapt to diverse occupancy patterns. The results highlight the proposed method's effectiveness in predicting arrivals and detecting early departures for the case study located in Montreal, reducing standby hours by 57% by initiating and shutting down the system later or earlier than the schedule-based operation mode. Additionally, as for the case study located in Vienna, the validation results reported standby hours reduction by 47%, proving the potential of the proposed method as a generalizable algorithm for promoting energy efficiency and enhancing HVAC operations. Future work includes validating the algorithm with new datasets, developing automation strategies to optimize adjustable parameters, creating a framework to capture zone-level dynamics, and deploying it in a real-world case study.

SUMMARY
A study on the thermal and air environment of open-plan classrooms in an elementary school in Tokyo, Japan, has been conducted. With the subsidence of the COVID-19 pandemic, it became possible to visit schools during the times when students are present. Therefore, a field survey was conducted where the status of window and door openings, the operation of heating, cooling, and ventilation systems, and the number of students were visually inspected over a full day. By comparing the results of the field survey with the data obtained from monitoring instruments, it was confirmed that differences in window openings had a significant impact on CO_2 concentration. Additionally, despite the air conditioner switches being centralized in one location, it was found that the operation of the air conditioners varied between classrooms.

Keywords: window opening, environmental control behavior, open-plan classrooms

1. INTRODUCTION

In Japan, there are few studies on thermal and air environments in open-plan classrooms. During the COVID-19 pandemic, air environment measurements in school classrooms were primarily conducted through remote monitoring using IoT devices, as visits during times when students were present were avoided. However, in May 2023, with the reclassification of COVID-19 to Category 5, same category as influenza under the Infectious Disease Control Law, restrictions were eased, allowing visits during the hours when students were in the classroom. Consequently, a field survey was conducted with the aim of understanding the relationship between environmental adjustment behavior and the thermal and air environment in open-plan elementary school classrooms.

2. OVERVIEW OF THE MEASUREMENT

The target of the field measurements was three classrooms located on the second floor of F Elementary School (a four-story, reinforced concrete building) in Tokyo. These are open-plan classrooms with no partition walls between the classrooms and the hallway (Figure 1). The air conditioning remote controls and mechanical ventilation system switches are installed on the wall of the open space. The ventilation system is an exhaust-type mechanical ventilation system, allowing only control of airflow (high or low settings). In principle, the system is instructed to operate on high while the room is occupied and on low even when unoccupied, running 24 hours a day. Moreover, the mechanical ventilation system is not operated individually for each classroom

but is controlled collectively for the three classrooms. In Figure 1, the classrooms are labeled U161, U162, and U163 from left to right. The instruments (RTR576, T&D) for CO_2 concentration, room temperature and relative humidity were installed above the blackboard in each classroom. Continuous monitoring using these instruments was conducted at one-minute intervals throughout the year. Long-term continuous measurements of CO2 concentrations showed no significant differences in CO2 concentrations in the three classrooms. The percentage of time that the CO2 concentration standard of 1000 ppm set by the Building Management Act met in December 2023 would be 93.8% for U161, 92.3% for U162, and 90.7% for U163. Since remote measurements without a visit cannot reveal actual residential conditions, we planned to conduct the on-site survey. In the on-site survey, we stayed at the school for a full day and conducted a visual survey of the window and door opening/closing conditions, the operation status of heating, cooling, and ventilation systems, and the number of students in each classroom. The results of this on-site survey were compared with the data obtained from monitoring equipment. The on-site survey was conducted on December 14, 2023. The three classrooms subject to the field measurement were sixth-grade classrooms. The open-plan classrooms being measured had sliding windows, mid-height windows, and transom windows facing the balcony on the south side, and mid-height windows facing the north-side balcony (Figure 2).

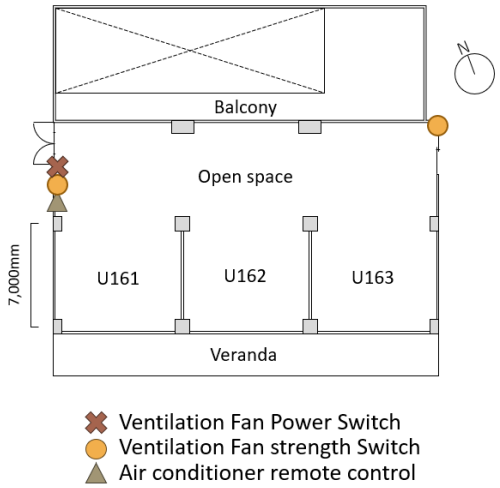

Figure 1. Open-plan classrooms of measurement target

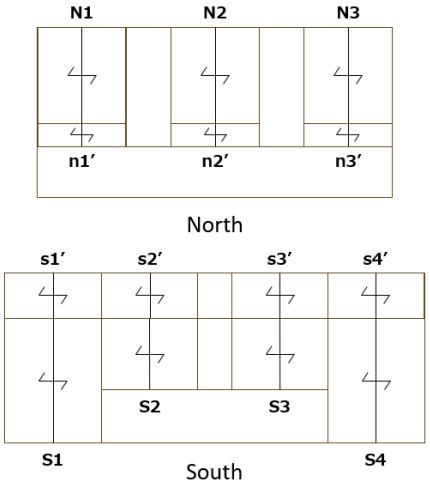

Figure 2. Interior elevation of the windows

3. RESULTS AND DISCUSSION

Table 1 shows the timetable for the day of the on-site survey and the number of students present during class in each classroom. Figure 3 illustrates the window opening ratio for each classroom, and Figure 4 shows the changes in CO_2 concentration over time in each classroom. In Figure 4, a significant difference in the variation of CO_2 concentration between classes and the influence of adjacent classrooms were observed. On the day of the on-site survey, the mechanical ventilation system was continuously operating on high mode, and the doors connecting to the hallway were kept open at all times. One possible factor contributing to the differences in CO_2 concentration between the classes is the variation in window opening ratio. The window opening ratio was defined as the proportion of the window surface area that was open, considering the windows on both the south and north sides, as shown in Figure 2. A window opening ratio of "1" indicates that

all openings were fully open, while a ratio of "0" means that all openings were closed. When looking at the CO_2 concentration trend during the second period in Figure 4, even though both U161 classroom and U162 classroom were unoccupied, there was a noticeable difference in their CO_2 concentrations. The faster decay of CO_2 concentration in U161 can be attributed to its higher window opening ratio, while the higher CO_2 concentration in U162 is likely influenced by its proximity to U163, which had students present. During the third period, when all three classrooms were occupied, the window opening ratio decreased in the order of U161, U162, and U163. Correspondingly, the CO_2 concentration increased in the same order, with U161 having the lowest concentration and U163 the highest. Since the same lesson (theme) was being conducted in all three classrooms during the third period, and the students' activity levels and the number of occupants were similar, it can be inferred that the differences in window opening ratio were a significant factor contributing to the variations in CO_2 concentration. This trend was similar to the difference in the rate of fulfilment of CO2 concentration standards between classrooms obtained from the long-term measurements mentioned above. The on-site survey is useful for investigating the actual situation of window opening and closing

Table 1. Timetable and number of students in the room during the class

Period		1	2	3	4			5	6	
Time	8:25 - 8:40	8:40 - 9:25	9:40 -10:25	10:40 - 11:25	11:40 - 12:25	12:25 - 13:10	13:25 - 13:40	13:40 - 14:25	14:30 - 15:15	15:15 - 15:30
U161	Morning meeting	34	0	34	0	Lunch time	Module learning	34	34	Leaving meeting
U162		0	0	32	0			32	32	
U163		33	33	33	0			33	33	

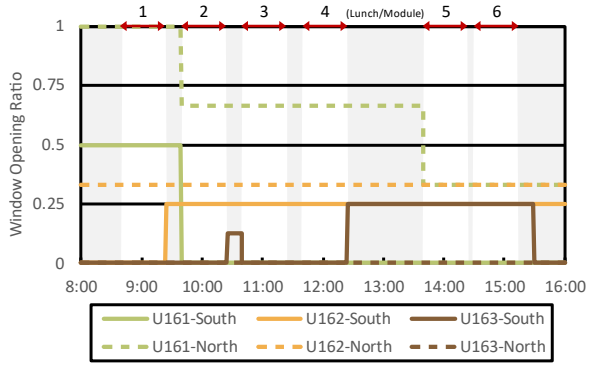

Figure 3. Opening ratio of the south and north windows in three classrooms

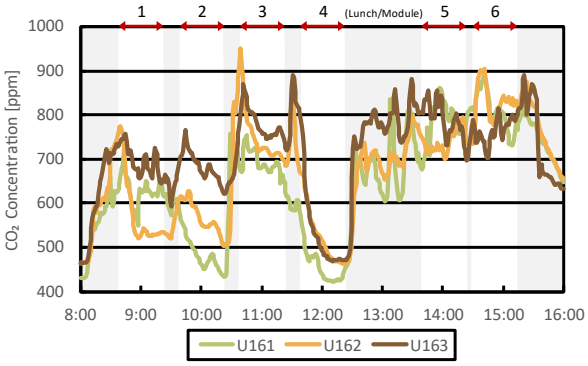

Figure 4. CO_2 concentration in three classrooms

Figure 5 shows the changes in room temperature and outside temperature over time for each classroom, while Figure 6 shows the changes in the set point temperature of the air conditioner for heating (AC) over time for each classroom. From Figure 6, it was confirmed that there were differences in how the AC was operated in each classroom. As shown in Figure 1, the AC switches are grouped together in one location for the three classrooms. Therefore, it was assumed that the air conditioning in the open-plan classrooms was centrally managed until the field survey were conducted. However, in practice, students frequently operated the AC during class in U161, which is the classroom closest to the switch, highlighting a difference in the frequency of AC operation due to the switch's location. Additionally, the results suggest that, in winter, the fluctuation in room temperature is more influenced by the AC set temperature than by the outside temperature. In

U162, where the AC was turned off after the third period, the room temperature remained around 26°C, even though the windows were open. The room temperature shown here was measured at the top of the blackboard (2 meters above the floor), but the air temperature at 10 cm above the floor in U162 also remained within the range of 20-21°C, even after the AC was turned off. Since the recommended room temperature range during winter, according to the School Environmental Health Management Manual (MEXT, 2018), is 18-20°C, it can be considered that the thermal environment is not uncomfortable. One reason the temperature in U162 remained at around 26°C, even with the windows open and the AC off, could be that the AC set temperatures in the adjacent classrooms were 30°C, and air from those classrooms flowed into U162. Furthermore, all three classrooms experienced periods when the room temperature was too high for the winter season, creating an environment unsuitable for learning. To improve the thermal environment, it is important to communicate room temperature conditions to the occupants and to position the AC switches in a location where they can be easily operated by each classroom independently.

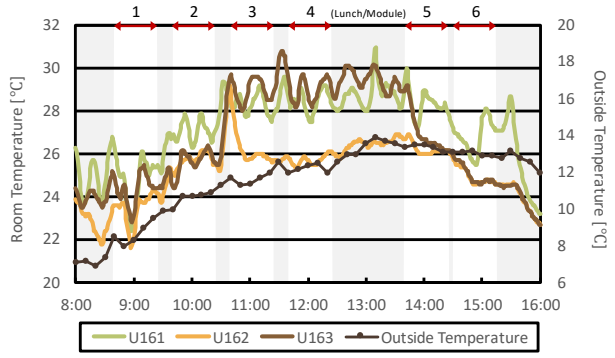

Figure 5. The room temperature in three classrooms with the outside temperature

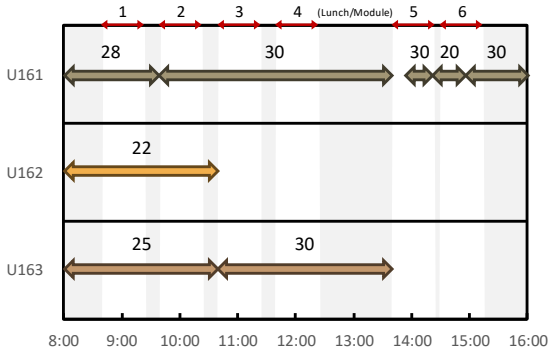

Figure 6. The set point temperature (°C) of the air conditioner for heating in three classrooms

4. CONCLUSIONS

The on-site survey revealed that the frequency of windows open/close had a large impact on the difference among the CO2 concentrations in the three classrooms, even these classrooms had the same floor plan and shared a ventilation system. Additionally, it was found that the frequency of temperature setting changes was affected by the difference in distance from each classroom to the air conditioning switch.

Previous long-term remote measurements have relied solely on measurement data using physical measurement instruments, making it unclear how occupants' behavior affects the indoor air environment. However, the on-site survey of living conditions enabled to understand the impact of occupant behavior on the air environment, complementing the analysis that was unclear during the long-term remote survey.

ABSTRACT
The implementation of non-uniform indoor thermal environments serves as an effective approach to simultaneously enhancing occupant thermal comfort and building energy efficiency. The core of this process lies in the real-time prediction of indoor temperature field. To enable real-time prediction of indoor temperature distribution, this study introduces an adaptive Spatio-temporal Graph Convolutional Network (ASTGCN) model, which operates efficiently with limited sensors. A case study was conducted in an office room in Beijing, where data were collected from 39 measurement points at various spatial locations over a 10-day period. Experimental results indicate that the proposed model, during its operational phase, can accurately reconstruct the temperature distribution across the remaining 32 locations within the space using only 7 fixed sensors. The model achieves a mean absolute error (MAE) of 0.34 °C and an average computation time of 8 s, demonstrating both high accuracy and computational efficiency.

Keywords: temperature distribution, temperature prediction, sensor network, graph convolutional network

1. INTRODUCTION
1.1 Background
A comfortable indoor environment significantly impacts work efficiency and occupant health. Temperature is the most directly perceptible parameter in the indoor environment for occupants and plays a significant role in human comfort. Traditional temperature control methods are based on the assumption of uniformly distributed temperature across the entire space, employing a constant target temperature for regulation[1]. However, due to the influence of factors such as outdoor environmental conditions, building layout, occupant activities, and equipment operation, the actual indoor temperature distribution is non-uniform. Traditional temperature control methods are unable to accurately capture temperature variations in different zones, potentially leading to localized overheating or underheating, thereby compromising occupant comfort. Moreover, traditional control modes typically adjust the entire space uniformly, which may result in significant energy waste. In summary, a single uniform temperature control strategy is insufficient to meet the diverse comfort requirements of occupants and the sustainability goals of buildings. he creation of a non-uniform indoor thermal environment represents an effective strategy for

addressing occupants' personalized comfort needs while enhancing energy efficiency. By selectively regulating the temperature in specific zones, it can effectively meet the comfort requirements of occupants in different areas. Furthermore, by avoiding excessive regulation of the entire space, it significantly enhances building energy efficiency. The key to achieving this goal lies in the acquisition, prediction, and control of indoor temperature parameters. Through precise real-time temperature regulation, it is possible to enhance indoor comfort while minimizing energy waste. Among these, rapidly understanding the patterns of indoor temperature distribution serves as a critical foundation for realizing real-time temperature control.

1.2 Related works

Indoor temperature distribution prediction methods primarily include numerical simulation-based, mathematical model-based, and data-driven approaches. Computational Fluid Dynamics (CFD) employs numerical techniques to simulate physical processes such as airflow, heat conduction, and radiative heat transfer, thereby providing high-precision predictions of temperature distributions. In 1974, Nielsen from Denmark first applied CFD technology in the field of heating, ventilation, and air conditioning (HVAC); since then, CFD has been progressively developed and widely utilized in simulation studies of indoor thermal environments in buildings [2]. For instance, Li et al. [3] used CFD methods to evaluate the indoor thermal environment of a station under three different air conditioning design schemes. Their study assumed a relatively fixed distribution and activity pattern of occupants within the station, although in practical scenarios, occupant distribution and behavior are often dynamic. Nonetheless, when applied to large spaces, CFD is limited by its substantial computational burden and the insufficient availability of field data for validation.

Mathematical models, by employing simplified equations and assumptions, can accelerate temperature prediction and reduce computational costs. In 2009, Zuo and Chen [4] firstly proposed the Fast Fluid Dynamics (FFD) model, which is about 50 times faster than the traditional CFD method. Kato et al. [5] proposed the Contribution Ratio of Indoor Climate (CRI), a metric designed to quantify the contributions of various heat sources and sinks to indoor temperature distribution under steady-state conditions. On this basis, Zhao et al. [6] developed a rapid prediction method for indoor temperature distribution by combining mobile sensors with the CRI methodology. However, their study considered only variations in heat source intensity, limiting its applicability to real-world settings where occupant activities dynamically influence thermal conditions. Furthermore, since the model relies on CFD computations to obtain the CRI, any changes in boundary conditions or heat sources necessitate recalculations, thereby compromising its real-time performance.

With the rapid advancements in computer and sensor network technologies, data-driven algorithms have substantially propelled the field of indoor temperature distribution prediction. Li et al. [7] developed a Room Thermal Reaction Model (RTRModel) and an Airflow Prediction Model (AFPModel). However, since these models were developed using CFD-derived datasets, they might not encompass all possible indoor operating conditions. Minassian et al. [8] deployed microclimate sensors on a university campus in Sydney and, based on the substantial data collected, compared the performance of CNN, LSTM, and CNN-LSTM models for indoor temperature prediction. It is important to note that this study relied solely on indoor sensor data for model training and did not account for the impact of external climatic conditions, occupant

movement, or equipment usage on the indoor temperature distribution. Consequently, data-driven temperature prediction methods, which depend on extensive historical data, may face challenges in practical applications due to the difficulty of acquiring large-scale, high-quality multivariate datasets.

1.3 Research gaps and objectives

In summary, existing research and technologies on predicting non-uniform indoor temperature distribution still face the following research gaps in practical applications. Firstly, Previous studies on indoor temperature distribution prediction are typically based on steady-state indoor environments. The influence of complex internal and external factors on temperature distribution is often overlooked. Secondly, Current data-driven temperature prediction models require extensive historical data to ensure accuracy. However, deploying numerous sensors in practical engineering applications is often infeasible. Therefore, achieving efficient and accurate temperature field prediction with limited sensors remains a critical unresolved issue.

This study aims to provide a solution that enables fast and accurate indoor temperature field prediction while ensuring practical applicability. The main contributions of this study are as follows:

(1) An adaptive spatio-temporal graph convolutional network (ASTGCN) based on limited sensors is proposed for rapid indoor temperature field prediction.

(2) For the first time, an adaptive graph learning-based GCN method is applied to optimal sensor selection for temperature field prediction. The approach dynamically adjusts the sensor network topology through adaptive graph learning and identifies key sensor nodes that contribute significantly to prediction accuracy. During building operation, this method enables high-resolution temperature field prediction using only a limited number of sensors.

2. METHODOLOGY

Indoor temperature is influenced by various thermal disturbances from both inside and outside the building, including solar radiation, outdoor temperature, air conditioning airflow, indoor occupants, and equipment. Spatially, the indoor temperature field is divided into several regular grids, with the temperature within each grid assumed to be uniform. Heat exchange occurs between different grids, and temperature fluctuations in one grid can affect the temperature of adjacent grids. Additionally, the temperature within each grid changes over time. Therefore, indoor temperature distribution exhibits both temporal and spatial dependencies. In this study, sensors are deployed in each grid to investigate the spatiotemporal patterns of indoor temperature distribution under complex thermal disturbances based on long-term monitoring data from these sensors.

2.1 Modeling Framework

In this study, we propose an adaptive spatiotemporal graph convolutional network model that integrates Graph Convolutional Networks (GCN) and Gated Recurrent Units (GRU) for the reconstruction and prediction of indoor temperature distributions, as depicted in the Fig. 1. The overall data processing workflow is divided into three main steps.

Step 1 is data preprocessing. Acquire the time-series data from sensors along with their spatial locations, and perform data preprocessing.

Step 2 is ASTGCN learning module. First, construct the graph structure for all sensor nodes, dynamically adjusting the relationships between nodes based on an adaptive adjacency matrix. Utilize multi-layer Graph Convolutional Networks to aggregate neighborhood information and update node features. Subsequently, based on the graph information generated by the GCN, the historical temperature data of each sensor is fed into a GRU module for temporal feature modeling.

During the model training process, compute the contribution value of each node in the adaptive adjacency matrix, and select nodes with higher contribution rankings. The selected sensors, along with additional sensors, are reintroduced as new input variables into the GCN.

Step 3 is temperature distribution prediction. Fuse the spatial features from the GCN and the temporal features from the GRU, and predict the values of target nodes through a fully connected layer. By consolidating the prediction results of all target nodes, the overall temperature field is obtained.

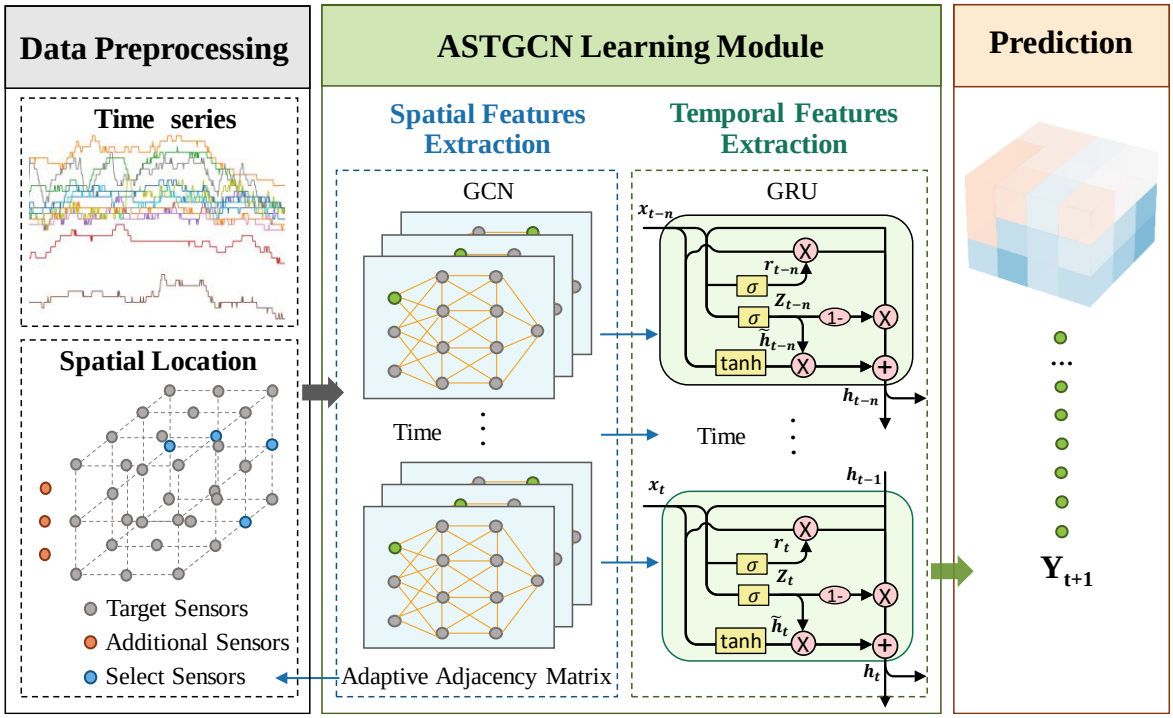

Figure 1. ASTGCN model framework.

2.2 Evaluation Metrics

Three metrics are used to evaluate the performance of the model: Mean Absolute Error (MAE), Mean Squared Error (MSE) and Root Mean Squared Error (RMSE). Their mathematical formulations are given by Eq. (1)-(3).

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|y_i - \hat{y}_i\right| \tag{1}$$

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 \quad (2)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (3)$$

where, y_i represents the actual values, $\hat{y}_i$ represents the predicted values, and n is the number of samples.

3. CASE STUDY

3.1 Experimental settings

The experiment was conducted in an office located in Beijing, with dimensions of 5.4m × 5.2m × 3.4m (length × width × height), which includes two south-facing windows. The internal disturbances of the room include personnel, monitors, a main computer, and a standalone air conditioner. The external disturbances include solar radiation and outdoor temperature. The room was divided into a three-dimensional grid, consisting of 12 points on the horizontal plane and 3 height levels (0.6m, 1.2m, and 2.4m). All these sensors have been measured, calibrated, and assigned unique identification numbers. The Fig. 2 shows the layout details of the measurement points. A total of 39 temperature measurement points were monitored over a 10-day period (from August 30 to September 8), with measurements taken daily from 08:30 to 21:30 at 1minute intervals.

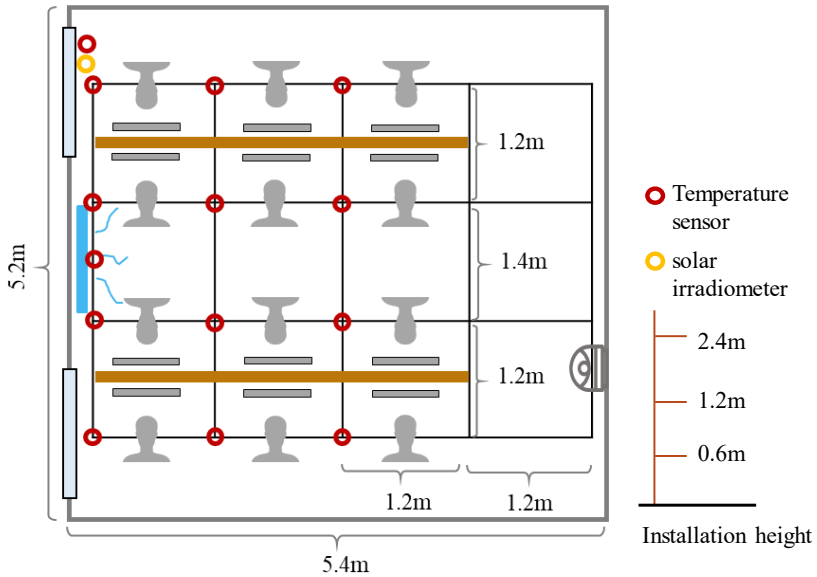

Figure 2. Schematic diagram of sensor installation location.

3.2 Dataset

First, data preprocessing was performed on the dataset, followed by basic visual analysis. Fig. 3 shows the temperature distribution across different height sections of the indoor space at a specific moment. It can be observed that non-uniform temperature distribution exists within the space, with a maximum temperature difference of 2.6 °C. The temperature distribution at the 0.6m

and 1.2m height sections exhibits significant non-uniformity, while the temperature distribution at the 2.4m height section tends to be more uniform. This is because, at the 0.6m and 1.2m heights, the primary heat sources are human occupants and equipment, and human activities have a considerable impact on temperature distribution. At the 2.4m height, the primary heat source is lighting, which is uniformly distributed and typically turned on and off collectively, resulting in a more uniform temperature distribution.

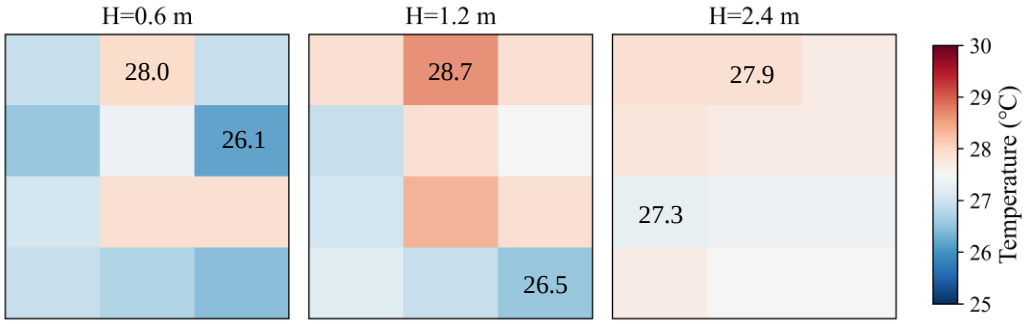

Figure 3. Temperature distribution at different altitudes.

4. RESULTS

4.1 Determination of the number of sensors

To determine the optimal number of sensors required for temperature distribution reconstruction, this study evaluated the model performance using the top 5-10 most contributive sensors as inputs. The model's prediction results are shown in Table 1 and Fig. 4. It can be observed that when 7 sensors were selected, the model achieved the highest average prediction accuracy and the smallest maximum root mean square error, indicating greater stability in the model's predictions. Furthermore, Figure. 3 illustrates that the model also performed well in terms of overall spatial prediction, with the maximum prediction error not exceeding 1.2°C. Therefore, using the historical data from 7 fixed sensors as input to the ASTGCN model yielded the best performance. Subsequent result analysis is based on this model.

Table1. Comparison of prediction results of different sensor numbers

Nodes	MAE (°C)	MSE ($°C^2$)	RMSE (°C)	Max MAE (°C)	Max MSE ($°C^2$)	Max RMSE (°C)
5	0.47	0.32	0.49	1.22	1.5	1.23
6	0.45	0.3	0.47	1.23	1.5	1.23
7	**0.34**	**0.17**	**0.36**	**0.96**	**0.93**	**0.97**
8	0.35	0.18	0.37	0.99	0.99	0.99
9	0.43	0.3	0.45	1.18	1.8	1.34
10	0.43	0.27	0.43	1.17	1.36	1.17

4.2 The predictive performance of the model at different heights

To further analyze the model's prediction performance, comparison charts of prediction accuracy and prediction error heatmaps at different heights were plotted. As shown in Fig. 5, the model exhibits higher prediction accuracy for sensors at a height of 2.4m, while at 0.6m and 1.2m heights, the prediction accuracy for certain sensors is lower. This is likely due to the greater influence of personnel on temperature distribution at 0.6m and 1.2m, leading to larger temperature fluctuations

at different locations. In contrast, the temperature distribution at 2.4m is less affected by heat disturbances, resulting in smaller temperature fluctuations. This is consistent with the characterization of the dataset in Section 3.2.

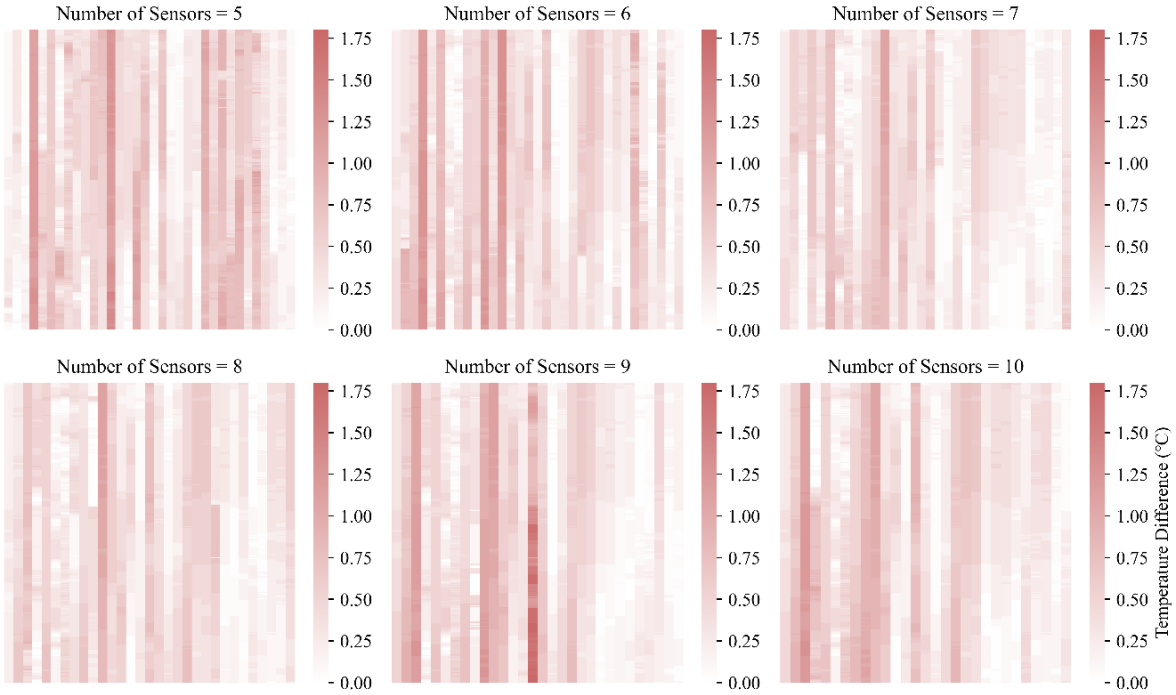

Figure 4. The heatmap of prediction errors for the model under different sensor quantities.

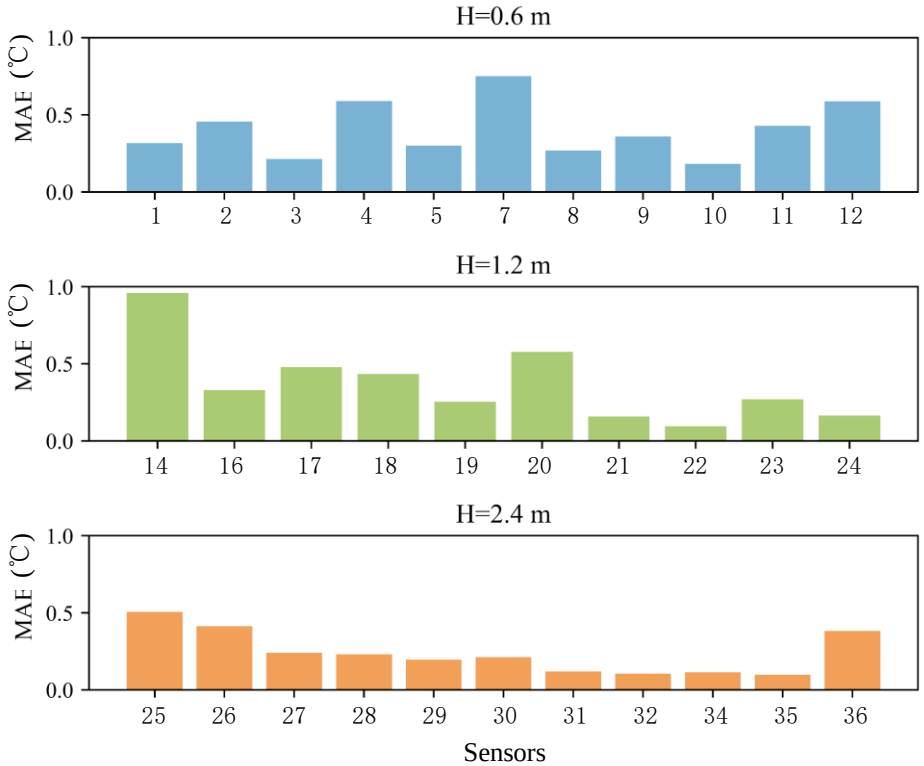

Figure 5. The prediction accuracy of the model at different heights.

5. CONCLUSIONS

This study proposes an ASTGCN model based on a limited sensors to achieve fast and accurate predictions of non-uniform indoor temperature field. First, the ASTGCN module employs an adaptive graph learning mechanism to capture spatial dependencies among sensors. By ranking node weights in the adaptive adjacency matrix, four sensors with significant contributions to temperature field prediction are selected and combined with three additional sensors as model inputs. Subsequently, a GCN is applied at each time step to perform graph convolution operations on the sensor network data, extracting spatial features. The outputs of the GCN are then fed into a GRU to model the temporal evolution of sensor data. Finally, a fully connected layer generates the predicted values for target nodes, reconstructing the indoor temperature field. The performance of the model was validated in a real office building.

The ASTGCN model can automatically identify key sensors that capture thermal sources and boundary conditions from historical data, enabling temperature estimation at unobserved locations based on a limited number of sensors. In the case study office, the model accurately predicted temperatures at 32 unmeasured locations using only 7 fixed sensors. This approach reduces the number of sensors by 82% while achieving high spatial resolution in temperature field reconstruction. Furthermore, compared to the POD-RBF and POD-STGCN models, the proposed model demonstrates superior prediction accuracy and robustness. For the case study office, the model achieves a MAE of 0.34°C. By comparing prediction performance across different heights and locations, the proposed model exhibits greater stability. Therefore, the model effectively addresses indoor environmental challenges under complex and dynamic thermal disturbances.

SUMMARY
To understand the variations in stress levels accompanying changes in thermal environments for different behaviours, this study took speech (continuous speaking) and conversation (intermittent speaking) as examples and conducted an experiment to detect the skin conductance level and skin conductance level fluctuation, which are two objective physiological parameters reflecting stress level, in different thermal sensations across speech and conversation. During the experiment, 30 subjects performed speech and conversation at three temperature settings, and reported their thermal sensation. Mann-Whitney U test was used to analyse the differences in stress levels between speech and conversation. Fitted curves for the two speaking behaviours under changes in thermal sensation were calculated. The results showed significant differences in stress levels between speaking behaviours under some specific thermal sensations, and the fitted curves show different trends in stress levels. The findings contribute to our understanding of the relationship between stress level, thermal comfort and speaking behaviours.

Keywords: Thermal comfort, occupant behaviour, stress level, electrodermal activity

1. INTRODUCTION

Stress has a negative impact on humans' physical and mental health as well as cognitive functions (Marin et al., 2011), and it has been regarded as one of the factors that seriously affect human life in the present generation (Whiteford et al., 2013). Today, human beings face increasing pressure from all walks of life, and more and more scholars are devoted to research on improving stressful situations from different perspectives.

There are many factors that affect stress, with many studies found that there is a relationship between the environment and stress levels, especially in indoor environments (Elsadek & Liu, 2021). As one of the significant perspectives of indoor environments (Wierzbicka et al., 2018), thermal comfort is an essential factor influencing the stress level of the occupants (Yang et al., 2022). In order to explore the stress levels under different thermal environment, many studies have been conducted (Choi et al., 2015; M. Kim et al., 2017). While thermal environmental factors are important, occupant behaviour and mood also influence stress (Koo & Kim, 2018; Lawanont & Inoue, 2018). Most prior studies focused on static conditions, neglecting the impact of occupant behaviours, which limits their real-world applicability. Speaking, a common indoor activity, has been shown to affect thermal comfort (Zhang et al., 2024). This research addresses the gap by analysing stress level variations under different speaking behaviours (continuous speaking and intermittent speaking) across thermal environments.

Stress levels can be measured through subjective questionnaires (Alkatheri et al., 2020; Dogan et al., 2019). or objective physiological signals. Physiological signals, collected using wearable, non-invasive devices, are increasingly favoured for stress measurement. EDA, particularly its tonic component (SCL), has proven effective in detecting stress due to its positive correlation with stress levels (Liu et al., 2020).

This study examines stress variations across thermal sensations during different speaking behaviours (speech and conversation) by analysing SCL, measured via smart wristbands, alongside thermal sensation votes (TSV). Statistical analyses and regression models were employed to explore the relationship between stress and thermal sensations. The findings provide insights into reducing stress in communication-intensive settings and designing low-stress indoor environments.

2. METHODOLOGY

2.1 Data collection

2.1.1. Experimental design and setup

In this study, an experiment has been designed and conducted to collect thermal sensations and their corresponding EDA between speech and conversation behaviours. In order to collect a variety of thermal sensations, this experiment set different temperatures in three identical office rooms quipped with an HVAC system to simulate different thermal environments during autumn. The room simulating the cold environment was set to 20°C, neutral was set to 24°C, and hot was set to 28°C, respectively, according to the room temperature set in the previous study (H. Kim et al., 2022; Shan et al., 2020; Xu et al., 2021). The subjects were asked to simulate continuous speaking (speech) and intermittent speaking (conversation). Environmental factors like air humidity (~55%), air speed (<0.10 m/s), and CO2 concentration (<880 ppm) were strictly controlled, with windows closed and covered for consistency. The neutral room (24°C) served as the preparation and rest area, while the other rooms were set to 20°C (Room 1), 24°C (Room 2), and 28°C (Room 3) based on the experimental design.

A total of 30 volunteers were recruited to participate in the experiment as subjects. The Anthropometrics information of the subjects is shown in Table 1. The subjects were asked to wear a long-sleeved top and trousers, with insulation of 0.61clo according to the ASHRAE 55 standard (American National Standards Institute, 2023) to standardise the clothing insulation level among subjects. Furthermore, to uphold the study's credibility.

Table 1. Anthropometrics of subjects

Variables	Average ± std	Minimum	Maximum
Age (years old)	29.5 ± 14.4	18	56
Body height (cm)	168.8 ± 9.7	153	188
Body weight (kg)	63.6 ± 13.9	43	100
BMIa(kg/m2)	22.1 ± 3.3	15.2	30.9

a BMI: Body mass index = Weight/Height2 (kg/m2)

During the experiment, the subjects were asked to simulate speech and conversation scenarios by reading the speaking materials provided by the organiser. To minimise any potential emotional influence from the content, the materials for both scenarios were kept identical for all subjects.

During the experimental setup, each participant was asked to read aloud from a script provided in the speech materials, simulating a speech context. Meanwhile, pairs of participants were instructed to read through a dialogue from the conversation materials, simulating a conversational context. When simulating the speaking behaviour, the subjects were asked to wear an Empatica E4 wristband to collect the EDA data with the sampling frequency of 4Hz. In the meantime, they were asked to report their thermal sensation regularly by ticking the TSV which is a Likert Scale from -3 to +3, representing cold, cool, slightly cool, neutral, slightly warm, warm, and hot, respectively. This TSV is suggested in ASHRAE 55 to evaluate thermal sensation (American National Standards Institute, 2023).

2.1.2. Experimental procedure

The experimental procedure is outlined in Figure 1. Subjects were paired and, on the experiment day, arrived at a pre-experiment room for 10 minutes of preparation. During this time, their clothing was checked, identification numbers assigned, and instructions provided on the procedure, precautions, and use of the Empatica E4 wristband. Subjects signed consent forms, completed a pre-experiment questionnaire, and randomly selected the order of room temperatures (20°C, 24°C, 28°C).

Figure 1. Experimental procedure timetable

Each subject completed the experiment in three temperature-controlled rooms, with each session lasting 105 minutes. Upon entering a room, subjects underwent 60 minutes of acclimation to stabilize their physiological state, during which the wristband was properly fitted. The order of speaking behaviors (speech and conversation) was also randomly assigned. Subjects then simulated their assigned behavior for 15 minutes, reporting thermal sensation (TSV) every 3 minutes, resulting in five TSVs per behavior. A 20-minute acclimation period separated the two behaviors to allow physiological recovery, after which the second behavior was performed under the same conditions.

After completing both behaviors in one room, subjects returned to the preparation room for a 1-hour break, during which they could remove the wristband and leave briefly if needed. They then repeated the same procedure in the next temperature-controlled room, following the same cycle:

acclimation, two 15-minute behaviors with TSV reporting, and rest periods between transitions. This process continued until all subjects completed the experiment in all three thermal environments.

This procedure ensured the collection of EDA data during speech and conversation under varying thermal sensations across different environments.

2.2 Data processing

A total of 30 subjects contributed to 90 series of EDA samples and 450 TSV results in three temperature settings. The SCL need to be extracted from the EDA data. The Neurokit 2 Python Tool (Makowski et al., 2021) was applied to extract the SCL from EDA data. The fluctuation data of SCL (SCLF) was also obtained by this tool. Then, the interquartile range (IQR) approach was applied to identify outliers, which were then substituted with the average values for that specific subject in that particular state. Since EDA data, as well as SCL data, have significant individual differences, the SCL and SCLF were log-transformed to alleviate this variation.

2.3 Statistical analysis

Statistical analysis was applied to test the differences in SCL and SCLF under different speaking behaviours. The SCL and SCLF were categorised according to the TSV. Firstly, the normality of TSV was tested by the frequency histogram. The results show that the TSV is normally distributed. The Shapiro-Wilk test was applied to test the normality of SCL and SCLF. All the SCL and SCLF data tested by the Shapiro-Wilk test resulted in p-values below 0.05 which rejected the null hypothesis (H_0: The SCL and SCLF data are normally distributed).

Due to the normal distribution situation of SCL and SCLF, the Mann-Whitney U test was used to assess the difference across different thermal sensations. If the Mann-Whitney U tests result in a p-value below 0.05, the alternative hypothesis (H_1: There are significant differences in SCL and SCLF between different speaking behaviours) will be retained. Otherwise, retain the null hypothesis (H_0: There are no significant differences in SCL and SCLF between different speaking behaviours). In addition, polynomial regression fitted curves of SCL and SCLF based on their distribution for 30 subjects under seven scales of thermal sensations have been derived.

3. RESULTS

3.1 Non-parametric test results

Table 2 presents the results of the Mann-Whitney U test, a non-parametric approach to comparing speech and conversation in SCL and SCLF. It has been found that there are significant differences between speech and conversation in some specific thermal sensation levels. To be specific, the p-values of SCL are lower than 0.05 at the thermal sensation levels of -3, -1 and +2, which means that at these levels, the H_1 (There are significant differences in SCL between speech and conversation) was retained. The results of SCL, at other levels of thermal sensation (-2, 0, +1 and +3), retained the H_0 (There are not significant differences in SCL between speech and conversation). For SCLF, the H_1 (There are significant differences in SCLF between speech and

conversation) was retained at the level of -2, -1 and +2 and was rejected at the level of -3, 0, +1 and +3. These results indicate that SCL and SCLF exhibit differently during speech and conversation at various thermal sensation levels. However, significant differences were not observed at all thermal sensation levels. These imply that the thermal sensation levels that minimise SCL or SCLF are different during speech and conversation.

Table 2. Mann-Whitney U test results of SCL and SCLF

	TSV	Group	N	Mean rank	Sum of ranks	Mann-Whitney U	Z	p (2-tailed)
SCL	-3	Speech	28	22.14	620	214	-2.241	0.025*

		Conversation	17	10.59	180			

Note: * indicates significance level (*p < 0.05). The significance level is based on a 2-tailed Mann-Whitney U between speech and conversation.

3.2 Distribution situation and fitted curves

In order to further explore the statistics results of SCL and SCLF, the data distribution of SCL and SCLF of 30 subjects was plotted separately in the form of boxplots. Based on these data, the multiple linear regression fitted curves of SCL and SCLF following the changes in thermal sensation levels were plotted separately. Figure 2 showed the boxplots and fitted curves of SCL and SCLF.

(a) Skin conductance level of speech and conversation under different thermal sensations and the polynomial regression fitted curves

(b) Skin conductance level fluctuation of speech and conversation under different thermal sensations and the polynomial regression fitted curves

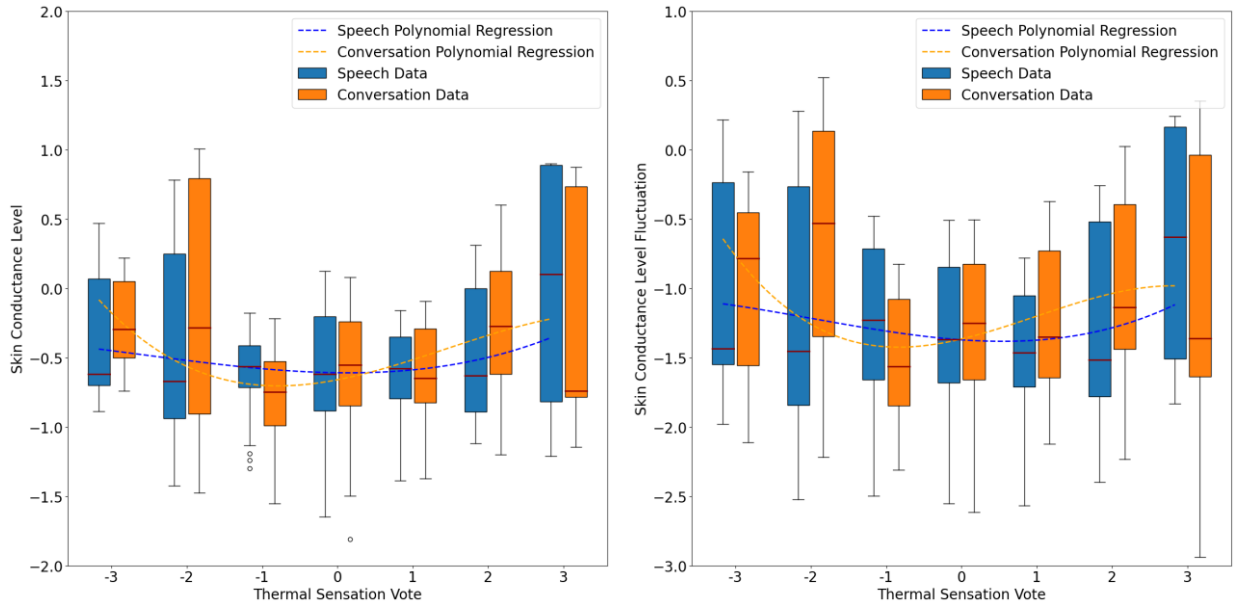

Figure 2. Boxplots and fitted cures of skin conductance level and skin conductance level fluctuation

3.2.1. Data distribution

The box plots provide insights into the distribution of SCL and SCLF across different thermal sensation levels during speech and conversation. For SCL, the IQRs are smaller for thermal sensation levels between -1 and 1, indicating lower variability and more consistent physiological responses near neutral conditions. In contrast, IQRs are larger at extreme levels (-2, +3), showing greater variability in skin conductance. Outliers are more frequent at these extremes, reflecting diverse responses. Median SCL values also vary, with more pronounced differences between speech and conversation at extreme levels (-3, -2, +3), suggesting distinct physiological responses under these conditions.

Similarly, SCLF shows smaller IQRs near neutral sensations (-1 to 1), indicating stable responses during speech and conversation. However, variability increases at extremes (-3, -2, +3), with frequent and more extreme outliers, suggesting heightened sensitivity to thermal extremes. Median SCLF differences between speech and conversation are noticeable at levels -2, 0, and +2, highlighting distinct responses based on activity. Overall, both SCL and SCLF demonstrate reduced variability near neutral conditions and increased variability under extreme thermal sensations, with notable differences between speech and conversation.

3.2.2. Polynomial regression fitted curves

For the SCL fitted curves, the equations represent the relationship between thermal sensation levels and SCL during speech ($\boldsymbol{y_{1s}}$) and conversation ($\boldsymbol{y_{1c}}$) within the -3 to +3 range.

The fitted curve for SCL during speech ($\boldsymbol{y_{1s}}$) is described by Equation (1). The fitted curve for SCL during conversation ($\boldsymbol{y_{1c}}$) is described by the Equation (2).

$$y_{1s} = -0.607 - 0.016x + 0.023x^2 + 0.003x^3 \quad (1)$$

$$y_{1c} = -0.675 + 0.086x + 0.058x^2 - 0.012x^3 \quad (2)$$

For the SCLF fitted curves, the equations represent the relationship between thermal sensation levels and SCL during speech ($\boldsymbol{y_{2s}}$) and conversation ($\boldsymbol{y_{2c}}$) within the -3 to +3 range. The fitted curve for SCLF during speech ($\boldsymbol{y_{2s}}$) is described by the Equation (3). The fitted curve for SCLF during conversation ($\boldsymbol{y_{2c}}$) is described by the Equation (4).

$$y_{2s} = -1.364 - 0.047x + 0.028x^2 + 0.005x^3 \quad (3)$$
$$y_{2c} = -1.385 + 0.109x + 0.064x^2 - 0.018x^3 \quad (4)$$

4. DISCUSSION

This study investigated variations in SCL and SCLF across thermal sensation levels during speech and conversation to understand how stress levels change with thermal sensations and speaking behaviours.The Mann-Whitney U test revealed significant differences in SCL at thermal sensation levels of -3, -1, and +2, indicating that speech and conversation elicit different stress responses. Similarly, SCLF showed significant differences at levels -2, -1, and +2, suggesting that verbal activity affects the stability of stress responses. Higher SCLF values imply greater instability and emotional reactivity. Data analysis showed that SCL variability (IQR) was wider at extreme thermal sensations, except at -3, and narrower near neutral levels (-1, 0, +1). Notably, the IQR at 0 was wider than at -1 or +1, indicating more individual differences at neutral sensations. For speech, individual differences were smaller at -2, while for conversation, they were smaller at +3. Both behaviours had the lowest variability at -1. For SCLF, variability was also lower between -1 and +1, with the lowest variability for speech at +1 and for conversation at -1. Fitted curves showed that SCL and SCLF changed more rapidly during conversation, especially when transitioning from cold to slightly cool. Stress levels and fluctuations were lowest during speech in the slightly warm to neutral range, but for conversation, they were lowest in the slightly cool to neutral range. This highlights that optimal thermal sensations for minimizing stress vary by speaking behaviour.

5. CONCLUSION

Through an experimental investigation, this study reveals significant differences in physiological stress responses, measured through SCL and SCLF, between speech and conversation across various thermal sensation levels. The findings indicate that stress levels in speech and conversation change differently along with the thermal sensation levels. Speech and conversation reach the minimum stress levels and stress level fluctuations at different thermal sensation levels. The individual differences in stress responses are notable depending on thermal sensations. These insights have important implications for designing more comfortable and stress-reducing environments in workplaces and educational settings. By understanding how thermal conditions and communication contexts impact stress, interventions can be tailored to improve well-being and performance of occupants. Further research should explore stress levels at different thermal sensation levels among a wider range of behaviours and activities. Additional perspectives on stress levels and behaviours can be considered in the design of thermal environments.

SUMMARY
Indoor air quality (IAQ) and ventilation are critical for maintaining healthy and comfortable living environments. Building energy retrofits, typically aimed at reducing energy consumption, must also address the impacts on IAQ, thermal comfort, and occupant behavior. In dormitories and similar residential settings, managing IAQ is particularly challenging due to diverse occupant activities and behavior. Existing ventilation systems, often designed for lower occupancy rates and less airtight building enclosures, may not meet current standards for air exchange and pollutant control. This study examines IAQ and ventilation performance before and after a comprehensive energy retrofit of a two-story multifamily townhouse-style building in Syracuse, New York, USA. By integrating environmental monitoring with occupancy data, the study evaluates the interactions between human behavior and indoor environmental conditions. The objectives are to: (1) assess IAQ and thermal comfort pre- and post-retrofit, (2) analyze the influence of occupant behavior, and (3) provide recommendations for future retrofits. Results show reduced CO_2 levels, changes in PM 2.5 concentrations, and altered window-opening behaviors, highlighting the importance of occupant-centered retrofit strategies.

Keywords: Indoor Air Quality, Thermal Comfort, Building Retrofit.

1. INTRODUCTION

Indoor air quality (IAQ) and thermal comfort are fundamental components of creating healthy, productive, and sustainable living environments, particularly in university dormitories where diverse occupant behaviors introduce unique challenges. Poor IAQ and thermal dissatisfaction have been linked to adverse health outcomes, including respiratory issues and mental discomfort (Coggins et al., 2024). Energy retrofits have gained prominence as a strategy for improving building sustainability by reducing energy consumption. However, these retrofits also have a profound impact on indoor environmental quality (IEQ), influencing factors such as air quality, thermal comfort (Coombs et al., 2016; Synnefa et al., 2017), and ventilation effectiveness. Studies show that retrofits can enhance occupant health and comfort by stabilizing indoor temperatures and reducing exposure to pollutants. Yet, the success of these interventions is intricately tied to occupant behavior, preferences, and activities, which often go overlooked in retrofit design and evaluation (Liu et al., 2022).

Existing ventilation systems in older dormitory buildings often fail to meet the needs of modern occupancy patterns and activities (Mannan & Al-Ghamdi, 2021). Behaviors such as window opening, vent blocking, and smoking can significantly alter air exchange rates, pollutant concentrations, and energy performance (Elsayed et al., 2023). For instance, studies have shown that 87% of air change rate (ACR) variability in residential settings can be attributed to occupant actions like opening doors and windows (Ortiz et al., 2020). These findings underscore the need for the analysis of retrofit strategies that account for the dynamic interplay between human behavior and building systems to achieve holistic improvements in IAQ and thermal comfort.

This study investigates the impact of energy retrofits on IAQ and thermal comfort in a university dormitory in Syracuse, NY. By comparing pre- and post-retrofit conditions and incorporating data on occupant behaviors, the research aims to provide a comprehensive understanding of how human activity shapes indoor environments of retrofitted buildings. The objectives are threefold: 1) to assess IAQ and thermal comfort before and after retrofits; 2) to analyze the influence of occupancy patterns and occupant behaviors on these conditions; and 3) to develop recommendations for retrofit strategies that promote both energy efficiency and occupant health. By bridging the gap between technical retrofit measures and behavioral insights, this study contributes to the development of strategies for optimizing IAQ and thermal comfort in residential environments. The findings will help inform future retrofits, ensuring they are designed with a holistic understanding of the complex interactions between building systems, occupant activities, and environmental conditions.

2. METHODS

This study focuses on the analysis of a two-story multifamily townhouse-style building located at Syracuse University's South Campus. The building was originally constructed between 1972 and 1973 and comprises eight two-bedroom units. Each unit accommodates two students, resulting in a total occupancy of 16 students. It was equipped with baseboard heaters and had no air conditioning (AC) nor mechanical ventilation before the retrofit. The building was retrofitted with exterior insulation and air-sealing, ceiling-mounted fan coil units in each living room and bedroom to replace the baseboard heaters and provide both heating and cooling, and energy recovery ventilation (ERV) systems in each unit.

Figure 1 illustrates the diagram for real-time building performance monitoring system which was installed during the pre-retrofit stage of the research (Mirzabeigi et al., 2024). The full description of this approach is provided in Mirzabeigi et al., (2024). The monitoring system includes unit-level interior monitoring for all apartments, measuring IAQ parameters, air temperature, humidity, and motion. Additionally, two units were equipped with detailed monitoring of window and door opening activities; these units are referred to as "research units" throughout the study. Weather data was also collected to provide additional context.

Indoor sensors were installed to measure air temperature, Relative Humidity (RH), concentrations of CO_2, TVOC, and PM 2.5, PM 10, motion, and door/window open and close status. Additionally, we collected various outdoor physical parameters including air temperature, RH, solar radiation and wind intensity and direction, CO_2, TVOC, and PM 2.5, PM 10. IAQ data was collected at 5-minute intervals, and window/door status was recorded based on the exact time of each opening/closing event using magnetic sensors. Motion sensor data was collected at 5-minute intervals, with immediate data transmission triggered upon motion detection. Measurements began

one year prior to retrofitting, with the building undergoing retrofits during the summer of 2024. Monitoring is planned to continue for at least one year following the retrofit to assess changes in indoor environmental quality and building performance.

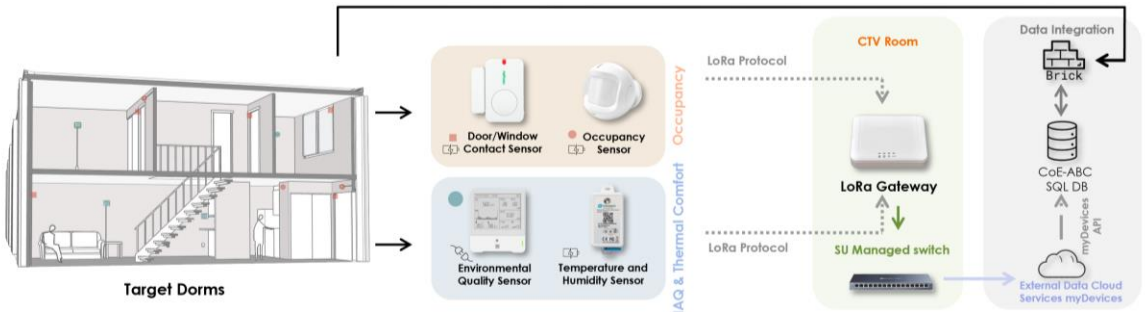

Figure 1. Conceptual diagram for real-time performance monitoring.

The data was analyzed using the Python environment, utilizing various packages and libraries such as NumPy (Harris et al., 2020), scikit-learn (Baranwal et al., 2019) and SciPy libraries. To assess the impact of the retrofit on indoor environmental quality, independent sample t-tests (Welch's t-tests) were conducted to compare pre- and post-retrofit hourly averaged data for CO_2 concentration, PM 2.5 levels, indoor air temperature, and relative humidity. Analyses were performed for two groups: (1) selected spaces in two representative research units (A-7 and A-8), and (2) all living rooms across the monitored units (A-1 through A-8). Welch's t-test was used to account for unequal variances between groups. A p-value threshold of 0.05 determined statistical significance. For the preliminary analysis of occupant thermal comfort, indoor temperature and humidity data were examined. A temperature range of 20–23 °C for winter and 23–26 °C for summer was used as the comfort quantification criteria, while a range of 35–55% for winter and 40–60% for summer was applied for humidity per ASHRAE Standard 55. For data from the window/door contact sensors, a post-processing step converted the data into a time series format indicating open and closed conditions. Then, we looked at the correlation on how the window/door status activity changed the indoor environment (e.g., CO_2 as an indication of ventilation). We looked at patterns of change of CO_2 during the day (weekdays and weekends) to understand how occupant activities affected various indoor air quality. For comparing PM 2.5 concentration for the pre- and post-retrofit, the data were categorized into six pre-defined classes based on EPA guidelines, enabling a clearer comparison of changes.

3. RESULTS AND DISCUSSION

The data analysis presented in this section represents a subset from the overall data collection period. Selected time periods are shown as examples, as post-retrofit data collection is still ongoing. A comprehensive analysis of the full dataset is beyond the scope of this paper. The analysis compared pre- and post-retrofit conditions to evaluate changes in thermal comfort, IAQ, and occupant behavior. Figure 2 shows the pre- and post-retrofit measured data from various spaces of two research units, during the warm and cold seasons, represented on the psychrometric chart. During warm weather, pre-retrofit temperatures reached up to 24 °C, while for the post-retrofit, the temperatures remained mostly within the comfort range. In cold weather, pre-retrofit temperatures reached close to 31 °C, indicating overheating. In contrast, post-retrofit temperatures were more comfortable. Overall, pre-retrofit conditions exhibited higher variability in temperature and humidity for both summer and winter scenarios, whereas post-retrofit conditions were more stable and controlled.

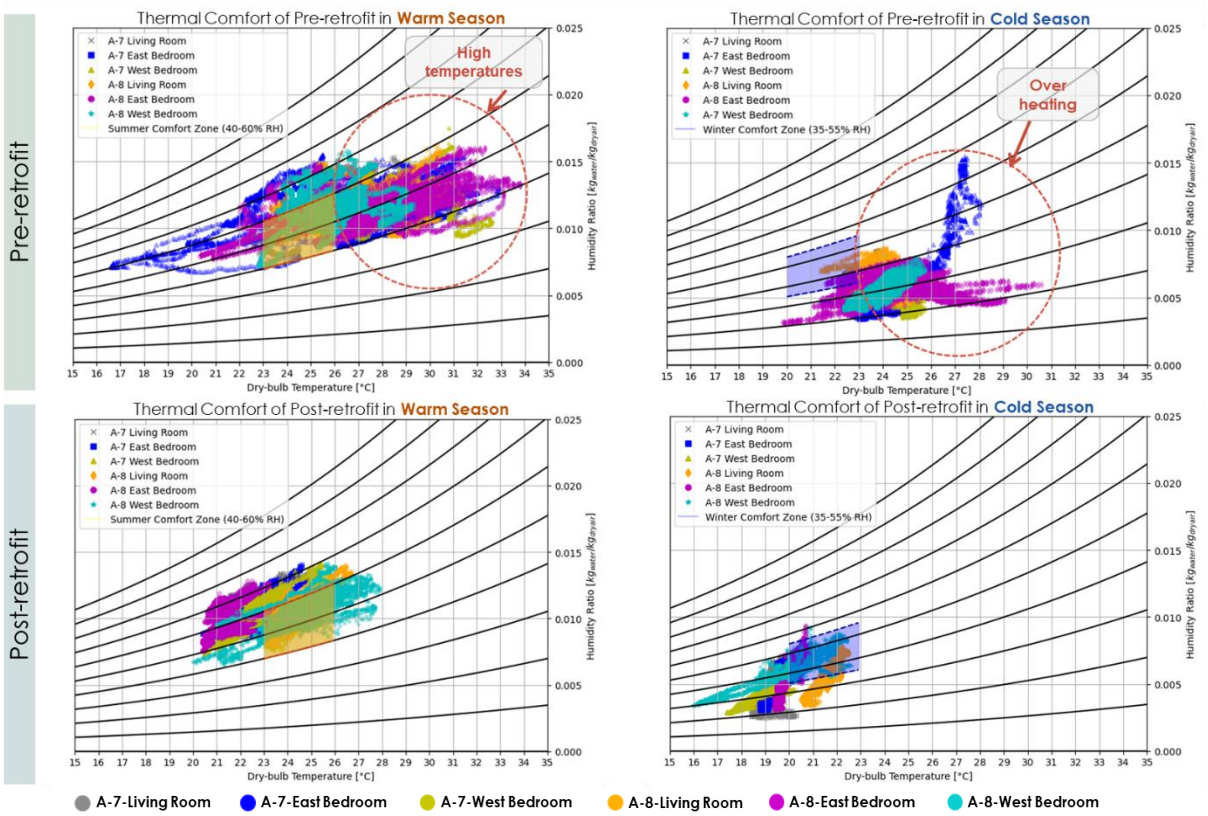

Figure 2. Indoor thermal condition for pre- and post-retrofit.

Figure 3 shows the average hourly CO_2 concentration for the two research units, categorized by weekdays and weekends. Higher concentrations were observed in the bedrooms compared to the living room, with elevated levels were also noted during weekends when occupants spent more time in their units.

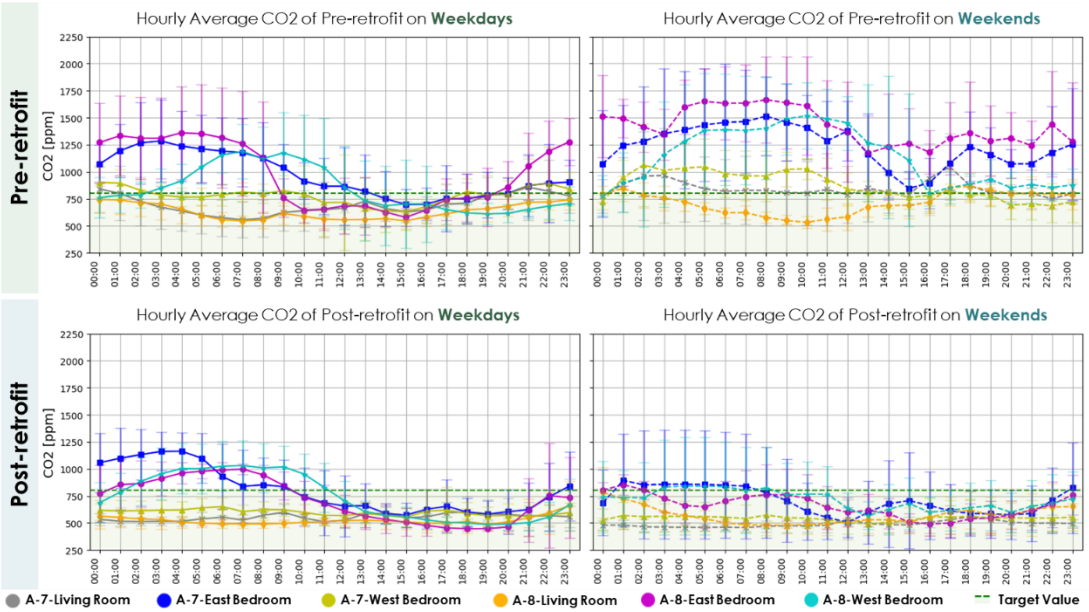

Figure 3. Hourly average CO_2 for pre- and post-retrofit (the whisker lines show the data variability).

During sleep hours, pre-retrofit CO_2 concentrations in one of the bedrooms exceeded 2000 ppm. However, post-retrofit, these concentrations have significantly decreased to below 1400 ppm.

Figure 4 shows the sample of PM 2.5 concentrations in the living rooms of three units before and after the retrofit. Each cell represents the average hourly PM 2.5 concentration. Concentration patterns varied among the units due to differences in indoor activities and occupant behavior. Additionally, as shown in Figure 5, overall PM 2.5 concentrations were lower following the retrofit, with an increased frequency of PM 2.5 levels falling within the 0–12 μg/m³ range. This improvement is attributed to enhanced ventilation, which helps reduce indoor PM 2.5 concentrations, particularly when the pollutant source is indoors, and the ventilation air is filtered. Occupant behavior also played a significant role, as different individuals occupied the units before and after the retrofit. Outdoor PM 2.5 concentrations were also considered in the analysis. Furthermore, it has been observed that the PM 2.5 decay rate has increased post-retrofit, which may impact the overall indoor air quality and its ability to recover after exposure to elevated pollutant levels.

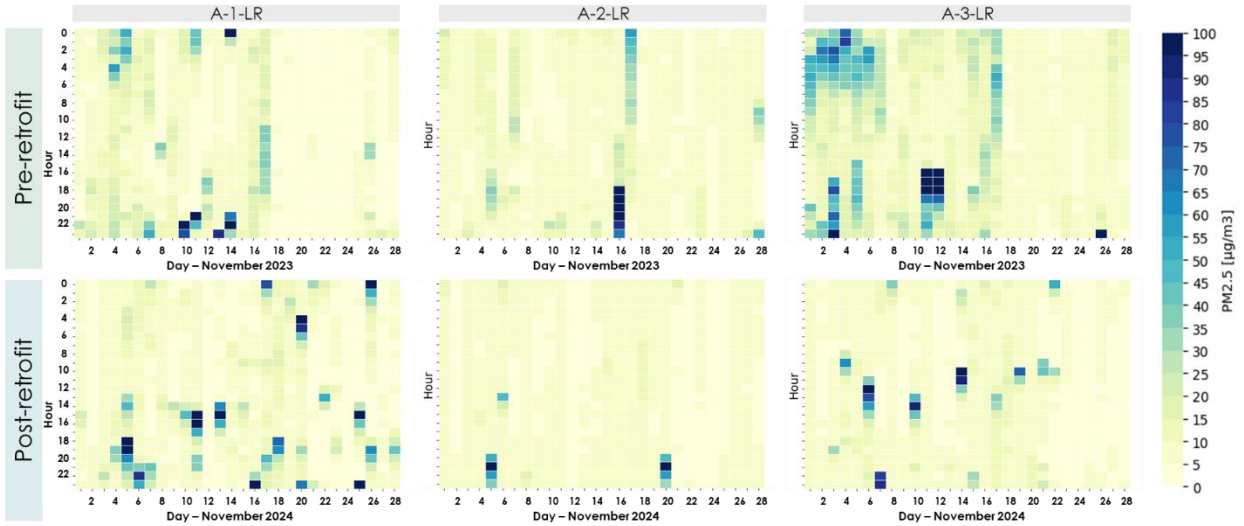

Figure 4. Sample data plots of PM 2.5 concentrations across three units pre- and post-retrofit for November.

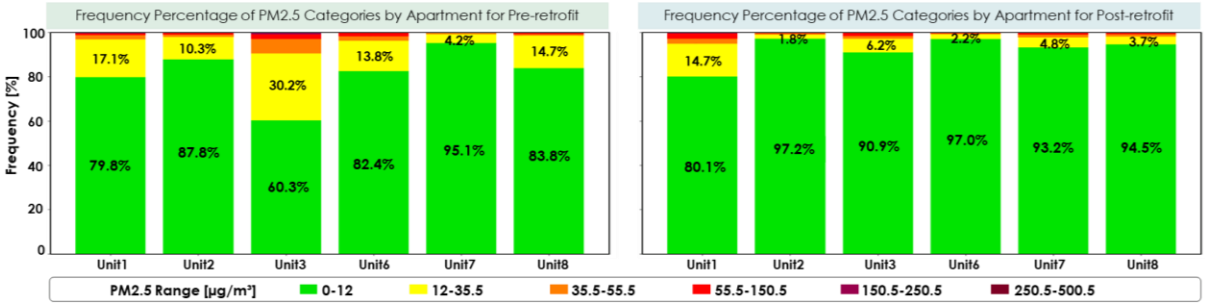

Figure 5. Frequency percentage of PM 2.5 categories by apartment for pre- and post-retrofit.

Figure 6 presents an example of window-opening behavior for two bedrooms in one of the monitored units. Pre-retrofit data are represented in green, while post-retrofit data are shown in blue. The size of each bubble indicates the duration for which the window remained open. During

the pre-retrofit period, occupants tended to open windows more frequently and for longer durations, particularly at higher indoor and outdoor temperatures, compared to the post-retrofit period. This behavior change suggests that the retrofit reduced the need for occupants to rely on window openings for cooling or ventilation. A similar trend was observed in the second research unit, where contact sensors monitored window activity.

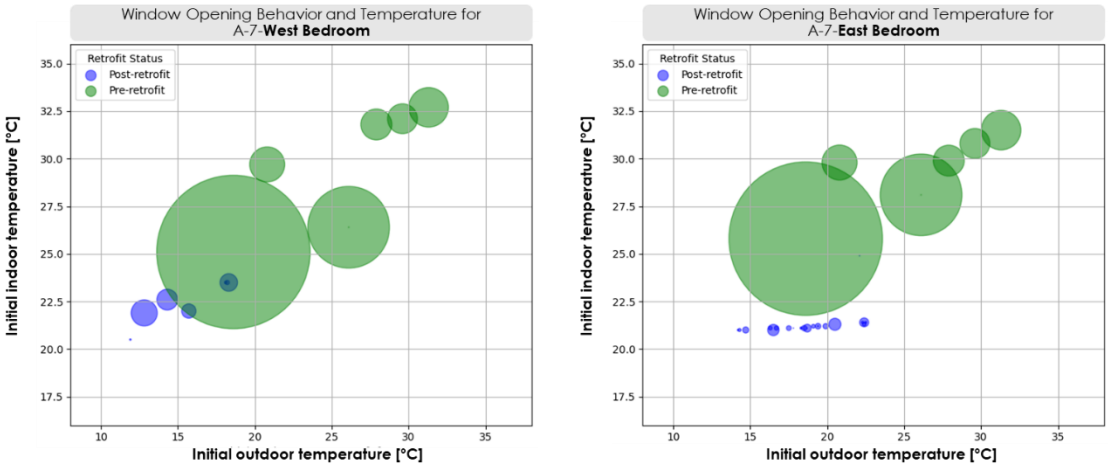

Figure 6. Window opening behavior pre-retrofit (green) and post-retrofit (Blue)

The air change rate (ACR) in the east bedroom was calculated using the decay method for both closed and open window scenarios during the pre-retrofit period. ACR was analyzed for one of the bedrooms under both pre- and post-retrofit conditions. For the pre-retrofit, window-opening behavior significantly influenced the ACR. Approximately 64% of the total ACR when the window is open is attributable to occupant window opening, highlighting the pivotal role of occupant actions in enhancing natural ventilation. For the post-retrofit, the average ACR increased by 87% compared to the pre-retrofit period, primarily due to the addition of mechanical ventilation systems, which provided consistent airflow and improved overall ventilation. Additional data collection is required to calculate the ACR for post-retrofit periods with open windows. This would allow for a direct comparison of the effect of occupant window-opening behavior on ACR in post-retrofit conditions, further clarifying the interplay between mechanical ventilation and natural ventilation.

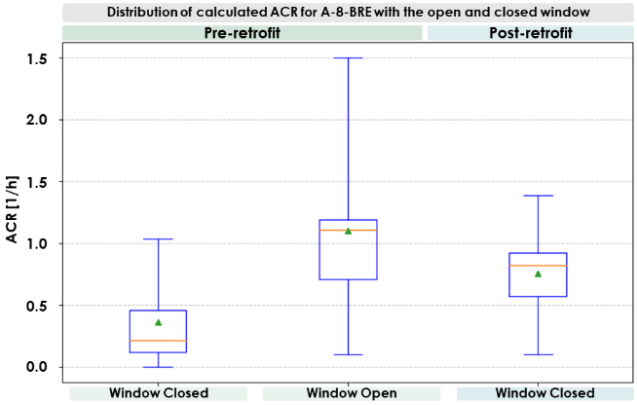

Figure 7. Calculated ACR for one bedroom and the effect of window opening.

Independent sample t-tests were conducted to compare pre- and post-retrofit indoor environmental quality parameters (CO_2, temperature, humidity, and PM 2.5) across two groups of residential spaces (spaces in research units and A-1 to A-8 living rooms). The results showed statistically significant differences ($p < 0.05$) for all parameters in both groups, indicating that the retrofit measures had a substantial impact on changing indoor air quality and thermal conditions.

4. CONCLUSION

This study highlights the critical role of energy retrofits in improving IAQ and thermal comfort in university dormitories, while also emphasizing the importance of integrating occupant behaviors into retrofit strategies. By comparing pre- and post-retrofit conditions in the dormitory building in Syracuse, NY, we observed notable improvements in IAQ and thermal comfort, including reduced CO_2 levels, lower PM 2.5 concentrations, and more consistent temperature and humidity levels. The results also reveal the significant influence of occupant activities on IAQ outcomes. Variations in window-opening behavior were closely linked to changes in ventilation rates, and this behavior changed before and after the retrofit. For instance, while retrofits improved baseline IAQ metrics, occupant behaviors such as extended window openings during specific temperature ranges had a profound impact on air exchange rates and pollutant dynamics. These findings align with prior research indicating that retrofit benefits are limited without addressing occupant-related factors (Luo et al., 2019; Zhong & Ridley, 2020). The analysis demonstrates that achieving optimal IAQ and thermal comfort in residential environments requires a holistic approach that combines technical interventions with behavioral insights. Retrofit designs that focus solely on building envelope and mechanical improvements risk unintended consequences, such as inadequate pollutant control or thermal dissatisfaction, if occupant behavior is not adequately accounted for. To maximize the benefits of energy retrofits, future efforts should incorporate the following recommendations:

1. Retrofit strategies must consider the preferences and habits of occupants, particularly regarding ventilation and window usage, to enhance overall effectiveness. For example, conducting pre-retrofit surveys and collecting measured data can reveal how often occupants open windows and their preferred ventilation practices. This information allows designers to tailor interventions—such as optimizing mechanical ventilation settings or improving natural airflow—that align with actual occupant behavior, ultimately balancing energy efficiency with comfort.
2. Promoting awareness among residents about the impact of their behaviors on IAQ can lead to better outcomes, as seen in prior studies that reduced pollutant exposure through targeted education (Noris et al., 2013). For example, engaging residents before and after the retrofit—through workshops, surveys, and interactive sessions—can educate them about how their daily actions (such as window usage, cleaning practices, or product choices) affect IAQ. This proactive approach not only informs residents but also gives them a sense of ownership over the process, leading to sustained improvements in air quality.
3. Continuous monitoring of IAQ, thermal comfort, and occupant activities can provide real-time feedback to guide adaptive management and improve building performance over time. Continuous monitoring should ideally span a minimum of one year. This timeframe ensures that seasonal variations in indoor air quality, thermal comfort, and occupant activities are captured, providing a comprehensive dataset for adaptive management and performance improvement.
4. Combining expertise from architecture, engineering, environmental science, and behavioral studies—and importantly budgeting the time and cost to integrate expert input early on—will enable the development of retrofits that align energy efficiency goals with occupant health and comfort.

In conclusion, while energy retrofits enhance building performance, their success depends on addressing the complex interplay between human behavior, building systems, and environmental conditions. By bridging this gap, future building energy retrofit initiatives can create healthier, more comfortable, and sustainable living environments that meet the diverse needs of occupants.

SUMMARY
This study quantifies the energy-saving potential of the warm room strategy, focusing renovation efforts on the living room of an apartment building. The warm room strategy proved most beneficial for corner apartments on the top floor, reducing heating loads by up to 41%, depending on residents' setpoint preferences. Results confirm that the warm room strategy can be viable when aligned with residents' heating practices, despite its effectiveness being often dismissed when decisions rely on standard occupancy. Future research could explore the impact of lower indoor temperatures on unheated rooms and assess residents' receptiveness to the warm room concept to expand its potential application in renovation projects.

Keywords: energy transition, thermal compartmentation, occupant behaviour, building performance simulation

1. INTRODUCTION

Efforts to integrate dwellings into the energy transition face significant challenges, primarily due to the mismatch between retrofit technologies and the diverse energy practices of residents (Furman; Hadjri, 2025). Current renovation strategies prioritize deep envelope insulation and upgrading of ventilation and heating systems, in line with European and national energy efficiency standards (European Commission, 2024; NTA 8800:23, 2024; RVO, 2021). However, these approaches often rely on standardized assumptions about thermal comfort, neglecting the variability in residents' heating practices. This oversight leads to energy savings that tend to be lower than expected after renovations, driven by prebound and rebound effects, undermining the effectiveness of energy renovations in achieving sustainability goals (van de Brom et al., 2019).

Recent research highlights a disparity between professional assumptions of uniform indoor heating norms and the diverse heating practices of residents (de Koning et al., 2024; van Wieringen et al., 2025). Field studies conducted with households in two Dutch municipalities by de Koning et al. (2024) and van Wieringen et al. (2025) highlight the importance of residents' know-how and preferences in keeping themselves warm. Residents reported that, instead of heating the entire dwelling, they prefer to keep the living room as a warm space for relaxation, while rarely heating the bedroom. They enjoy sleeping in a cooler, "fresh" environment, as it creates a pleasant contrast with the warmth of their blankets (De Koning et al., 2024; van Wieringen et al., 2025). Understanding residents' heating practices allows for a revaluation of space usage by distinguishing between areas with higher comfort demands and those with lower comfort requirements (Verbeeck; Bosserez, 2021).

The concept of energy sufficiency has emerged as an alternative to energy efficiency, suggesting a shift from a building-centred to a resident-oriented approach. It emphasizes providing sufficient

energy services that align with residents' heating practices, while avoiding unnecessary oversupply (Fawcett; Darby, 2018). Considering the residents' preference for warmer living rooms and cooler bedrooms, focusing renovation efforts on the living room to create a warm room offers a promising strategy for advancing energy sufficiency in renovation projects. The approach of warm room was previously tested by Rovers et al. (2020) in a field study involving three Dutch terraced houses, demonstrating improved thermal performance of the dwelling after renovating the living area. Building on this, the current study aims to quantify the energy-saving potential of applying the warm room strategy to an apartment building. This study considers two types of apartments (corner and middle) across three levels (ground floor, middle floor, and top floor), considering three profiles of heating practices (only the living room heated pre-retrofit and a wider range of setpoint preferences).

2. METHODS

1.1 Reference building

A 'typical' medium-rise apartment was selected as a reference building, based on Guerra-Santin et al. (2017) (Figure 1a). The representative building consists of three floors: ground (with a crawl space), intermediate, and top. It includes two apartment types: corner units and central units (Figure 1b). Constructed in the 1960s, the building was poorly insulated at the time of construction, The building envelope characteristics were selected based on the Voorbeeldwoningen 2022 (RVO, 2022), described on Figure 1c.

a) Reference building

b) Apartment floor plan

Envelope component	U-value (W/m².K)
External walls	1.64
Flat roof	1.55
Internal wall	1.69
Ventilation type	Natural ventilation
Infiltration	0.7 ACH

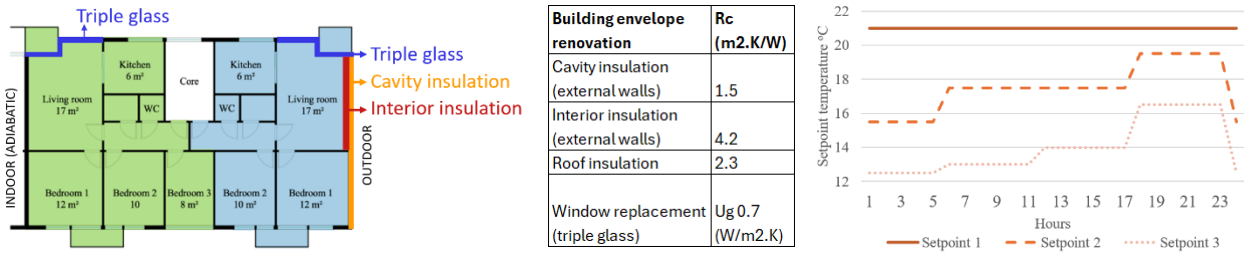
c) Construction characteristics

Figure 1: Reference building based on Guerra-Santin et al. (2017).

1.2 Warm room and residents' heating practices

The initial concept of thermal compartmentation, proposed by Rovers et al. (2020), involved insulating both external and internal walls of the living room to isolate it from all the neighbouring rooms within the dwelling. However, an important finding from the building performance simulations conducted in the present study is that insulating internal walls results in negligible energy savings, and heat in the living room can be retained by simply closing doors. Additionally, modest heat flow between the heated living room and the rest of the dwelling can be considered as beneficial. From a technical perspective, we proposed cavity insulation for the main external walls of the living room and bedroom, interior insulation along the living room's external wall in corner apartments, and the replacement of single-pane windows with triple-glass windows exclusively in the living room, as detailed in Figure 2a and 2b.

To capture the variability in residents' heating practices in Dutch social housing, quantitative data was extracted from the Energy Module of the national WoON2018 database (BZK, 2018). Residents were considered to heat only their living room, as 60% of the residents in the database reported that bedrooms are cooler spaces and are rarely heated. Three setpoint preferences were selected to represent (i) high temperatures throughout the whole day, (ii) evening peak, and (iii) a case with lower setpoints (Figure 2c) .



Building envelope renovation	Rc (m2.K/W)
Cavity insulation (external walls)	1.5
Interior insulation (external walls)	4.2
Roof insulation	2.3
Window replacement (triple glass)	Ug 0.7 (W/m2.K)

a) Warm room b) Thermal properties c) Setpoint preferences

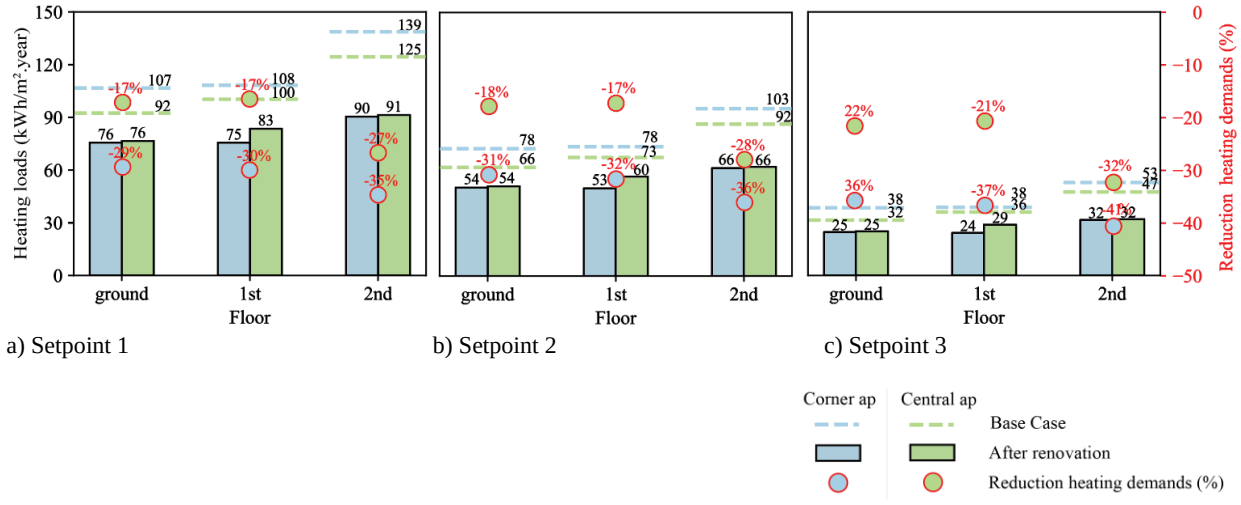
Figure 2: Warm room setting and setpoint preferences

1.3 Building performance simulations

Building performance simulations were performed using EnergyPlus. The envelope materials for the reference case and the energy saving measures were modelled as described in Figures 1 and 2. Annual building simulations were performed using a typical meteorological year derived from the period between 1996 and 2015 in De Bilt, the Netherlands (NEN 5060, 2018) Two key performance metrics were defined to evaluate the efficiency of the warm room: heating demands (kWh/m^2.year) and reduction in heating demands (%).

3. RESULTS

The warm room strategy showed to be more beneficial for the corner apartment on the top floor, with greater opportunities for insulation improvements in the living room. In this apartment, the warm room concept reduced heating load by 35% for setpoint 1 and 2 and 41% for setpoint 3. For apartments on the ground and 1st floor, the percentage of reduction in heating demands was similar for all three setpoints, with improvements ranging from 17% to 22% for central apartments and 29% to 32% for corner apartments. The heating loads required to heat the living room is strongly influenced by residents' setpoint preferences. For instance, heating loads for setpoint 1 is three times higher than for setpoint 3, both before and after renovations.



a) Setpoint 1 b) Setpoint 2 c) Setpoint 3

Figure 3: Heating loads and energy savings

These findings suggest that, even though the warm room can achieve up to 41% in reduction of

heating loads, the setpoint preferences also plays an important role in energy savings. Additionally, although energy renovations focused on the entire apartment are more likely to lead to heating in other rooms, the warm room strategy can be considered as a measure against less conscious heating behaviours, that could lead to rebound effects.

4. CONCLUSIONS

This study aimed to quantify the energy-saving potential of the warm room strategy for an apartment building, considering two apartment types (corner and middle) across three levels (ground floor, middle floor, and top floor), and exploring three profiles (living room heated only pre-retrofit, and a broader range of setpoint preferences). This study identified an optimal configuration for the warm room: cavity insulation in the external wall, interior insulation in the living room's external wall, window replacement with triple glazing in the living room, and no insulation for the internal walls, as it was found to have a negligible effect on energy savings. The warm room strategy was shown to be an effective and more sustainable solution when aligned with residents' heating practices. However, it is often dismissed as a viable solution when decisions are based on standard occupancy and uniformly heated dwellings, therefore not complying with insulation regulations. The efficiency of this approach depends on residents' behaviour, being effective if other rooms in the house remain unheated. Future research could explore the impact of lower indoor temperatures on the hygrothermal performance of unheated rooms and assess residents' receptiveness to the warm room concept, thereby expanding its potential application in renovation projects.

SUMMARY
The PECS survey tool is a novel desktop application designed to gain feedback and enhance personalized thermal comfort in indoor office environments through high quality occupant feedback. Integrated with a Personal Environmental Control System (PECS), the survey tool enables obtaining subjective occupant feedback to provide an optimal microclimate to its user through machine learning methods. To address the limitations of conventional survey tools related to survey fatigue, user engagement, and data quality, the tool has several features such as dynamic unfolding questionnaires that adapt based on user response, automated reminders, and gamification through a leaderboard-based point system. This tool was deployed on 23 users' workstations for 14 days obtaining hourly feedback from users to test its performance. While the current use-case is data collection, future versions will enable real-time PECS control. This paper presents the features, design, and the experiment outcomes of PECS survey tool.

Keywords: Survey Tool, Subjective Feedback, Personal Comfort, Indoor Environmental Quality.

1. INTRODUCTION

Human beings spend around 80% of their lifetime indoors (Zhao et al., 2004). Hence Indoor Air Quality (IAQ) and Thermal Comfort (TC) are fundamental to their well-being, productivity, and the overall quality of life. Heating, Ventilation, and Air Conditioning (HVAC) systems help to maintain IAQ and TC levels in favourable conditions. However, HVAC systems consume 10-20% of total energy demand in Europe and USA (Verhaart et al., 2015). This makes HVAC sector a significant energy demand factor. Despite the high energy demand for HVAC sector, the studies indicate that only 11% of the buildings meet the standard thermal comfort requirements, which require an 80% satisfaction rate among occupants (Katić et al., 2020).

One of the challenges faced by conventional HVAC systems are the individual differences among the users. Conventional HVAC systems are designed to operate as a centralized thermal comfort solution for all individuals (one-size-fits-all approach) while individual thermal preference varies among individuals substantially. Hence a single temperature setting does not provide the optimal thermal comfort to all. Despite the high energy consumption, HVAC systems fail to meet the standard thermal satisfaction rate (80%) making it highly inefficient.

Personal Environment Control System (PECS) is developed to address the inefficiencies in conventional HVAC systems. PECS can offer individualized thermal comfort through a combination of personalized ventilation and heating.

PECS has three main parts. The hardware system including the personal ventilation

system and heated seat, the user interface (survey tool), and the system backend consisting of the Application Programming Interface (API), the database, business logic, and machine learning modules.

PECS operates by obtaining subjective (occupant feedback) data and objective data (temperature, relative humidity) to learn the thermal preference of the user using a machine learning algorithm. Based on the learned personal thermal preferences, the PECS will predict the settings for personalized ventilation and heated seating to provide the optimal thermal comfort to its user.

In this process, obtaining subjective data from the users is critical for prediction of personal thermal comfort. Hence, the quality of PECS automation depends especially on the quality of subjective feedback obtained from the user. However, traditional surveys often suffer from low response rates and poor user engagement due to negative sentiments towards answering repetitive questions. PECS survey tool is designed and developed to overcome the issues and improve the overall quality and consistency of subjective data gathering.

This paper presents the design and key features and their performance of the PECS Survey Tool, explaining how it enhances the user engagement and data quality to support improved indoor climate personalization.

1.1. Related Work

Existing survey tools, such as the web application developed by Zagreus et al. (2004) which is one of the first large-scale web based Indoor Environmental Quality (IEQ) surveys, have suffered from low user engagement due to survey fatigue. Further, Peretti and Schiavon (2011) highlights the importance of improving the user experience of the application to uplift user engagement. Based on this, Wargocki and Da Silva (2015) shows that timely prompts can increase the user engagement of the application. Additionally, Laign and Kuhl (2020) shows that integrating gamification into thermal feedback tools can significantly improve the user engagement of survey applications.
Our work addresses designing a user-centric application tailored to integrate seamlessly user workflows to improve the user engagement and data quality.

2. METHODOLOGY

2.1. Requirement Analysis

The proposed application enables the collection of subjective data from the PECS users. The first phase of application development was requirement gathering and analysis.

A third-party mobile software tool was utilized in the older PECS version to get users' feedback. However, data that could be collected from the experiments through this third-party tool was limited due to users not using the application regularly.

To identify the issues related to the data collection process, several interview sessions were arranged with users and the surveyors who have been working on the PECS project previously. The interviews identified following pain points in the user's experience and data quality.

- Too many questions
- Lengthy user flow
- Mobile apps being seldom used while working
- Users forgetting to answer
- Uninviting user interface

Considering the above issues, several decisions were made before developing the application. Special attention was given to the user

experience of the application. Listed below are the key design decisions made before developing the application.

- **Develop a desktop application** : Since the office users seldom use mobiles while working, it was decided to develop a desktop application. PECS survey tool expects the users to send feedback from the location where PECS is installed. The PECS are usually installed at the users' workstations. Therefore, a desktop application is more suitable compared to a mobile application.
- **Develop a Windows application** : Since all users that contribute to the experiments in the living lab are using the Windows operating system, it was decided to develop a windows application. But the codebase must be compatible to build the application for other platforms such as MacOS.
- **Introduce an Unfolding Questionnaire** : This is a new concept introduced in obtaining subjective feedback from users. Unfolding questionnaire unfolds the questions based on previous responses from the user. In this way, the number of questions asked can be substantially reduced and only ask the most relevant follow-up questions from the user. Adaptive surveys such as unfolding questionnaires are proven to reduce survey fatigue and improve response quality (Van der Zanden et al., 2015).
- **Triggering Windows notifications** : Triggering windows notifications to remind the user to answer and submit a given survey at a specific time. The application is added to the startup processes in Windows and will run as a background process so that users don't have to open the application every time they want to send feedback.
- **Minimalistic user interface** : Improve the user interface in such a way that users can easily understand the user flow and submit the surveys. Users can also communicate with the admins regarding any problem related to PECS through the application. In addition, a better user interface can make the application more appealing to the user.
- **Introduce a Leaderboard** : Leaderboard keeps track of the number of surveys and questions answered by each user. For each survey completed, some contribution points will be added to the user account. Based on the contribution points, users will be ranked. This feature is added to introduce some sense of competition between users and reduce the survey fatigue.

The above decisions made on the design of the application to improve its user experience.

2.2. Design and Development

2.2.1. Frameworks Utilized

Two frameworks were utilized to develop the PECS survey tool. Flutter framework was utilized for the frontend and Django framework for the backend system. Both frameworks are robust and scalable solutions.

2.2.2. Flutter (Frontend Development)

Flutter is an open-source user interface (UI) development framework created by Google. Flutter allows the developers to create natively compiled applications for mobile, web, and desktop applications. All of this is using a single codebase using the dart programming language.

Flutter offers following advantages:

- **Cross platform development** : Allows the developer to use the same codebase to deploy the application across multiple platforms with the same performance and UI.
- **Rich UI components** : Flutter consists of a comprehensive set of customizable widgets that can be utilized in building a UI with high responsiveness and visual appeal.

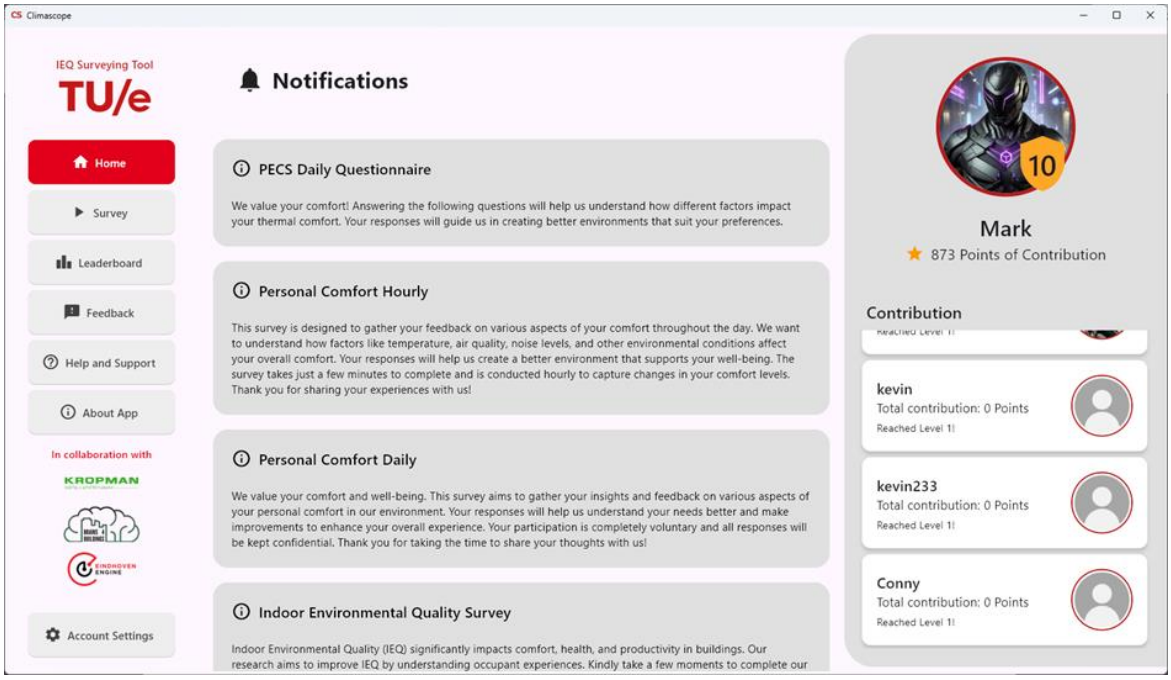

Figure 1. User Interface Home Page of PECS Survey Tool

- **High performance**: Compiles to native machine code allowing fast rendering and smooth performance.

2.2.3. Django (Backend Development)

Django is a robust high level python web framework that encourages rapid development utilizing Model-View-Controller (MVC) architecture. This architectural pattern offers a clear segregation between data management, UI, and business logic.

Django offers following advantages:

- **Rapid development** : Availability of built in features and modules speed up the backend development process
- **Scalable** : Django can handle high traffic loads making it suitable for large scale applications
- **Security** : Built in security features against vulnerabilities such as SQL injection, cross-site scripting, cross-site request forgery offers extra protection.
- **Support for Machine Learning** : Availability of libraries that can cater for machine learning requirements making it suitable for high-tech applications.

2.2.4. MVC Architecture in the PECS Tool

Both the frontend and the backend of PECS survey tool is built according to the Model-View-Controller (MVC) architecture.

- Model : Manages data and business rules of the application.
- View: Views are used to display data to the user.
- Controller: Controller acts as the mediator between the Model and the View. It handles the business logic of the application as well as the application state.

2.3. Description of PECS Survey Tool Features

The PECS survey tool was developed with the objective of collecting high-quality subjective feedback and maximizing the user

engagement. To achieve these requirements, the application was developed with following innovative features:

2.3.1. Dynamic Unfolding Questionnaire

The survey records all the answers given by the user to selectively ask only relevant follow-up questions based on the answers provided. This feature allows the user to provide the feedback in the shortest possible time and with minimal effort. Hence this feature is designed specifically to reduce the survey fatigue and improve the quality of data collected.

2.3.2. Notification and Reminder System

Survey tool is designed to send automated notifications at predefined intervals. Whenever a survey is being triggered at a set time, a notification is popped up in the screen. When the notification is clicked, it routes to the active survey. Notifications feature is included in the application to remind the user to engage with the active surveys. This feature enables the user to access the survey swiftly and engage with the survey smoothly.

2.3.3. Gamification Elements

Integration of leaderboard and a point-based system for users is to boost the user engagement by introducing an element of gamification into the survey tool. It's designed in such a way that the users will earn contribution points for each completed survey, which will ultimately affect their rank. This gamified approach is proven to positively influence the user engagement, especially in non-entertainment contexts such as IEQ surveys (Deterding et al., 2011).

2.3.4. Integration into User's Work Routine

The application is designed in such a way that the user doesn't have to learn any new skills to interact with it. The minimalistic user interface makes it self-intuitive for the users to understand the workflow of the application. When the user installs the application and logs in, it will save the logged in status even after restarting the operating system. User also can close the application if it hinders the daily work routine. The application is developed to run in the background in Windows operating system. It will notify the user only when there is a survey triggered for submission. These features are available in the application to reduce the friction in integrating a new application into the daily work routine of users. Further, the users are also able to provide feedback or request support through the application itself.

2.3.5. Example User Flow of PECS Survey

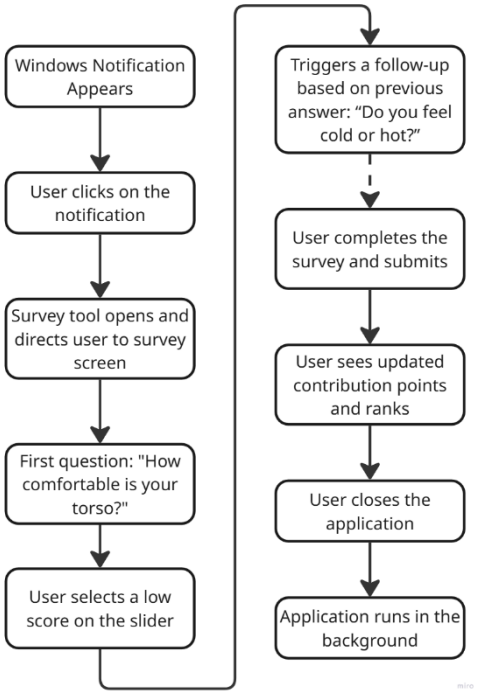

Figure 1: User flow of PECS session

2.4. Experimental Setup to Test PECS

The effectiveness of the PECS survey tool was tested by utilizing the survey tool in an experiment to evaluate indoor environment quality targeting users in an office environment. The study was conducted to gather feedback on user's perceptions of indoor environment quality while analysing

user engagement patterns.

2.4.1. The Participation and Duration of the Study

The PECS survey tool was installed in 23 users' computers. The survey was conducted for 14 consecutive days allowing to analyse user trends and response behaviours over time. The users were initially notified of the development status of the application. Furthermore, users were provided with a user guide to reduce any confusion in the workflow of the application.

2.4.2. Survey Time Slots and Trigger Strategy

Three time slots were selected to prompt the survey to users each day.

- 1st Time Slot - 09:30 to 10:30
- 2nd Time Slot - 11:30 to 12:30
- 3rd Time Slot - 14:30 to 15:30

If the users missed the survey within the designated timeslot, the same survey will be triggered again just after each time slot to ensure that the feedback was gathered consistently. After the survey was triggered for the second time, the users were notified in person to remind them of the survey.

2.4.3. Subjective Data Collection

The survey tool is used to capture subjective feedback on occupants' perceptions of the indoor environment. Users responded to quantitative questions with Graphical Rating Scales (GRS) numbered from 0 to 100. The responses are analysed to determine overall response patterns across time slots and days.

3. RESULTS

3.1. Overall Submission Pattern Overtime

The overall submission pattern (Figure 2) shows the number of submissions gathered on each day of the experiment. The chart shows daily fluctuations in user engagement. The 5th and 10th of February shows the peaks of user

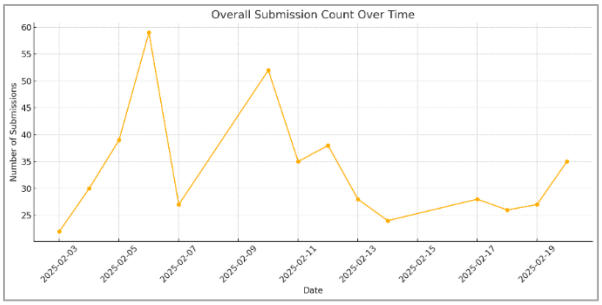

Figure 2: Plot of overall submission pattern overtime

engagement with 59 and 52 engagements respectively. The number of submissions significantly decreased after 12th February. There is a significant dip on the 7th of February depicting a significant variation from the general trend. This is because the experiment was not conducted on this day but the survey tool was programmed to run continuously.

3.2. Main Slot vs Second Trigger Responses

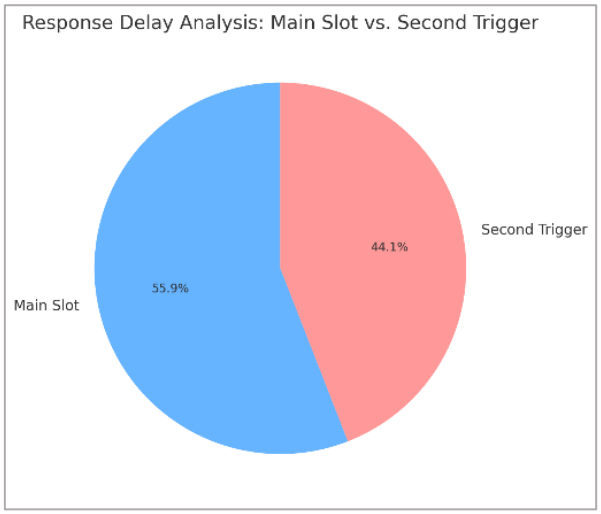

Figure 3: Responses in main slot vs second slot

The percentage of responses gathered in the main time slot and second trigger is presented in Figure 3. A total of 55.9% of the responses were collected in the first trigger in the main time slot by the help of notifications generated

by the application. 44.1% of the responses were gathered through second triggers which included both automated reminders and human follow-ups.

3.3. Responses by Time Slot

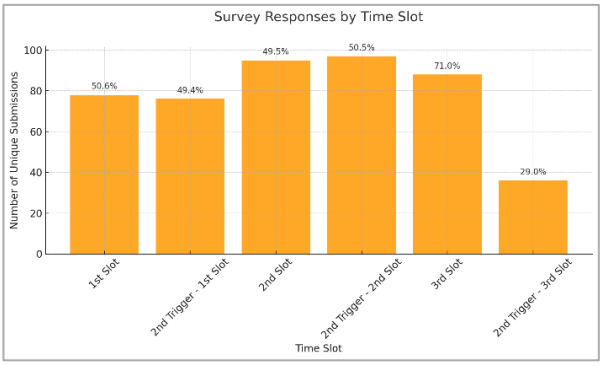

Figure 4: Responses by time slot

The number of submissions gathered across time slots is represented in the chart given in Figure 4. The first two time slots show a response distribution of around 50% between the main trigger and the second trigger. But the responses in the third time slot have gathered 71% of the responses in the first trigger and 29% submission in the second trigger.

3.4. User Engagement Heat Map Across the Experiment

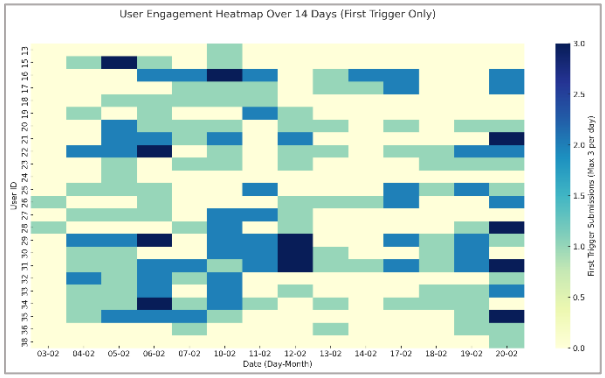

Figure 5: User engagement heat map

Figure 5 shows a heatmap of the user engagement across a total period of the experiment. The heatmap was created by the responses gathered in the main time slot (through app notifications) only. A significant reduction of the engagement can be noticed in 13th and 14th of February. Overall decrease can also be noticed after the 12th of February.

4. ANALYSIS AND DISCUSSION

Meaningful insights into user engagement were derived from the data collected over the 14-day experiment period.

4.1. User engagement variability

The standard deviation of total submissions per participant is 10.49 showing a high variability in user engagement across participants. This means that some participants were consistently responsive while others engaged with the survey less frequently. To evaluate the difference between user engagement, the users were divided into two groups. High engagement group are the participants with submissions above the median while the low submission group is the participants with submissions below the median. A two-sample t-test resulted in a t-statistic of 6.12 with a p value of 9.99×10^{-6}, which is lower than the significance threshold 0.05. This suggests that there is a statistically significant difference between engagement level of the two groups.
It confirms that the differences in participation rates are not due to random variation but are influenced by external factors such as work schedules, site visits, workload, technical issues, or reduced motivation levels.

4.2. Effectiveness of Notifications

The bar chart shown in Figure 3 and 4 depicting the survey responses by time slots shows important patterns related to the effectiveness of the application's notification system. It shows a higher engagement for the first trigger in the main time slots compared to the second trigger. This demonstrates the effectiveness of the notification system. In

addition, the reliance on the notification system was also observed when some participants reporting technical issues related to Windows notifications which led to miss the survey in the main time slot.

4.3. Remarks on Ease of Use

Daily submissions (Figure 2) show a high positive gradient in the first three days of the experiment with a peak on February 6th registering the maximum number of submissions per day within the 14-day period. This suggests that the participants adapted to the application within two days. This highlights the intuitiveness and the ease of use of the application.

4.4. Low Engagement on Fridays

Reduced activity towards the end of the week (Fridays – 7th and 14th February) of all participants is also noticeable in the heatmap.

5. CONCLUSION

This study evaluated the effectiveness of PECS survey tool that has unique features designed to collect subjective feedback on indoor environmental quality. The field study highlights the automated notification feature effectively prompted surveys during the designated time slots. Recording the highest number of survey responses after three days of use indicates the intuitiveness and ease of use of the application.

The higher engagement in main time slots and user consistency confirms that the features included in the application (dynamic unfolding questionnaire, leaderboard, and notification system) has positively impacted on user experience.

6. ACKNOWLEDGEMENT

The authors would like to thank Team TCC and Team Breda from Kropman B.V. for their continuous support for making the experiments a success. The authors would also like to express their gratitude to the Netherlands Enterprise Agency (‘Brians 4 Buildings’ project number MOOI32004 and ‘Brains for Buildings, Eindhoven Engine, APK 2.0 Project’ with project number RT104151) for their financial support.

ABSTRACT
Taiwan's existing buildings make up 97% of its total stock, playing a vital role in achieving near-zero carbon goals and the 2050 net-zero emissions target. This study explores retrofitting a bank branch into a nearly zero-energy building. Using EnergyPlus, a baseline energy model was created and validated with utility data, on-site surveys, and performance checks. Energy Efficiency Strategies included upgrading lighting and HVAC systems, paired with solar photovoltaics and green electricity purchases. The results showed that Energy Efficiency Strategies reduced the Energy Use Intensity, contributing 56% of the targeted energy savings, while Renewable Energy Technologies provided the remaining 44%, surpassing the near-zero energy target of 72 kWh/m²·year. Overall, the combination of proven Energy Efficiency Strategies and Renewable Energy Technologies successfully transformed the existing building into a near-zero carbon building. This case provides valuable insights and a reference model for retrofitting existing buildings in Taiwan to support sustainable development goals.

Keywords: Energy Use Intensity, Energy Efficiency Strategies, Renewable Energy Technologies, nearly zero-energy buildings.

1. INTRODUCTION

Zero-Energy Buildings (ZEB) are increasingly prioritized. In March 2022, Taiwan announced its "2050 Net-Zero Emissions Strategy" for the building sector. By 2030, all new public buildings must meet nearly zero-energy (nZEB) standards. By 2040, 50% of existing buildings will be retrofitted, and by 2050, all new buildings and over 85% of existing ones will comply. With 97% of Taiwan's buildings being older, privately owned structures, retrofitting poses challenges. The government has adopted a phased approach, requiring public building retrofits and offering subsidies to incentivize private owners. The plan requires over 50% of energy reductions through Energy Efficiency Strategies (EES), with the rest from Renewable Energy Technologies (RET). Since 2023, pilot projects have retrofitted buildings using cost-effective EES, such as envelope and system upgrades (HVAC, lighting, hot water), and RET, including photovoltaics (PVs), wind turbines, solar thermal, and green electricity.

Existing buildings must prioritize cost-effective EES before adding renewable energy. Retrofitting them for nZEB is more complex than designing new ones, with most research focusing on residential and new buildings, leaving retrofits of commercial and governmental buildings

underexplored. A 40% energy reduction was achieved in an Italian office through retrofits and onsite renewables (Ferrari, 2017). Investigated the retrofitting of a Kuwaiti university building using EES and building-integrated solar systems, achieving experimental feasibility for a nZEB (AlAjmi, 2016). Achieved a 45% energy demand reduction in Canada through airtightness and insulation improvements, with solar panels facilitating net-zero energy (Charles, 2019). Demonstrated a 60% energy savings in a U.S. office building using EES, with PV supplying 31.4% of the remaining demand (Alajmi, 2020). Similarly, Analyzed retrofitting a typical administrative building in Cairo into an nZEB, showing EES could reduce energy use by 11.9% and PV by 29.5% (El-Sherif, 2020). Upgrades to a Cairo educational building showed a 36% energy savings through envelope improvements and 50% through HVAC systems, with PV panels covering the remaining demand (Emil, 2021).

This paper explores the nZEB retrofit of a bank branch in Kaohsiung, Taiwan, as part of the net-zero carbon initiative. The project, in construction and testing, involves two stages: validating the EnergyPlus model with pre-retrofit data and applying EES, followed by integrating solar systems and green electricity. This study demonstrates the feasibility of transforming a high-energy-consuming building into an nZEB under Taiwan's hot and humid climate.

2. RESEARCH METHODOLOGY

2.1. Description of the Building

The investigated case is located in Kaohsiung City, southern Taiwan, with a climate featuring a maximum temperature of 36.8°C, a minimum of 18.8°C, an average of 24.8°C, and 79.1% relative humidity. With a cooling degree-hour of 25,680°C·hours (based on 23°C), air conditioning is needed year-round. The branch, occupying 630.8 m² across the first and second floors of a 2013 commercial building, faces east-northeast at 20° and features concrete walls, low-emissivity glass windows (SHGC = 0.5), and a 0.16 window-to-wall ratio. Internal heat sources include lighting, equipment, and occupant activities.

The HVAC system, lighting, and equipment operate from 8:00 AM to 6:00 PM, Monday to Friday. Before the retrofit, lighting used 20W and 40W T8 fluorescent lamps, consuming 7.9 kW with a lighting power density (LPD) of 12.5 W/m². The HVAC system includes a chiller, cooling tower, and water pumps on the rooftop, with fan coil units and two fresh air systems in the office. HVAC specifications and performance details before the retrofit are in Table 1. A site survey of equipment revealed a plug load of approximately 16 W/m². In 2023, monthly electricity consumption ranged from 7,335 kWh in January to 11,137 kWh in August, totaling 112,155 kWh annually, with an EUI of 178 kWh/m²·year (Figure 1).

2.2. Retrofit Strategies

For the retrofit, proven technologies approved by the bank were implemented, including advanced lighting, HVAC upgrades, a PV system, and green electricity. Regarding lighting systems, energy-efficient LED fixtures replaced 20W and 40W T8 fluorescent lamps, reducing power to 14W and 28W, with excess fixtures removed. These upgrades lowered total lighting power to 4.1 kW and the LPD to 6.5 W/m².

The HVAC retrofit included replacing the chiller with an Energy Efficiency Class 1 variable

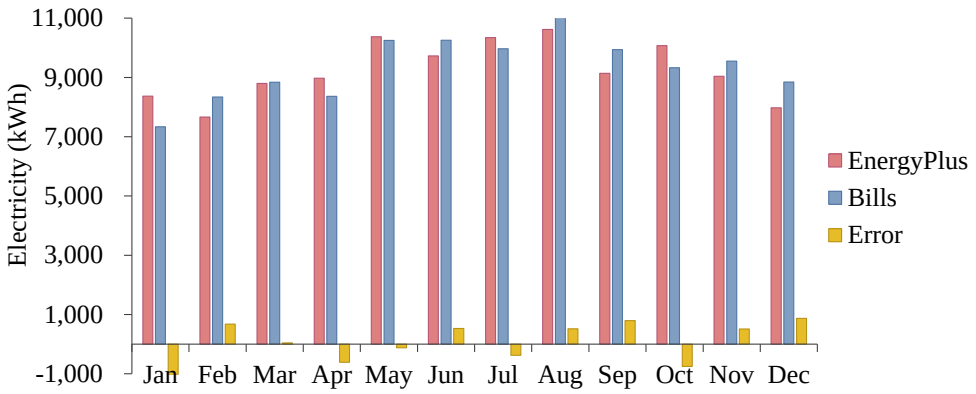

Figure 1. Monthly Actual Electricity Consumption of the Bank Branch

Table 1. Specifications and Performance of the HVAC System Before and After Retrofit

Equipment Name	Pre-retrofit	Post-retrofit
Chiller	Two scroll chillers with total cooling capacity of 60 RT and total input power of 51.2 kW.	One screw chiller with a cooling capacity of 50 RT and an input power of 34.1 kW, with VFD.
Cooling Tower	Two cooling towers with 80 RT heat rejection capacity and 1.5 kW input power, without VFD.	One cooling tower Two cooling towers with a heat rejection capacity of 80 RT and a 1.5 kW VFD fan.
Cooling Water Pump	Two pumps with a total flow rate of 630 LPM and 7.5 kW total input power.	One pump with a flow rate of 650 LPM and a power input of 3.7 kW.
Chilled Water Pump	Two pumps with a total flow rate of 504 LPM and total power input of 7.5 kW.	One pump with a flow rate of 500 LPM and total power input of 3.7 kW.
Fan-Coil Unit	21 units, each with an airflow of 680 to 1,360 CMH and a total power input of 2.2 kW.	Same as pre-retrofit
Outdoor Air	Two DOAS units with a total airflow of 1,600 CMH and a power input of 1.16 kW, without heat recovery.	Two DOAS units with 1,600 CMH airflow and 1.16 kW power input, featuring heat recovery and CO2 DCV.

frequency model, reducing capacity from 60 RT to 50 RT to match demand. A high-efficiency cooling tower with variable frequency drive fans was installed to lower the outlet water temperature and improve chiller efficiency. The fresh air system was upgraded with an enthalpy heat exchanger and CO_2-based volume control to optimize air quality. An Energy Management System (EMS) was implemented to monitor, and analyze energy use, supporting the net-zero energy target. The specifications and performance of the retrofitted HVAC system are in Table 1.

Based on the availability of renewable energy, a rooftop PV system was installed, covering 51.2 m^2 with a 9.6 kWp capacity, generating 12,916 kWh annually. Due to the limited rooftop area, the electricity generated by the system is insufficient to fully meet the requirements of a nZEB. Therefore, an additional 28,338 kWh of green electricity is purchased annually from the utility company.

2.3. Measurement and Verification of Building Retrofit

The Measurement and Verification (M&V) process for building retrofits consists of two phases: pre-retrofit and post-retrofit. Pre-retrofit M&V calibrates the energy model by comparing simulated data with actual consumption. Post-retrofit M&V, conducted after the retrofit, is beyond

the scope of this study, as the project is still under construction. This study uses a calibrated energy model to simulate and predict energy savings from the proposed EES. The model incorporates building geometry, orientation, façade structure, window specifications, lighting, equipment, HVAC systems, interior layout, occupant schedules, and climate data. Variables such as plug loads, lighting intensity and schedules, and indoor temperature setpoints were adjusted based on site visits, architectural documentation, and feedback from facility management personnel. A one-week field measurement campaign recorded power consumption with analyzers and chilled water flow/temperature differences with thermal meters, providing insights into cooling needs and system performance. The EnergyPlus V22.2 simulation program, using local weather data, was employed to simulate the model and produce 12 months of energy usage results. Monthly consumption calibration was performed with 2023 data, adjusting the model until power consumption fell within an acceptable error range. Calibration is considered successful if the Mean Bias Error (MBE) and the Coefficient of Variation of the Root Mean Square Error (CV(RMSE)) are within ±5% and ±15%, respectively, as per ASHRAE Guideline 14. The calculations for MBE and CV(RMSE) are shown in equations (1)-(3).

$$MBE(\%) = \frac{\sum_{i=1}^{n} S_i - M_i}{n} \times 100 \quad (1)$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n} (S_i - M_i)^2}{n}} \quad (2)$$

$$Cv(RMSE) = \frac{RMSE}{M_{avg}} \times 100 \quad (3)$$

Where n represents the period, S_i and M_i are the simulated and measured energy consumptions, respectively, and M_{avg} is the average measured energy consumption.

3. RESULTS AND DISCUSSION

3.1. Chiller Measurement Results

To further analyze the cooling demand of the building and the operational status of the chiller system, this study monitored a five-day period from May 20 to May 24, 2024. The results are presented in Figure 2 During this period, the total electricity consumption of the chiller system was 1,215 kWh, with daily consumption ranging from 225 kWh to 262 kWh. The analysis revealed that the energy consumption distribution of the chiller system remained relatively stable, with the chiller compressor accounting for 69%, the cooling tower for 3%, the chiller pump for 13%, and the cooling water pump for 15%. The total cooling load was 697 RTh, averaging 139 RTh/day. Chiller efficiency ranged from 1.10 to 1.25 kW/RT (average 1.21 kW/RT), while overall system efficiency ranged from 1.67 to 1.80 kW/RT (average 1.74 kW/RT). These findings provide key insights into system performance and validate the energy model.

3.2. Analysis of Calibration Results

The building energy simulation model was developed using EnergyPlus, a comprehensive program for building energy simulation. The design of each floor's structural elements, including floors, exterior walls, internal partitions, and windows, was based on the as-built construction drawings.

Specifications for HVAC equipment, lighting, and plug loads were derived from on-site

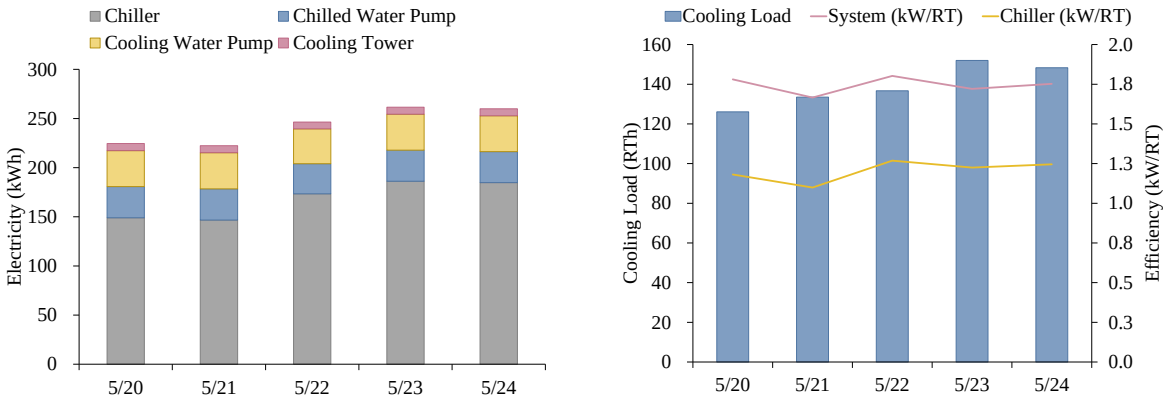

Figure 2. (a) Total electricity consumption of the chiller system and (b) cooling load demand and efficiency during five typical working days in May 2024.

observations. The efficiency of the HVAC system, measured on-site, was incorporated into the simulation model as input data. Additionally, the weather data file used for the simulation was based on the Typical Meteorological Year (TMY) rather than the actual meteorological year, a common practice in building energy modeling.

Lacking a sub-metering system, the building energy model calibration relied on total electricity consumption data from the utility. Figure 1 compares EnergyPlus estimated and actual monthly electricity consumption. The simulation's predicted annual electricity consumption is 111,105 kWh (176 kWh/m²·year), while the actual building's annual consumption is 112,155 kWh (178 kWh/m²·year), with the simulated prediction being 99% of the actual consumption. The error between actual and simulated monthly consumption ranges from -14% to 10%, caused by discrepancies in weather data, occupancy rate estimation, and uncertainties in plug load power and usage. In the calibration based on monthly data, the normalized mean bias error (NMBE) and the coefficient of variation of the root mean square error (CV(RMSE)) for the simulation model are 1% and 7%, respectively. The results meet the ASHRAE Guideline 14 criteria of 5% NMBE and 15% CV(RMSE), confirming the simulation model's high accuracy for energy analysis. The calibrated model shows the bank branch's pre-retrofit annual electricity consumption (Figure 3): HVAC at 70,829 kWh (64%), lighting at 17,665 kWh (16%), and plug loads at 22,611 kWh (20%).

3.3. The effect of Energy Efficiency Strategies

The lighting system was upgraded from T8 fluorescents to LEDs, reducing wattage from 7.9 kW to 4.1 kW and annual energy use by 48% (from 17,665 kWh to 9,115 kWh). HVAC, which accounts for 76% of energy use, underwent significant upgrades: the old chiller (1.21 kW/RT) was replaced with a more efficient model (0.68 kW/RT), and a DOAS with energy recovery and CO_2 control was added. Figure 4 shows HVAC energy consumption decreased by over 2,800 kWh/month (40%) during peak months and 1,800 kWh/month (41%) in cooler months, totaling 27,624 kWh annually (39%), making the upgrade essential for achieving nZEB. Figure 3(b) shows a significant EUI drop after the retrofit, with lighting EUI reduced by 14 kWh/m²·year and HVAC by 69 kWh/m²·year. The branch's EUI fell from 176 to 119 kWh/m², achieving 32% total energy savings, advancing toward NZEB.

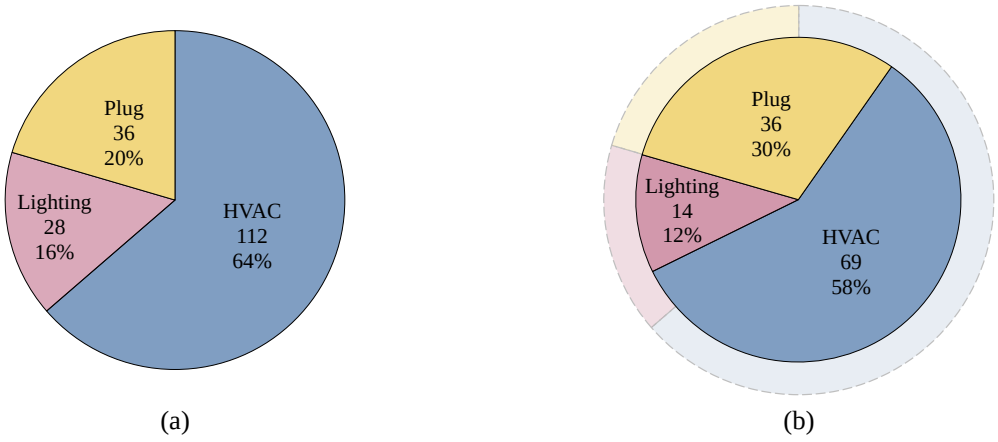

Figure 3. The sub-metered EUI of the bank branch (a) before and (b) after the retrofit.

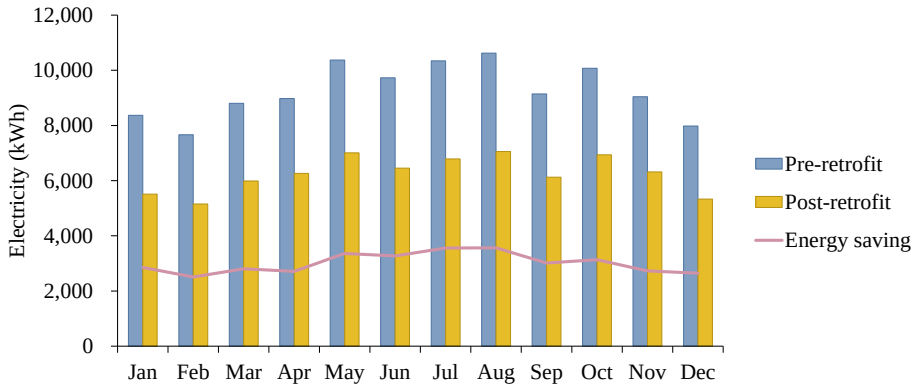

Figure 4. Comparison of monthly electricity consumption before and after HVAC retrofit.

3.4. Renewable energy system

The 51.2 m² rooftop PV system, rated at 18% efficiency by the manufacturer and 15% in simulation considering effective area and inverter efficiency, supplies power directly on working days and stores holiday excess in batteries for later use.

The solar PV system's performance was evaluated using TMY data to convert horizontal solar radiation to the collector array, predicting power generation. The total solar radiation in Kaohsiung is 1.492 MWh/m² annually. Figure 5 shows monthly performance, peaking at 1,325 kWh in July with lower output in winter. The system is expected to generate 12,916 kWh annually (17% of total consumption), with the bank purchasing 28,388 kWh/year of green electricity (38%) during non-summer months (October to April), accounting for 38% of the total electricity usage.

3.5. Post-retrofit nZEB Performance

Figure 6 compares monthly electricity consumption and renewable energy production, showing a shortfall in offsetting the building's usage. The peak energy deficit occurs from May to October, requiring additional non-renewable energy. August's 3,200 kWh deficit suggests doubling the PV area to 135 m² for net-zero energy.

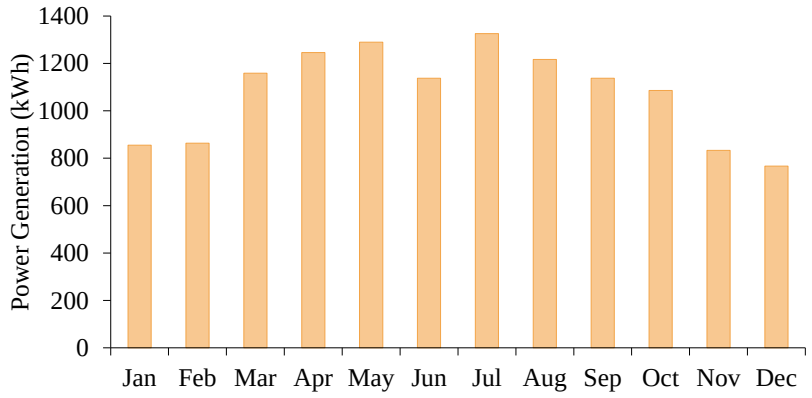

Figure 5. Monthly power generation of the solar PV system.

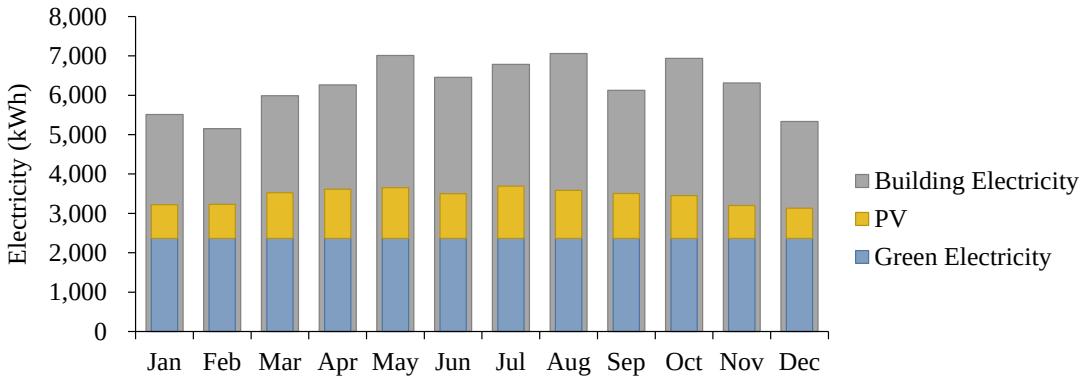

Figure 6. Comparison of Monthly Electricity Consumption and Renewable Energy Generation of the pre-retrofit.

Figure 7 illustrates the path to nZEB, with EES lowering the EUI from 176 to 119 kWh/m²·year. Lighting EES saved 14 kWh/m²·year, and HVAC EES cut 44 kWh/m²·year. The proposed EES measures achieved 56% of the total energy savings, reducing EUI from 176 to 73 kWh/m²·year. This fulfills the requirement for EES to provide over 50% of savings, but the branch still falls short of Taiwan's nZEB standard, requiring RET to meet the remaining demand.

Integrating RETs reduced the EUI to 55 kWh/m²·year, with PV providing 20 kWh/m²·year and green power contributed an additional reduction of 44 kWh/m²·year, meeting the nZEB target. This renovation underscores the importance of practical technologies in cutting energy use, modernizing Taiwan's buildings, and achieving near-zero energy goals.

4. Conclusion

This study evaluated the accuracy of the pre-retrofit building energy model and analyzed the impact of EES and RET on energy consumption. The project successfully converted an existing bank branch office into an nZEB. The following conclusions were drawn:

- The simulated pre-retrofit EUI of 176 kWh/m²·year closely aligned with the measured 178 kWh/m²·year, achieving an NMBE of 1% and a CV(RMSE) of 7%, meeting ASHRAE Guideline 14 criteria and confirming model accuracy.

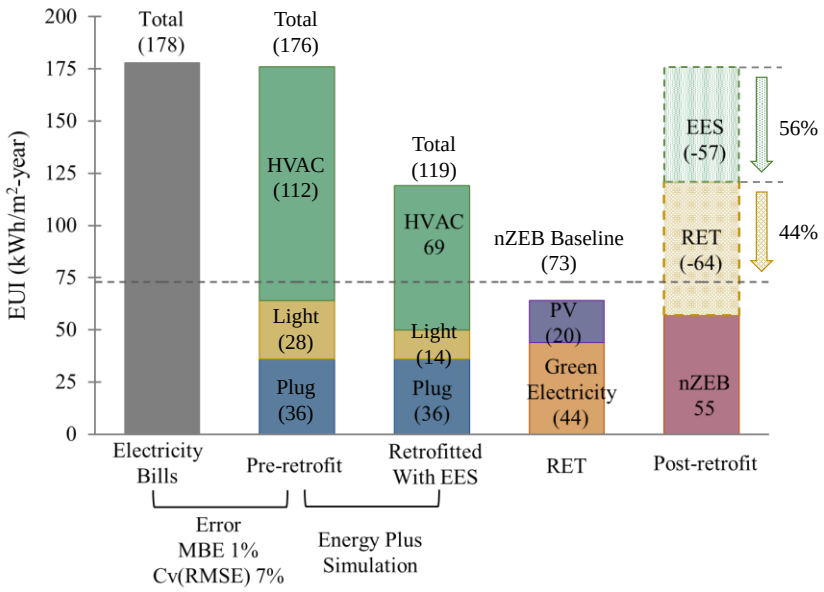

Figure 7. Pathways to achieving nZEB for the bank branch.

- Lighting system optimization reduced the building's EUI by 14 kWh/m²·year, while HVAC efficiency improvements reduced energy consumption by 44 kWh/m²·year. EES provided 56% of the target energy savings.
- Two RETs were introduced: a PV system and green electricity purchase, supplying 64 kWh/m²·year of green energy. The PV system generated 20 kWh/m²·year annually, and 44 kWh/m²·year was purchased from the grid.
- After implementing EES and RET, the building's EUI was reduced from 176 kWh/m²·year pre-retrofit to 55 kWh/m²·year post-retrofit, significantly below the 73 kWh/m²·year benchmark, achieving substantial energy savings.

In conclusion, retrofitting existing buildings to nZEB standards is technically feasible and provides valuable insights for advancing sustainable development goals. This area merits further research and greater emphasis from policymakers to accelerate its implementation.

SUMMARY
The rapid growth of data centers has led to substantial energy consumption and waste heat production, creating both environmental challenges and opportunities for energy recovery. This study aims to investigate how adsorption heat pumps can utilize low-grade waste heat from data centers to improve overall energy efficiency and reduce the environmental footprint. A numerical analysis is performed using a Linear Driving Force (LDF) model on a two-bed adsorption chiller (e.g., silica gel-water pair). Key parameters (inlet temperature range of 53°C–73°C, chilled water temperature of 25°C–20°C) are optimized for typical data center conditions. Results show that the proposed system significantly enhances cooling efficiency and can achieve a reasonable coefficient of performance (COP) when applied to time-varying data center loads. Waste heat from immersion-cooled servers was successfully converted into usable cooling capacity for additional air-cooled racks, thereby reducing the electricity demand of the data center. Adsorption chillers, when integrated with immersion cooling systems, offer a promising pathway for waste heat recovery in data centers. This integrated solution supports sustainable development by reducing both operational costs and environmental impact.
Keywords: Data Center, Adsorption Chiller, Immersion Cooling, Calculation.

1. GENERAL INSTRUCTIONS

With the rapid expansion of information and communication technology (ICT) and the surge in data processing requirements, constructing large-scale data centers has emerged as a core development strategy for major economies (Masanet et al. 2020; Cho and Lee 2024). Driven by the so-called ABC technologies—artificial intelligence, big data, and cloud computing—both current and future data centers are reshaping not only the ICT sector and newly emerging industries, but also the service landscape of established fields (Cho et al. 2022). Traditional areas such as manufacturing, agriculture, and fisheries are likewise undergoing profound changes through digital transformation.

IT equipment (ITE) can demand power densities of 50 kW per rack or higher, depending on workload and equipment performance. Although the average density generally remains below 10 kW per rack, data centers with IT capacities of 5 MW or more often see higher values (Davis et al. 2022). Nearly all power consumed by ITE is eventually converted into heat, and the majority of new and existing data centers worldwide rely on air-cooled ITE. However, with rising rack-level heat loads—driven by generative AI and other applications—many data centers are approaching the limits of airflow and cooling capacity (Zhang et al. 2014; Sohel Murshed and Nieto de Castro 2017). As a result, more efficient cooling approaches are needed, and liquid cooling has emerged as one of the most promising alternatives. By transferring waste heat through the liquid refrigerant to a utility heat source, liquid cooling can significantly reduce the airflow needed in racks and may further enhance ITE performance by lowering operating temperatures (Cho and Lim 2023).

In this context, the present study proposes new data center concept of cooling system that integrates an immersion cooling system, addressing the heightened demand and power density of ITE, with an adsorption heat pump. Crucially, the adsorption heat pump recovers a large portion of cooling waste heat and repurposes it as a secondary cooling source, thus enabling a shift from existing air-based cooling systems. To validate this concept, the study provides an optimal design of the adsorption heat pump employing waste heat and offers a quantitative assessment of the overall energy efficiency for the proposed data center cooling solution.

2. METHODOLOGY

2.1. System Description

A key requirement for implementing liquid cooling is having liquid-cooled IT equipment (ITE). Because such ITE is not yet widely adopted, designing liquid cooling systems can involve uncertainty about cooling needs. In this study, a 200 kW ITE load is cooled via immersion cooling and a 50 kW adsorption heat pump, which together provide cooling to air-cooled ITE through a 20 kW rear door heat exchanger (RDHx). Waste heat from the immersion process supplies hot water to the adsorption heat pump; the pump's output, in turn, cools the RDHx. The central challenge lies in establishing suitable operating conditions for the integrated components. Optimizing the adsorption heat pump requires examining adsorbents such as silica gel, MIL-101Cr, or SAPO-34, and considering hot water temperatures between 53°C and 73°C to achieve an adequate coefficient of performance (COP).

Standard metrics like power usage effectiveness (PUE) are not ideal for liquid cooling because they alter both total data center power and ITE power (Avelar et al. 2012). Alternative measures, such as total usage effectiveness (TUE) (Patterson et al. 2013), can be more informative. Conventional data centers often use air cooling, generating low-temperature waste heat of limited reuse value (Jang and Cho 2024). Liquid cooling, however, can recover higher-grade waste heat without extra heating requirements.

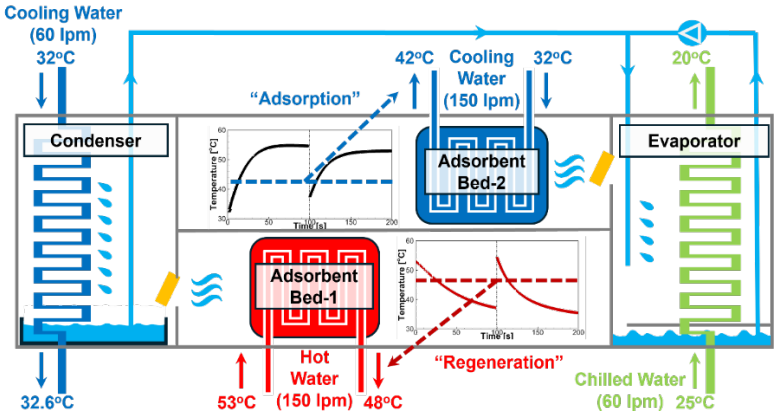

Figure 1. Adsorption chiller concept for data center with waste heat recovery

In this study, 50 kW of the 200 kW immersion-cooling waste heat is directed to an adsorption heat pump that provides chilled water for the RDHx. Two coolant distribution units (CDUs), each with six 34 kW immersion tanks, handle the 200 kW total load. The CDU system is split into two units: one providing 50 kW for the adsorption heat pump and the other managing the remaining 150 kW via a cooling tower. The RDHx cools a rack at 18 kW/rack, with a 10°C air differential and 100 m^3/min airflow. Chilled water is circulated at 20 kW (110% of RDHx capacity), at a 20°C outlet from the adsorption heat pump, with a 6.6 m^3/h flow at a 5°C temperature difference. Lastly, the

condenser water loop is sized for 38.4 m³/h at a 32°C tower outlet temperature; two parallel pumps circulate 28.8 m³/h for immersion cooling and 12.6 m³/h for the adsorption heat pump plus RDHx.

2.2. Model Description

Figure 1 illustrates a simplified schematic of a two-bed adsorption cooling system, comprising an adsorber, a desorber (or regenerator), a condenser, and an evaporator. As adsorption is exothermic, a cooling water supply removes heat from the adsorber, maintaining the cooling effect while the refrigerant is adsorbed. The vapor then condenses and feeds into the evaporator, ensuring continuous cooling (Al-Mousawi et al. 2016; Gediz et al. 2021). The subsequent focus is on the adsorbent bed, where the Linear Driving Force (LDF) model is applied. The LDF model (Linear Driving Force) is adopted to describe the transient adsorption/desorption rates. Let q be the instantaneous adsorbate concentration, and $q*$ be the equilibrium concentration. The governing equation is expressed as

$$\frac{dq}{dt} = k_{\mathrm{LDF}}(q^* - q) \tag{1}$$

where k_{LDF} is the overall mass transfer coefficient. This formulation assumes the adsorption process is primarily controlled by macropore diffusion rather than micropore diffusion. Additionally, isothermal conditions are assumed within each bed layer, and the bed thermal capacity is accounted for by coupling with energy balance equations.

3. RESULTS

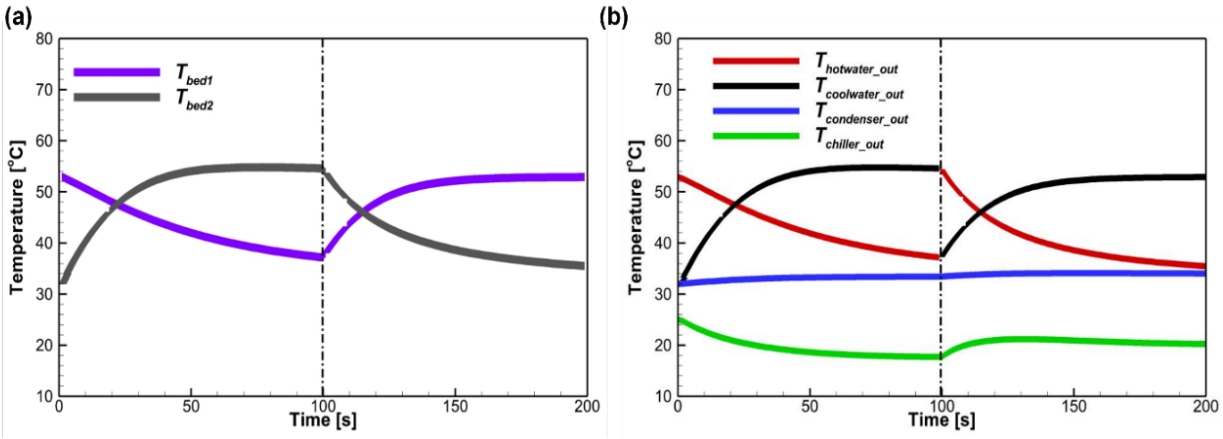

Figure 2. (a) Two beds temperature for Silica gel-water and (b) liquid output temperature at each component.

Figure 2(a) displays the temperatures in each adsorbent bed, illustrating how one bed absorbs while the other regenerates. Both beds receive water initially heated to 53.0°C for regeneration and water at 32.0°C for adsorption. Figure 2(b) shows outlet temperatures after heat exchange in the beds, indicating that a short cycle time of about 200 seconds is required at 53.0°C/32.0°C. The condenser temperature remains stable between 32.0°C and 33.5°C. Globally, data centers relying on air cooling have maintained a PUE of 1.55–1.59 since 2020 (Davis et al. 2022). A 200 kW immersion-cooled data center would consume 210.16 kWh total power (cooling: 10.16 kWh), producing a $\mathrm{PUE}_{\mathrm{cooling}}$ of 1.051. When adding an adsorption heat pump plus 18 kW of air-cooled ITE, total power climbs to 232.16 kWh (cooling: 14.16 kWh), yielding a $\mathrm{PUE}_{\mathrm{cooling}}$ of 1.064. Although slightly higher, the extra 18 kW of cooling energy can be more effectively utilized. The TUE metric shows a starker difference: 2.131 for a pure air-cooled approach and 1.345 for immersion

cooling alone. With the combined waste heat recovery system, the $TUE_{cooling}$ is 1.367, a marginal increase but one offset by the advantages of recovering waste heat.

4. CONCLUSIONS

This study introduces an innovative system that pairs immersion cooling with an adsorption heat pump, converting waste heat into a secondary cooling source. Three main goals are addressed: (1) designing an integrated 200 kW waste heat recovery system, (2) determining optimal conditions for operating the adsorption heat pump on immersion-cooling waste heat, and (3) assessing energy efficiency via PUE/TUE. Two adsorbents were tested under the LDF model for adsorber, desorber, evaporator, and condenser energy balances. Silica gel achieved a higher COP at 53.0°C, while MIL101Cr recorded a COP near 0.4, indicating good regeneration potential. For a 200 kW immersion-cooled ITE load plus 18 kW of air-cooled ITE, power usage reached 232.16 kWh, corresponding to a $PUE_{cooling}$ of 1.064. Separating liquid- and air-cooled loads yielded a $TUE_{cooling}$ of 1.367—slightly above immersion cooling alone, yet still advantageous for waste heat recovery. Future research should address stable adsorption cycle operation and low efficiency while considering real-world variables such as cooling tower availability. Developing real-time control algorithms for adsorption cycle phases could optimize both throughput and energy efficiency. Also, investigating next-generation adsorbents, such as metal-organic frameworks (MOFs) and advanced composites, to improve regeneration under moderate-temperature inputs. Lastly, evaluating how surplus heat could be fed into local district heating networks, thus expanding the beneficial re-use of waste heat beyond the data center itself.

SUMMARY
This study aims to develop a predictive model based on recurrent neural networks for the rapid and accurate prediction of the complex heat transfer processes within PCM earth-to-air heat exchangers (PCM-EAHE), thereby facilitating system design. Recurrent neural networks, long short-term memory networks, gated recurrent units, and bidirectional recurrent neural networks were primarily employed to assess the performance of various neural network architectures in predicting the heat transfer performance of PCM-EAHE. The model can rapidly and accurately predict the outlet air temperature by using the inlet air temperature, pipe geometry, and inlet air velocity as inputs. A validated numerical model of the PCM-EAHE was developed, and datasets for neural network training were generated based on variations in geometries, inlet air velocities, and inlet air temperatures. After training various neural networks, the bidirectional gated recurrent unit demonstrated the best predictive performance following hyperparameter optimization, achieving an RMSE of 0.9944, an R^2 of 0.8781, and an MAE of 0.6726.

1. GENERAL INSTRUCTIONS

In modern energy management and sustainable building design, the integration of phase change materials (PCM) with soil-air heat exchangers can form PCM-EAHE systems. This system utilizes phase change materials to facilitate the spatiotemporal transfer of natural energy stored in outdoor air, thereby enhancing the preconditioning effect of fresh air within the system. In recent years, research in this field has grown rapidly (Ren et al., 2024b). However, the complex heat transfer processes within PCM-earth-to-air heat exchangers (PCM-EAHE), involving mechanisms such as phase change and convection, pose challenges for traditional computational fluid dynamics (CFD) methods, which are computationally expensive and time-consuming. With the development of machine learning, particularly neural network technologies, researchers have begun exploring their application in predicting the heat transfer performance of PCM soil-air heat exchangers to enhance prediction efficiency and accuracy (Wang and Wang, 2021).

In recent years, neural networks have found increasing applications in fluid mechanics and heat transfer problems. Deep learning frameworks, such as convolutional neural networks (King et al., 2024), long short-term memory networks (G. Li et al., 2024), feedforward backpropagation

artificial neural networks (Ermis et al., 2007), and physics-informed neural networks (Eivazi et al., 2022), have been successfully applied to model and predict various fluid heat transfer problems, including natural and forced convection. Particularly with the aid of computational fluid dynamics (CFD), neural networks can approximate complex nonlinear heat conduction and fluid flow equations by learning from large datasets of simulation or experimental data, enabling rapid and accurate predictions of heat transfer performance (Wang et al., 2023; Yue et al., 2024).

Although neural networks have seen extensive applications in computational fluid dynamics and heat transfer prediction, research on their application in predicting the heat transfer performance of PCM-EAHE systems remains limited. This study first developed an experimentally validated numerical model of a PCM-EAHE to generate the requisite datasets for training. Various models were then trained on the same dataset to evaluate their predictive performance, aiming to promote the application and adoption of this technology in practical engineering.

2. NUMERICAL MODELS

2.1. Physical model description

This study focuses on an EAHE integrated with PCM, where cylindrical PCM materials are placed inside the pipes of the soil-air heat exchanger. This pipe system is primarily used in summer to precondition fresh air for air conditioning. As air flows through the pipes, it exchanges heat with the PCM materials and the surrounding soil, thereby preconditioning the air, reducing the fresh air load during the summer, and lowering air conditioning energy consumption, as illustrated in Figure 1.

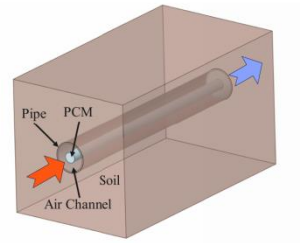

Figure 1. Schematic diagram of CPCM-EAHE（cylindrical phase change material -filled earth-air heat exchanger) device shape.

2.2. Control Equations

The numerical model of the PCM-EAHE was developed using the finite volume method. To facilitate subsequent computational analysis, it is assumed that the air is incompressible, and that the effect of moisture content variation inside the shaft on heat transfer is neglected. Only sensible heat exchange in the buried pipe is considered. The soil and PCM are treated as isotropic materials, and thermal contact resistance within the system is neglected. The effects of pipe wall thickness and air gravity are also disregarded. Additionally, it is assumed that the PCM-soil air heat exchanger is buried in a region where the soil temperature is constant throughout the year.

The computational domain of the model encompasses the air, phase change material, and soil regions. The air region is divided into uniform blocks, with a grid size of dz and a total number of grids equal to Z/dz. Radially, the air is assumed to be uniformly distributed, and no radial grid division is performed. The phase change material (PCM) has a radius of r_p and is uniformly divided into M radial layers, with a radial grid size of $\Delta r_p = r_p/M$. The axial grid size is consistent

with that of the air region. The soil region has an inner radius of r_{s1} and an outer radius of r_{s2}, with J radial grids and a radial grid size of $\Delta r_s = (r_{s2} - r_{s1})/J$. The axial grid size is consistent with that of the air region.

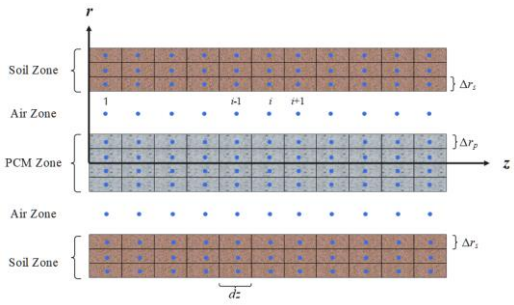

Figure 2. Grid division and structure diagram of CPCM-EAHE system.

The detailed parameters of the phase change material (PCM) are provided in Table 1.

Table 1. Thermophysical parameters of phase change materials.

Characteristics	Phase change materials
$\lambda(\mathrm{W \cdot m^{-1} \cdot ^{\circ}C^{-1}})$	5.43(s)/3.26(l)
$\rho(\mathrm{kg \cdot m^{-3}})$	904.5
$c_p(\mathrm{J \cdot kg^{-1} \cdot ^{\circ}C^{-1}})$	1750
$T_m(^{\circ}\mathrm{C})$	28.16-32.68
$L_p(\mathrm{kJ \cdot kg^{-1}})$	135.7

2.1.1. Energy governing equation of the air layers

Based on the energy conservation equation and the mathematical model, the energy governing equation for the air region, as shown in Equation (1). From left to right, the terms represent the unsteady term, convective term, diffusion term, and convective source term, respectively.

$$\pi(r_a^2 - r_p^2)\rho_a \frac{\partial T_a}{\partial \tau} + \pi(r_a^2 - r_p^2)\rho_a u \frac{\partial T_a}{\partial z} = \pi(r_a^2 - r_p^2)\frac{\lambda_a}{C_a}\frac{\partial^2 T_a}{\partial z^2} + \frac{S_c}{C_a} \quad (1)$$

In the above equation, r_a represents the equivalent radius of the vertical shaft channel; ρ_a is the air density; C_a denotes the specific heat capacity of air; λ_a is the thermal conductivity of air; T_a represents the air temperature; u is the airflow velocity; and S_c denotes the source term for convective heat and mass transfer in air.

2.1.2. Energy governing equation of the phase change material layers

Similarly, based on the energy conservation equation, the energy governing equation for the PCM region, as shown in Equation (2).

$$\rho_p C_p \frac{\partial T_p}{\partial \tau} = \lambda_p\left(\frac{\partial^2 T_p}{\partial r^2} + \frac{1}{r}\cdot\frac{\partial T_p}{\partial r} + \frac{\partial^2 T_p}{\partial z^2}\right) \quad (2)$$

In the equation, C_p represents the specific heat capacity of the phase change material (PCM); ρ_p is the density of the PCM; and T_p denotes the central temperature of the PCM layer..

2.1.3. Energy governing equation of the soil layers

Based on the energy conservation equation, the energy governing equation for the soil region, as shown in Equation (3).

$$\rho_s C_s \frac{\partial T_s}{\partial \tau} = \lambda_r \left(\frac{\partial^2 T_s}{\partial r^2} + \frac{1}{r} \cdot \frac{\partial T_s}{\partial r} + \frac{\partial^2 T_s}{\partial z^2}\right) \tag{3}$$

In the equation, C_s represents the specific heat capacity of the soil; ρ_s is the density of the soil; and T_s denotes the central temperature of the soil layer.

2.2. Experimental Validation

The experimental parameters from Zhou (Zhou et al., 2020) for the PCM-soil-air heat exchanger are applied to the numerical model in this study. The results from the numerical model are compared with the experimental data. As shown in Figure 3, the final results demonstrate that the numerical model achieves good agreement with the experimental data. The average absolute error in outlet air temperature is 0.46°C, with a maximum absolute error of 1.1°C and a maximum relative error of 1.79%.

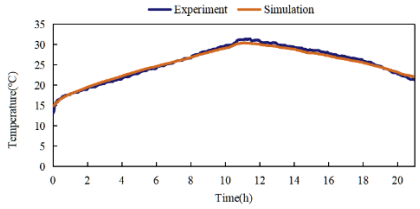

Figure 3. Comparison of numerical model calculations with experimental data.

3. NEURAL NETWORK MODEL

3.1. Neural Network Architecture

3.1.1. Recurrent Neural Network (RNN)

Recurrent Neural Networks (RNNs) are a type of artificial neural network designed for sequence modeling. Unlike traditional feedforward neural networks, RNNs allow data to flow horizontally between neurons, capturing the correlation between data points. The distinctive feature of RNNs lies in the interconnections among neurons in the hidden layer, which enable the sequential transmission of time-dependent input data within a sliding window. Its mathematical expression is provided in Equation (4) (King et al., 2024).

$$Y_t = tanh(Ux_t + WY_{t-1} + b_h) \tag{4}$$

In the equation: Y represents the state value at each time step; U is the weight of the input at time t; W is the weight of the state at time $t-1$; b_{h} is the bias term.

3.1.2. Long Short-Term Memory Neural Network (LSTM)

Although RNNs can effectively process nonlinear time series, they suffer from the vanishing gradient and exploding gradient problems, which limit their ability to handle time series with excessively long sliding windows. Moreover, training an RNN model requires a predefined window length, which is challenging to optimize automatically in practical applications. To

address these issues, the LSTM model introduces a mechanism called the "cell state," which effectively captures long-term dependencies. Its forward computation can be expressed as follows (Wan, 2024):

$$i_t = \sigma(W_{xi}x_t + W_{hi}Y_{t-1} + b_i) \quad (5)$$
$$f_t = \sigma\left(W_{xf}x_t + W_{hf}Y_{t-1} + b_f\right) \quad (6)$$
$$c_t = f_t c_{t-1} + i_t tanh(W_{xc}x_t + W_{hc}Y_{t-1} + b_c) \quad (7)$$
$$o_t = \sigma(W_{xo}x_t + W_{ho}Y_{t-1} + W_{co}c_t + b_o) \quad (8)$$
$$Y_t = o_t tanh(c_t) \quad (9)$$

In the equation: i_t, f_t, c_t, and o_t represent the input gate, forget gate, cell state, and output gate, respectively; W and b denote the corresponding weight matrices and bias terms; σ and tanh represent the Sigmoid and hyperbolic tangent activation functions, respectively.

3.1.3. Gated Recurrent Unit (GRU)

The GRU model is a simplified version of the LSTM model, retaining its long-term memory capabilities. The primary modification involves replacing the input gate, forget gate, and output gate in the LSTM cell with an update gate and a reset gate. By introducing this gating mechanism, the GRU controls the flow of information and captures long-term dependencies more effectively. Its mathematical expression is provided in the equation (Sui et al., 2024):

$$z_t = \sigma(W_z h_{t-1} + U_z x_t + b_z) \quad (10)$$
$$r_t = \sigma(W_r h_{t-1} + U_r x_t + b_r) \quad (11)$$
$$\tilde{Y}_t = tanh(W_h x_t + U_h(r_t Y_{t-1}) + b_h) \quad (12)$$
$$Y_t = (1 - z_t)h_{t-1} + z_t \tilde{Y}_t \quad (13)$$

In the equation: r_t represents the output of the reset gate; z_t represents the output of the update gate; $\tilde{Y}_t$ denotes the hidden state at the current time step; W_{r} and U_{r} are the weights of the reset gate to the hidden state and input, respectively; W_{z} and U_{z} are the weights of the update gate to the hidden state and input, respectively; U_{h} and W_{h} represent the weights of the hidden state to itself and to the cell input, respectively; b_{r} and b_{z} are the biases of the reset and update gates. σ denotes the Sigmoid function, and tanh denotes the hyperbolic tangent function.

3.1.4. Bidirectional Recurrent Neural Network (Bi-RNN)

If a complete sequence is available during training, a Bidirectional Recurrent Neural Network (Bi-RNN) can be constructed. Traditional RNNs process sequential data in a unidirectional manner, from past to future, whereas Bi-RNNs capture contextual information from both the past and the future at each time step, leading to improved performance in many tasks. The hidden states are computed for both the backward and forward directions (F. Li et al., 2024). In this study, the Bi-RNN will be applied to both the GRU and LSTM models to construct Bidirectional Gated Recurrent Unit (Bi-GRU) and Bidirectional Long Short-Term Memory (Bi-LSTM) networks, and their performance will be compared.

3.2. Hyperparameter Fine-tuning

The hyperparameters of the neural network are determined using a grid search method, with the specific settings listed in Table 2. This study employs Python as the programming environment and PyTorch as the deep learning framework for training and prediction.

Table 2. Setting of hyperparameters.

Learning rate	Iterations	Batches	Layers	Neurons
0.0005	100	4	4	16
0.001	500	8	5	32
0.005	1000	16	6	64

3.3. Evaluation Index for Network

This study primarily employs three key performance metrics: $RMSE$, R^2, and MAE, to evaluate the model. The specific calculation formulas are as follows:

$$R^2 = 1 - \frac{\sum_{i=0}^{m}(y_i - \hat{y}_i)^2}{\sum_{i=0}^{m}(y_i - \bar{y})^2} \tag{14}$$

$$RMSE = \sqrt{\frac{1}{m}\sum_{i=1}^{m}(y_i - \hat{y}_i)^2} \tag{15}$$

$$MAE = \frac{1}{m}\sum_{i=1}^{m}|y_i - \hat{y}_i| \tag{16}$$

In the equation: y_i is the true value, $\hat{y}$ is the predicted value, and m is the number of samples.

4. DATA SETS

Based on the design parameters of the PCM soil-air heat exchanger in practical applications, five variables were defined: PCM pipe diameter, ventilation pipe diameter, pipe length, inlet temperature, and inlet air velocity. Considering the actual diameter of PCM ventilation pipes, the PCM pipe diameter and ventilation pipe diameter were set between 0.05 m and 0.3 m, while the pipe length ranged from 10 m to 45 m. The inlet temperature was selected from hourly temperature measurements during the summer months (May to September) in a typical meteorological year in Chongqing (Ren et al., 2024a), and the inlet air velocity was set between 0.5 m/s and 2.5 m/s. The specific training and test sets are presented in Tables 3 and 4.

Recurrent neural networks require input time series data for computation. In this study, the time series for all models was set to 15 days, comprising 360 hours of temperature data. The 360-hour temperature data, along with the PCM pipe diameter, ventilation pipe diameter, and pipe length, were organized into a (360, 5) matrix as input data for the model. A corresponding (360, 1) matrix containing the 360-hour outlet temperature data served as the output data.

Table 3. Parameters for the experimental setup of the training dataset.

Level	PCM pipe diameter (m)	Ventilation pipe diameter (m)	Pipe length (m)	Inlet air velocity (m/s)	Inlet temperature date
1	0.05	0.05	10	0.5	May 16 - May 30
2	0.12	0.17	28	1.5	May 31-June 14
3	0.2	0.3	45	2.5	June 15 - June 29

Table 4. Parameters for the experimental setup of the test dataset.

Level	PCM pipe diameter (m)	Ventilation pipe diameter (m)	Pipe length (m)	Inlet air velocity (m/s)	Inlet temperature date
1	0.08	0.07	15	0.8	July 30-August 13
2	0.14	0.18	24	1.3	August 13-August 28

3	0.18	0.25	40	2.4	August 29-September 12

5. ANALYSIS OF RESULTS

Firstly, the dataset and initial hyperparameters described earlier were used to train each model. The initial hyperparameters are shown in Table 6. After training, the prediction accuracy of each model was obtained before hyperparameter tuning. Then, hyperparameter tuning was performed for each model, and the prediction errors after tuning were obtained. The prediction performance of each model was evaluated using three metrics (RMSE, R^2, and MAE), as shown in Table 7. The final results indicate that the prediction performance of all models improved by an average of 17% after hyperparameter tuning. The BiGRU model demonstrated the best prediction accuracy, with an RMSE of 0.9944, R^2 of 0.8781 and MAE of 0.6726 after hyperparameter tuning.

Table 5. Initial hyperparameters for each model.

Learning rate	Iterations	Batches	Layers	Neurons
0.005	500	8	4	64

Table 6. Accuracy of the models' predictions.

	Before/after hyperparameter tuning		
Model	$RMSE$	R^2	MAE
RNN	2.1947/1.4309	0.4064/0.7477	1.6593/1.0581
LSTM	1.4468/1.2216	0.7420/0.8161	1.0498/0.8324
GRU	1.5245/1.0217	0.7136/0.8714	1.2225/0.7424
BiLSTM	1.4960/1.2638	0.7242/0.8031	1.0690/0.9144
BiGRU	1.2206/**0.9944**	0.8164/**0.8781**	**0.9165/0.6726**

Furthermore, to provide a more intuitive analysis of the prediction results from different models and verify their prediction accuracy, all models, after hyperparameter tuning, were tested using a 360-hour dataset. The comparison between predicted and actual results is presented in Figure 4. As shown in the figure, all models effectively captured the output temperature variation trend, with their predictions closely following the actual values. The Bi-GRU model produced predictions that were closest to the actual values, consistent with the accuracy evaluation metrics.

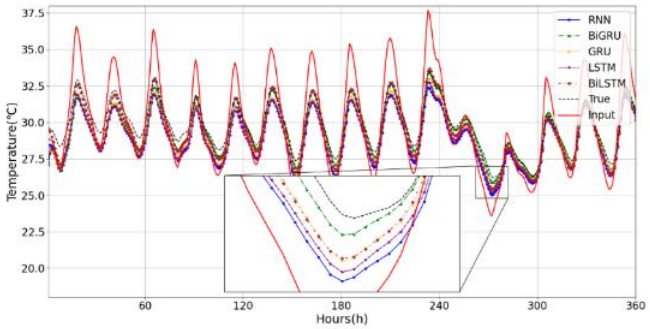

Figure 4. Comparison of the predicted results of the models with the true results.

6. CONCLUSION

To efficiently and accurately predict the heat transfer performance of PCM-soil-air heat exchangers, this study proposes a prediction model based on recurrent neural networks (RNNs). By comparing different RNN models and conducting an exhaustive hyperparameter search, the model's full potential was explored. The following conclusions were drawn: five different types of recurrent neural networks were trained using the original dataset. After hyperparameter tuning, the best-performing model was the Bi-GRU, which achieved an RMSE of 0.9944, R^2 of 0.8781, and MAE of 0.6726. The results indicate that RNNs can effectively predict the heat transfer performance of PCM-soil-air heat exchangers. However, due to limitations in the training dataset size and input parameters, the overall prediction accuracy of the neural network remains suboptimal. Future work should focus on further enhancing the training dataset to identify more robust datasets and comprehensively improve model performance.

ABSTRACT
With the wide application of building integrated PV systems, there is an increasing demand for DC inverter heat pumps in buildings. In this paper, the performance of a DC inverter heat pump system for integration in a PV integrated building was analyzed. The PV power fluctuation and demand-side load characteristics were first analyzed based on the operational data obtained from two case study buildings located in hot-summer and cold-winter regions in China. Then, the numerical models for the heat transfer and energy conservation of the integrated system in a reference building were developed. A control strategy for the heat pump was proposed accounting for the characteristics of PV power generation and demand-side heating load. By using MATLAB software, the performance of the integrated system was simulated. The simulation results indicate that the proposed strategy can achieve stable operational characteristics of the DC inverter heat pump while maintaining the thermal comfort level of the indoor thermal environment. Therefore, the heat pumps employ a start-up and standby control strategy. Adjusting the setting range of the room temperature can significantly affect the allowable standby time of heat pumps. The standby time duration of heat pumps can be extended to about 20~30% by reducing the room temperature from Class I to Class II comfort criteria in Chinese national standards.

Keywords: DC inverter heat pump, PV power fluctuation, Demand-side characteristic, performance analysis.

1. INTRODUCTION

Climate change and energy crises are major global challenges. With population growth and rapid increase in energy demand, traditional energy consumption and environmental pollution are becoming increasingly serious (Tan et al. 2022) (Wang et al. 2023). China is committed to achieving a "carbon peak" by 2030 and "carbon neutrality" by 2060 (Chen et al. 2022), and building energy consumption accounts for 45.6% of the country's total energy consumption, with the power sector and the building sector accounting for about 21% and 59% of carbon emissions, respectively (Lin et al. 2022). Therefore, energy saving and carbon reduction in the power industry and buildings are urgent. As a renewable energy source, solar energy is clean and economical, allowing it to be exploited for a variety of applications, including power generation and heating for domestic and industrial processes (Krishnan et al. 2023). In order to meet the needs of carbon neutrality, Jiang proposed the “Photovoltaics, Energy storage, Direct current and flexibility” (PEDF) technology. It connects photovoltaic systems directly to building DC buses, reducing energy conversion losses, and allows buildings to flexibly adjust their energy supply and demand, participating in grid dispatch. (Liu et al. 2022; Jiang 2021). However, the indirectness, randomness,

volatility of new energy generation and the uncertainty of building user loads have led to prominent supply and demand balance problems in the power system (Wang et al. 2019; Zhu et al. 2023), and there is an exigent need to research and develop DC power equipment and related regulation strategies that can be used in PEDF buildings (Notton et al. 2018).

DC inverter heat pump systems have become an important part of energy-efficient technologies for buildings due to their high energy efficiency and flexibility. These systems can directly utilize building-generated DC power, omitting energy conversion losses and improving the efficiency of energy use (Liu et al. 2022). However, the operation of DC inverter heat pump systems is affected by fluctuations in photovoltaic (PV) power generation and demand-side load characteristics, and flexible operation strategies need to be developed to accommodate these variations (Liu et al. 2022). In hot-summer and cold-winter regions, these systems not only have to cope with the heat load demand under extreme climatic conditions but also have to take into account the seasonal and intra-day fluctuations of PV power generation, as well as the uncertainty of building occupant loads (Wang et al. 2019).

Although some studies have explored regulation strategies for heat pump systems based on source-side and load-side characteristics, few focus on DC heat pump systems in PEDF buildings. Given the instability of new energy generation and the uncertainty of building occupant loads, combining unit power regulation and indoor temperature regulation to develop a reasonable DC heat pump system strategy is crucial for safe and reliable system operation (Jiang 2021). Currently, theoretical and practical applications of such heat pump systems in PEDF buildings are limited, mostly based on demonstration projects (Chen et al. 2021).

The research is motivated by the urgent need for energy-saving and carbon reduction in the power and building industries. PEDF buildings, as a key solution, require effective regulation strategies for their DC heat pump systems to balance the instability of power generation with load-side consumption characteristics. Fig. 1 shows the schematic diagram of the DC inverter heat pump system. The research aims to address the energy-saving and carbon-reduction needs in power and building sectors by developing effective regulation strategies for DC heat pump systems in PEDF buildings, balancing power generation instability with load-side consumption.

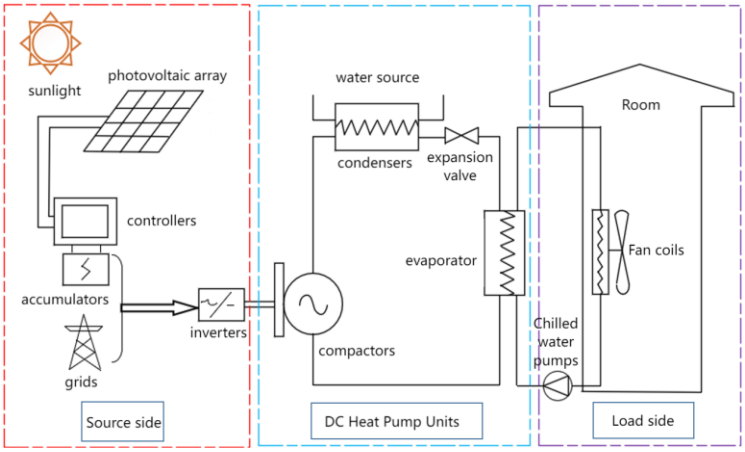

Figure 1. DC heat pump system composition schematic

2. METHODOLOGY

2.1 Case Study Buildings

Two case buildings located in hot-summer and cold-winter regions were selected for analyzing the power generation and demand-side characteristics. Both of them are office buildings, and located in industrial parks Shanghai, and Suzhou respectively, as shown in Fig. 2. In summer, the region has sufficient solar radiation and continuous sunshine hours, and the PV power generation is sufficient; while in winter, the number of sunshine hours is significantly reduced, and the solar radiation time is greatly shortened, compared with the summer PV power generation decreased significantly.

Figure 2. Conceptual overview of office buildings (left) and distributed photovoltaic systems (right)

2.2 Modeling of DC heat pump system

Based on the fluctuating characteristics of bus voltage, experiments were conducted on the rated operating conditions of the unit at different bus voltages to study the effect of variable bus voltage on the rated heating and cooling capacity of the DC heat pump unit. The performance of the heat pump unit under rated bus voltage conditions is investigated for different partial load rates, customer-side inlet water temperatures, and water-side outlet pump temperatures. Then, the variable operating condition performance experiment of the unit under fixed voltage is carried out. Based on the analysis of the experimental data, the performance model of the DC heat pump unit under different operating conditions is constructed, which provides a basis for the establishment of the overall model of the subsequent system.

2.3 Numerical modeling of heat transfer and energy conservation

A standard office building model was established, with an office building in Shanghai as a prototype. Energy Plus software was used to simulate the building load and energy consumption, and an equivalent RC model was established for the standard building.

According to the analysis of each node in Fig. 3, the indoor and outdoor heat balance equations of the building are shown in Eq. (1); the amount of cold and heat delivered by the HVAC system for the interior of the building is shown in Eq. (2); and the hour-by-hour solar radiation heat gain approximation replaces the heat gain through solar radiation illuminance calculations is shown in Eq. (3). The unknown parameters of the RC model were identified using a genetic algorithm with the data obtained from the simulation in Energy Plus as the driving source, and a load prediction

model was obtained for the building. On this basis, load calculations and predictions for a standard building model are obtained, which have an important impact on the regulation of the DC heat pump system. In this way, the control strategy of the heat pump can be proposed taking into account the characteristics of PV power generation and demand side heat load.

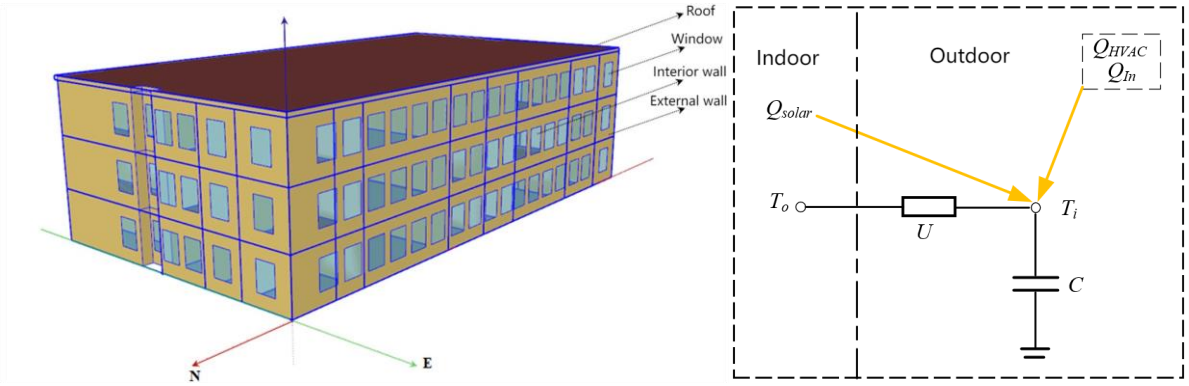

Figure 3. Office building 3D model schematic (left) and First-order equivalent RC model of a building(right)

$$C\frac{dT_i(t)}{dt} = \frac{(T_o(t)-T_i(t))}{R} + Q_{HVAC}(t) + Q_{\text{mn}}(t) + Q_{\text{solar}}(t) \quad (1)$$

$$Q_{HVAC} = \rho m c_p(\triangle T) \quad (2)$$

$$Q_{\text{Solar}}(t) = pI(t) \quad (3)$$

$$Q_{\text{load}} = Q_{HVAC} \quad (4)$$

Where T_O(℃) is outdoor air temperature node,T_i(℃) is indoor air temperature node, C(J/K) is Combined equivalent heat capacity of the whole building, R(K/W) is the combined thermal resistance of the building, the reciprocal of which is the combined heat transfer coefficient of the building, Q_{HVAC}(W) is Cooling/heating provided by the air conditioning system to the interior of the building, as negative/positive values, Q_{Solar}(W) is Heat gained by buildings through solar radiation, Q_{in}(W) is indoor heat, ρ(kg/m³) is density of water, m(m³/s) is water flow, $C_P(J/(kg \cdot K))$ is Constant pressure specific heat capacity of water, ΔT(℃) is Inlet and outlet water temperature difference, Q_{load}(W) is Building load, I(W/m^2) is solar radiation intensity, P(m^2) is Aggregate coefficients related to building surface area, absorptivity, reflectivity, etc.

2.4 Heat pump control strategy and simulation

The indoor design temperature has a direct impact on the power of the DC heat pump unit, and in PEDF buildings, the upper limit temperature of comfort level I is selected as the maximum PV consumption temperature, and the lower limit temperature of comfort level II is selected as the peaking temperature. In view of the fact that PEDF buildings can observe the state of the building power system through the bus voltage, a method of indoor design temperature setting based on the bus voltage is proposed. Table 1 shows the indoor temperature setting table designed based on the above principles, and the current heat pump operating mode and indoor temperature setting value are determined by the interval of the determined bus voltage.

Table 1. Indoor temperature setpoint based on bus voltage

Model name	Heat pump unit operation status	Bus voltage	Winter indoor temperature setting	Summer indoor temperature setting	comfort level
Down Frequency mode	Down Frequency	DC500V-DC576V DC656V-DC676V	18℃	28℃	Level II
Normal mode	Energy-saving	DC576V-DC596V	18℃	28℃	Level II
	Normal	DC596V-DC636V	22℃	26℃	Level I
	Overlimit	DC636V-DC656V	24℃	24℃	Level I
Standby mode	Shutdown	Less thanDC500V More thanDC676V	N/A	N/A	N/A

- When the bus voltage is at DC576 V~DC596 V, the electricity consumption of the building is mainly supplied through the utility power supply, and in order to minimize the electricity consumption of the HVAC system, the indoor temperature should be set to the lower bound of the comfort degree of level II;
- When the bus voltage is DC596 V~DC636 V, the photovoltaic power generation system normally supplies power for the building users, and the indoor temperature shall be set to the lower bound of Level I comfort;
- When the bus voltage is DC636 V~DC656 V, the PV power generation resources are relatively abundant, and the indoor temperature should be set as the upper limit of level I comfort in order to maximize the consumption of PV resources;
- When the bus voltage is DC500 V~DC576 V or DC656 V~DC676 V, the PV resources are extremely scarce or abundant, and too low or too high a voltage may lead to the burnout of the DC heat pump unit, and at this time, the power of the heat pump should be reduced to protect its safety;
- When the busbar voltage is at DC0 V~DC500 V or greater than DC676 V, it has exceeded the working range of the heat pump, and at this time, the DC heat pump unit should be temporarily shut down.

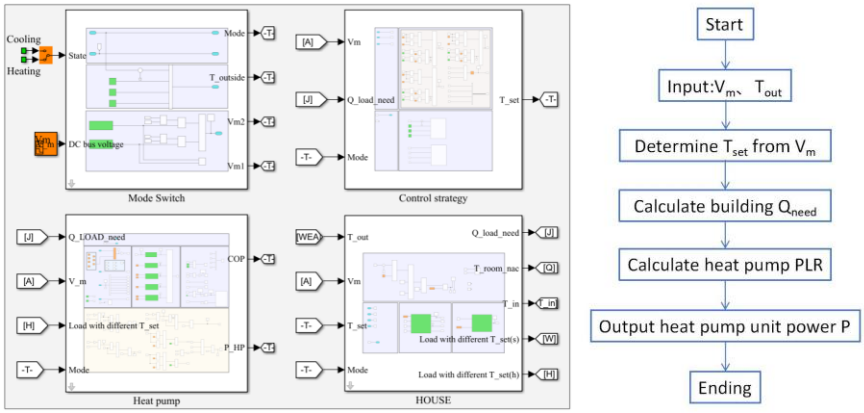

Figure 4. DC Heat Pump System Model (left) and DC heat pump unit control logic (right)

Then, the performance of the integrated system was simulated using MATLAB software. Fig. 4 illustrates some of the operational processes. The simulation model combines the developed numerical model and the proposed control strategy to evaluate the performance of the system in different scenarios.

3. RESULTS

3.1 Analysis of PV power fluctuation and demand-side load characteristics

By analyzing the PV power fluctuation and demand-side load characteristics of the case building, the instability of PV power generation is mainly caused by weather changes, seasonal differences, and intraday fluctuations. In terms of intraday fluctuations, the PV power is affected by the weather, and the maximum difference can be up to 260.1 kW, which poses a challenge to the safety and stability of the building's power equipment. Moreover, the energy consumption of the HVAC system of the office building accounts for a large proportion of the total energy consumption of the building, which is 61.71% and 39.36% on weekdays and days off, respectively. This high percentage of energy consumption and the intermittent mode of operation of the air conditioning system provide significant load regulation potential for the building.

3.2 Analysis of building load forecasting effects

Load calculations and forecasts have a significant impact on the regulation of DC heat pump systems. Load prediction is carried out for the data of the winter working week and the summer working week, respectively, and the results are shown in Fig. 5. The maximum heat load value of the building in winter is 105.81 kW at point 7 and the maximum cold load value of the building in summer is 156.88 kW at point 15. The results show that the MBE indicator of the winter load forecast value is 3.28 % and the RMSE indicator is 11.37 %, while the MBE indicator of the summer load forecast value is 4.78 % and the RMSE indicator is 14.19 %, which has a good forecasting effect.

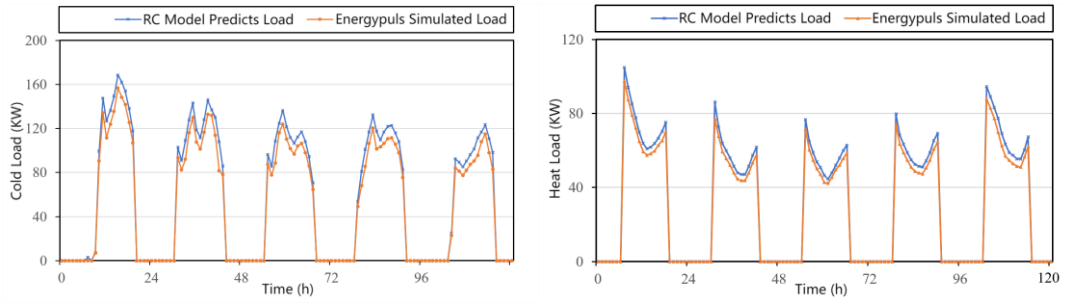

Figure 5. Building load forecast results for summer (left) and winter (right)

3.3 Analysis of model energy efficiency

In the normal bus voltage range, the strategy based on bus voltage compared with the traditional indoor temperature setting strategy can provide 9.29% and 14.32% of the additional photovoltaic consumption in the heating season and cooling season, and 22.81% and 11.98% of the power consumption reduction when the photovoltaic power generation is small. The variation curves of bus voltage, heat pump power, and outdoor temperature for heating conditions and cooling conditions are shown in Fig. 6. Compared with the basic working conditions, the heating season

and the cooling season can reduce the electricity consumption demand by 21.88% and 13.26% on the source side, respectively. In addition, the adjustment of the room temperature setting significantly affects the standby time of the heat pump. By gradually lowering the room temperature from level 1 comfort to level 2, the standby time can be extended to about 20~30%, making the heat pump operation more flexible and effectively reducing energy consumption during periods of low demand while maintaining the comfort level of the occupants.

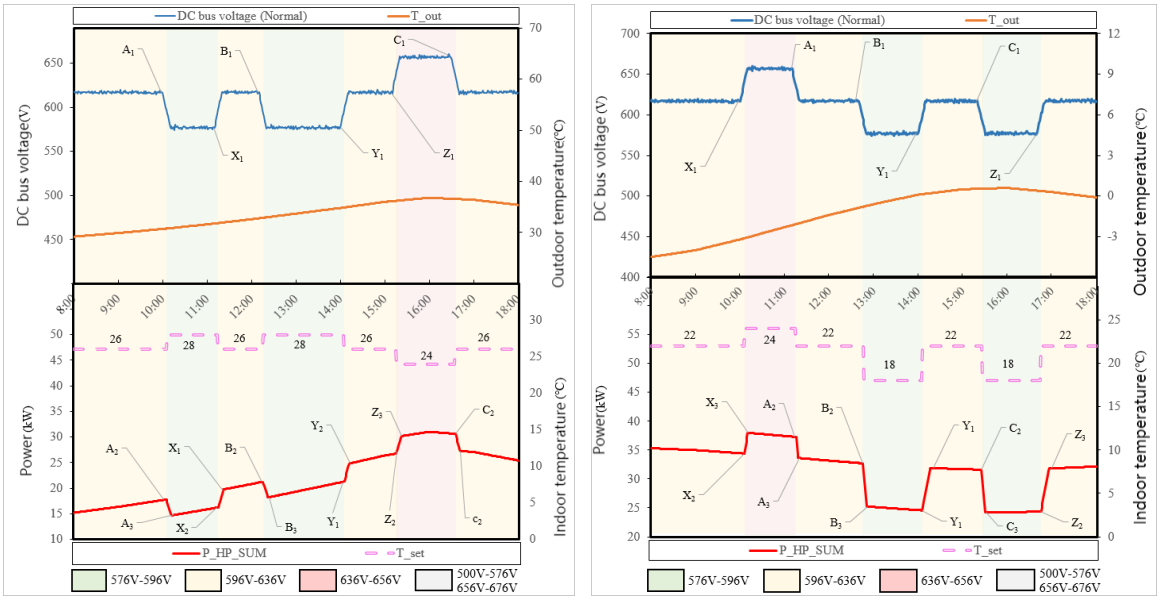

Figure 6. The variation curves of bus voltage, heat pump power, and outdoor temperature for heating condition (left) and cooling condition (right)

4. DISCUSSION

While the traditional strategy uses a constant indoor temperature setting (22~24°C in winter and 24~26°C in summer), this strategy dynamically adjusts the indoor temperature setting according to the fluctuation of the bus voltage and extends the standby time to reduce the start-stop time, reduce the energy consumption of the heat pump, and improve its safety. However, the strategy has only been studied by theoretical simulation, and experiments have not verified its effectiveness. Future research can further optimize the safe heating and cooling capabilities of the heat pump, propose a more effective control strategy by combining multiple climate zones and thermal comfort indicators, and verify the strategy's effectiveness through experiments.

5. CONCLUSIONS

This study takes the DC heat pump system as the research object, and based on the analysis of the characteristics of the source-side power supply and load-side power consumption of the actual PEDF building, it proposes a DC heat pump system regulation strategy that can adapt to the fluctuating bus voltage and meet the indoor comfort demand. The main research results are as follows:

- Substantial load regulation potential in the HVAC system of the case study buildings. The load

forecasting model showed good accuracy, with MBE and RMSE values indicating reliable predictions for both winter and summer periods.

- The proposed control strategy based on bus voltage demonstrated significant energy efficiency improvements. Compared to traditional indoor temperature setting methods, it increased PV consumption by 9.29% in the heating season and 14.32% in the cooling season. Additionally, it reduced power consumption by 22.81% in the heating season and 11.98% in the cooling season.
- Adjusting the indoor temperature settings from level I to level II comfort criteria significantly extended the allowable standby time of the heat pumps by approximately 20% to 30%.

In conclude, this strategy effectively balances the fluctuating PV power generation with the varying demand-side heating and cooling loads, ensuring stable operation of the heat pump system while maintaining indoor thermal comfort. The innovation of the strategy lies in its ability to dynamically adjust the room temperature setting range, thereby extending the heat pump's standby time and improving PV utilization. Future research should explore different priorities and weights for factors like energy use, comfort, and system stability to enhance the strategy's versatility and effectiveness.

Heating energy use analysis based on virtual energy meters: results from a Canadian institutional building

Qiwei Qin [1], Guy Labelle [1], Etienne Saloux [1]

[1]*CanmetENERGY, Natural Resources Canada, Varennes, QC, Canada*

SUMMARY
Virtual meters offer a cost-effective alternative to physical meters by using models that estimate energy usage from readily available data. This study aims at developing different virtual energy meters based on building automation system data to provide key insights on heating usage at sub-system level. It focusses on air handling units, variable air volume boxes, hydronic perimeter units and heat recovery systems and uses an existing Canadian institutional building as a case study. Building operators and facility managers can then make informed decisions to improve building energy efficiency, and to prioritize the implementation of retrofit measures for decarbonizing the built environment. This work highlights the potential of virtual energy meters for improving building operation, contributing to broader goals of energy conservation and climate change mitigation.

Keywords: virtual energy meter, data-driven model, heating load, building automation system.

1. INTRODUCTION

Energy use in buildings represents a significant portion (~30%) of global energy consumption and institutional buildings account for nearly 30% of this amount, making energy use estimates critical for improving energy efficiency and reducing greenhouse gas emissions (Intergovernmental Panel on Climate Change (IPCC), 2023). Energy mapping can help building operators better understand energy flows in different sub-systems, detect inefficiencies and optimize control strategies. Building automation systems (BAS) rely on a monitoring infrastructure that has been mainly used for local controls or fault detection diagnostics but that can now provide an untapped opportunity for energy mapping as operational data becomes increasingly available (Saloux et al., 2023). Unlike simulation studies that estimate full-scale building energy use based on simulation parameters and energy balance equations, virtual energy meters leverage readily available data to estimate specific quantities while taking into account sensor uncertainty and missing variables. Indeed, not all key energy variables are directly measured or readily available. Installing physical meters may be expensive and bring practical challenges, and virtual meters have emerged as a cost-effective and scalable solution for analyzing building energy performance.

The application of virtual sensors and virtual energy meters (VEMs) has gained significant attention in recent years due to their ability to provide granular insights into building energy performance. (Li et al., 2011) conducted a comprehensive review of virtual sensors across a wide range of applications, emphasizing their critical role in enabling cost-effective and robust optimal control strategies. When applied to specific system components, (McDonald and Zmeureanu, 2015) developed a virtual flow meter (VFM) for monitoring the energy performance of a cooling plant. Furthermore, a detailed investigation of cooling energy usage of a large commercial building was conducted in (Saloux and Zhang, 2022). Their subsequent work (Saloux and Zhang, 2023)

delved into the applications of VEMs for improving building controls as well as the uncertainties associated with these meters, highlighting the importance of understanding and mitigating potential inaccuracies in virtual energy metering applications. Virtual flow meters that rely on BAS data were investigated in (Cotrufo and Zmeureanu, 2018) for estimating outdoor air flow rate in air handling units (AHU). Similarly, a virtual flow meter was developed in (Yu et al., 2011) for supply air flow rate in rooftop air-conditioning units. Virtual energy meters based on steady-state and transient inverse grey-box model, and water-side load disaggregation were proposed by (Darwazeh et al., 2021) to calculate heat supplied by hydronic perimeter units. Based on these VEM, a visualization tool (Darwazeh et al., 2022) was developed for showing energy flows in AHU systems, which can help support decision-making and improve building performance.

This paper provides two main contributions. (1) It applies virtual energy meter methods in a real-world institutional building, offering a detailed visualization of energy flows across components at seasonal and hourly levels. These insights help identify inefficiencies and optimization opportunities, bridging the gap between theory and practice in energy management. (2) It provides a comprehensive comparison of different VEM to assess strengths and limitations in terms of accuracy, scalability, monitoring infrastructure, computational resources, and applications.

2. DEVELOPMENT OF VIRTUAL ENERGY METERS (VEM)

2.1 Case study building

Virtual energy meters were developed for a typical heating system in a 5,257 m² institutional building in Varennes, Quebec (climate zone 7A). The system serves a 330-m² section built in 2017, with hot water supplied by a dual-fuel heating plant. During non-occupied periods, the ventilation system is off, and only perimeter units provide heating. In contrast, during occupied periods (5:30-17:30, Monday-Friday), fresh air is preheated via a heat recovery system, mixes with return air, is heated up by a water-based heating coil in the AHU and distributed to variable air volume (VAV) boxes. Electric reheat coils located in VAV boxes can eventually fulfill the demand while heating is also provided by water-based perimeter units. Data for three winter seasons (Nov-Mar, 2020-2023), available at 5-min intervals, are used for analysis.

2.2 Applications and limitations of virtual energy meters

Although VEMs can be used for various applications such as inefficiency detection and optimization, this paper focuses on performance tracking and energy mapping. VEMs can provide a comprehensive energy mapping, tracing energy flows from sources to end-uses and visualizing heating energy distribution. This helps operators pinpoint energy-intensive components, sources of heat losses, and potential energy savings of control strategies. It is worth mentioning that in simulation studies, calculations are compared with the measured performance, which is considered as the reference. In contrast, VEMs aim to estimate this reference, and different methods can be used to cross-compare and validate results. VEMs address among others sensor instrumentation, bias and random errors, operating conditions, error propagation and uncertainties, which all impact the accuracy of estimations. VEMs provide a cost-effective alternative to physical sensors and leverage existing data to extract operational insights. Their scalability depends on sensor availability and quality, which vary across buildings. To ensure broad applicability, especially in diverse Canadian buildings, VEMs prioritize adaptability, build upon readily available datasets and leverage manufacturer information and building plans. Missing data is inferred from

assumptions or virtual sensors, focusing on its impact on energy predictions. Balancing simplicity, accuracy, and monitoring needs, VEMs validate both detailed and simple methods, ensuring practical scalability while maintaining performance insights tailored to specific applications.

2.3 Mechanical ventilation system

Fig. 1 illustrates the simplified schematic of the mechanical ventilation system. In commercial buildings, standards like ASHRAE 62.1 ASHRAE, 2022) require minimum fresh air during occupied periods, causing heat losses as cold fresh air is introduced. However, fresh air flow rates are rarely measured, but can be estimated using mass and energy balance equations:

$$\rho_a \dot{V}_f = \rho_a \dot{V}_s - \rho_a \dot{V}_r \Rightarrow \dot{V}_f = \dot{V}_s - \dot{V}_r \quad (1)$$

$$\rho_a \dot{V}_f (T_r - T_{f2}) = \rho_a (T_r - T_m) \dot{V}_s \Longrightarrow \dot{V}_f = \frac{T_r - T_m}{T_r - T_{f2}} \dot{V}_s \quad (2)$$

Eq. (1) uses mass balance equation, expressed using volumetric flow rates (which are typically measured), and requires flow rate sensors for both supply and return air; however, in some cases, only one of these sensors may be available. To overcome this, (Cotrufo and Zmeureanu, 2018) have successfully applied energy balance equation and proposed Eq. (2). This equation has been used in (Zmeureanu and Vandenbroucke, 2015) and its validity is evaluated for this case study.

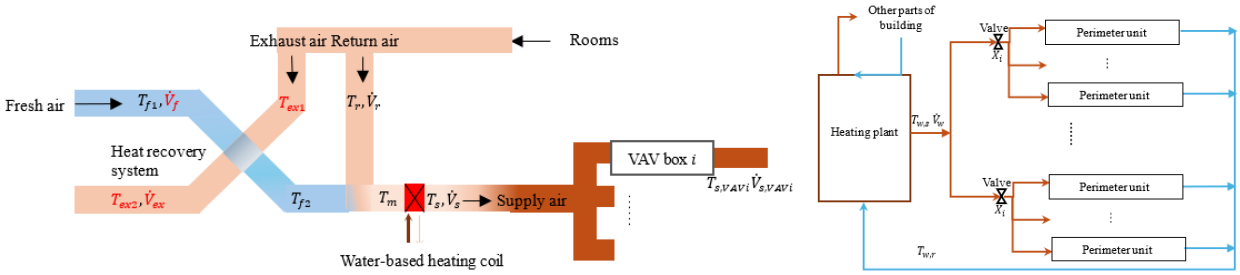

Figure 1. Simplified schematic of ventilation system (left) and water-loop of perimeter units (right). *T* means temperature (℃), *V* is flow rate (L/s) and X_i is valve opening (%); unmeasured variables are marked in red.

Heat recovered from return air in the heat exchanger can be calculated using fresh air flow rate and energy balance equation:

$$\dot{Q}_{heat\ recovery} = c_a \rho_a \dot{V}_f (T_{f2} - T_{f1}) \quad (3)$$

Heat losses associated with mechanical ventilation (i.e. incorporating fresh air in the building) is calculated as the enthalpy difference between exhaust and fresh air. Since there is no dehumidification in winter, air humidity is neglected. Exhaust air flow rate is assumed equal to that of fresh air to ensure pressure balance in the building. The following VEM is used for evaluating heat losses due to mechanical ventilation:

$$\dot{Q}_v = c_a \rho_a \dot{V}_f (T_r - T_{f1}) - \dot{Q}_{heat\ recovery} \quad (4)$$

The first term of Eq. (4) represents heat losses due to ventilation in the absence of a heat recovery system and represents the energy required for heating cold fresh air up to the room air temperature (assumed equal to the return temperature). Eq. (4) can then be used to evaluate the contribution of

heat recovery systems.

2.4 Water-based heating coil in the air handling unit

During occupied period, a water-based heating coil (see Fig. 1) is used to increase air temperature up to the required setpoint. Heating coil power can be calculated using enthalpy difference applied to air-side measurements or water-side measurements. Since there are typically no measurements for water flow rate and return water temperature, air-side measurements are used:

$$\dot{Q}_{AHU_coil} = c_a \rho_a \dot{V}_s (T_s - T_m) \tag{5}$$

Depending on the application, other models could be developed using only water-side measurements (e.g. valve modulation) or both air-side and water-side measurements.

2.5 Electric reheat coil in variable air volume boxes

Electric reheat coils installed in VAV boxes adjust air conditions to local needs before being distributed to the rooms. Applying the enthalpy difference method to air yields to:

$$\dot{Q}_{e_coil} = \sum_{i=1}^{N} c_a \rho_a \dot{V}_{s,VAVi} \left(T_{s,VAVi} - T_s\right) \tag{6}$$

Another VEM can be developed to calculate electric reheat coil power from the coil modulation:

$$\dot{Q}_{e_coil} = \sum_{i=1}^{N} X_{e_coil,i} C_{n_coil,i} \tag{7}$$

where $X_{e_coil,i}$ is the modulation (%) and $C_{n_coil,i}$ is the nominal capacity of electric coil *i*. Eq. (6) requires measurements for air flowrate ($\dot{V}_{s,VAVi}$), inlet and outlet temperature ($T_{s,VAVi}$) for each VAV box. In the case study, inlet temperatures before electric coils are not measured and are assumed to be equal to AHU supply temperature (T_s). Eq. (6) depends on 3 sensors, which increases uncertainty whereas Eq. (7) only relies on the coil modulation but may not account for electric coil performance degradation with time.

2.6 Water based perimeter units

The hydronic heating system supplies 29 perimeter units and the AHU heating coil (see Fig. 1), all connected in parallel. The perimeter units are divided into 9 distinct groups supplying different thermal zones. For each group, one valve controls the hot water flow rate. Only one flow meter is installed on the main water supply branch ($\dot{V}_w$) along with supply ($T_{w,s}$) and return ($T_{w,r}$) water temperature sensors to measure heating energy delivered to the 330-m² building section (see Section 2.1). The total heat supplied to the 29 units is determined as follows:

$$\dot{Q}_{perimeter\ units} = c_w \rho_w \dot{V}_w \left(T_{w,s} - T_{w,r}\right) - \dot{Q}_{AHU_coil} \tag{8}$$

While the first term represents the total heat supplied to the building section through the hydronic loop, the second term is the AHU heating coil power from Eq. (5). Eq. (8) is based on enthalpy difference and depends on 6 air-side and water-side sensors, which increases uncertainty while being less scalable. Moreover, (Darwazeh et al., 2021) proposed a multi-linear regression (MLR)

model to calculate heating power in each perimeter unit group; the authors highlighted that the model error increases with the number of perimeter units. This approach was tested in this case study and heating power is calculated as follows:

$$\dot{Q}_{perimeter\ units} = \sum_{i=1}^{n} (a_i X_i) + e \tag{9}$$

where X_i is the valve position of each individual group. Coefficients a_i are calibrated using Eq. (8) and e is the error. Although Eq. (9) requires Eq. (8) for calibration, its advantage is its ability to disaggregate total energy use into individual groups, enabling additional distribution insights.

2.7 Other parts of the Sankey diagram

The remaining sections of the Sankey diagram are derived from energy conservation principles. The heating energy supplied to the AHU and perimeter units comes from a dual energy heating system, composed of electric and natural gas boilers. It is worth reminding that the Sankey diagram only covers a single section of the entire building.

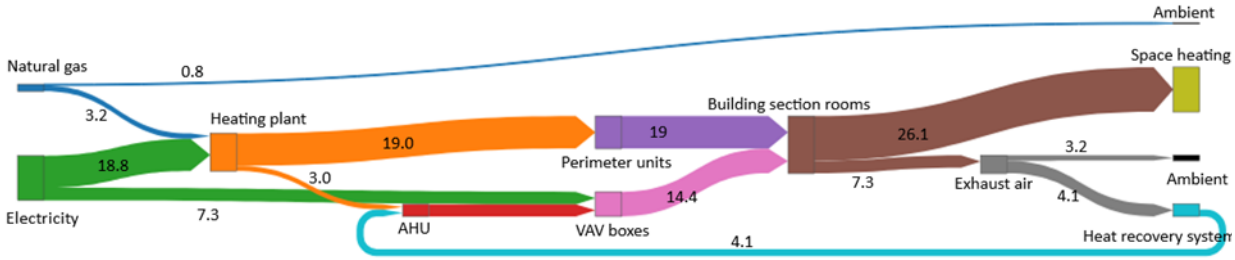

Figure 2. Sankey diagram of thermal energy flows for the case study building in winter (units: MWh/season)

3. ENERGY USE ANALYSIS AND VIRTUAL ENERGY METER COMPARISON

3.1 Sankey diagram

The Sankey diagram provides a detailed visualization of energy flows (average values calculated from three winter seasons) for the building section, showcasing the interactions between primary energy sources, heating plant, and building systems. Heating energy is distributed through perimeter units, AHUs and electric reheat coils in VAV boxes. The AHU and VAV boxes supply 14.4 MWh/season of heat, with 4.1 MWh/season from the heat recovery system, reducing by 58% the AHU heating coil contribution (3.0 MWh/season). While the AHU operates only during occupied hours (33% of the time), perimeter units are continuously in operation to maintain indoor air temperature setpoints and supply 57% of the whole heating demand (19 MWh/season). Only 3.2 MWh/season is associated with ventilation losses, an amount that could have reached 7.3 MWh/season without a heat recovery system. The Sankey diagram underscores the importance of space heating and the added value of heat recovery system for improving building performance.

3.2 Hourly heating usage distribution

Fig. 3 shows the hourly average distribution of heating among the different heating sub-systems. The heating demand on weekdays shows a morning peak (particularly during 6:00-9:00), which is mainly caused by the transition from nighttime to daytime conditions. On weekends, heating demand is predominantly from perimeter units, with no contribution from the AHU and VAV

boxes, as they remain inactive. As shown in Fig. 4 (left), the heat recovery system reduces heating demand by 12%, contributing only during AHU operation and being particularly effective from mid-morning to early afternoon. While the heat supplied to the building and the heat losses due to ventilation have been calculated, other energy terms related to space heating –heat losses through the envelope, solar gains, internal heat gains from plug loads and occupants, and room conditioning (indoor temperature variations)– cannot be easily separated. They would require additional modelling with potential challenges in terms of model structure (e.g. Resistance-Capacitance thermal network; electric load disaggregation) and accuracy, which is beyond the scope of this paper. However, Fig. 4 (right) still provides valuable insights. By comparing nights (22:00 to 4:00) and working hours (9:00 to 16:00) when indoor temperature remains rather constant, space heating is notably lower during the day despite higher room temperatures, which could be attributed to higher solar gains and internal gains (equipment, occupancy), coupled with reduced temperature differences between indoor and outdoor environments. In turn, the morning peak is mainly driven by the heating demand required to increase indoor temperatures to meet daytime conditions.

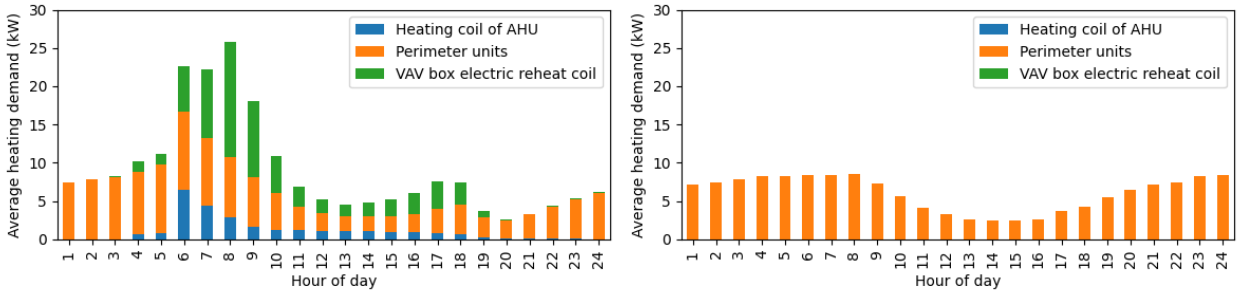

Figure 3. Hourly average heating demand provided by the different heating sub-systems against hour of day: on weekdays (left) and weekends (right)

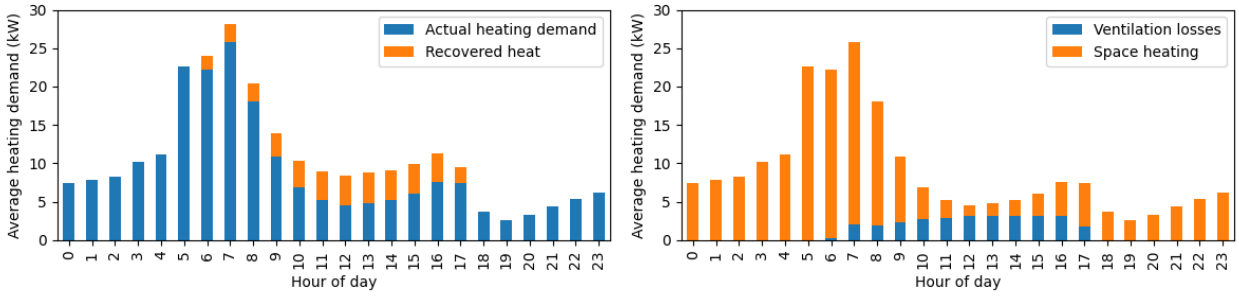

Figure 4. Hourly average distribution against hour of day: actual heating demand vs recovered heat (left) and ventilation losses vs space heating (right)

3.3 Comparison between different methods

Instrumentation level, sensor quality, and operational scenarios vary from one building to another, and several VEMs could be used to cross compare results for a given variable and to validate and increase confidence in the approach. The diversity of VEMs ensures adaptability in different contexts while enhancing robustness and reliability. Eqs (1)-(2) estimate fresh air flow rate, which is critical for virtual energy metering of heat recovery system and ventilation losses. According to the control sequence document, the fresh air flowrate is set at 400 L/s. Using Eq. (1), an average value of 398 L/s is obtained (95% of the data is among 350-450 L/s) and is consistent with the control sequence document. However, although successfully applied in previous studies, Eq. (2) shows significant discrepancies, which may be attributed to the uncertainty of temperature sensors

while the fresh air flow rate is rather low (~25%) compared with supply air flow rate. In previous studies, this ratio could be 80% (Cotrufo and Zmeureanu, 2018). Fig. 5 shows the uncertainty of Eqs (1)-(2) with bias errors of ± 0.45°C for temperature and ± 5% of the mean value for flow rate, and highlights the limitations of using Eq. (2) under specific operational conditions.

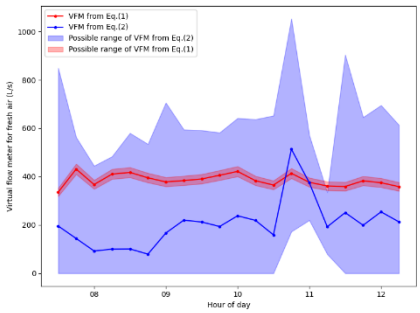

Figure 5. Comparison between VFM from Eq. (1) and Eq. (2)

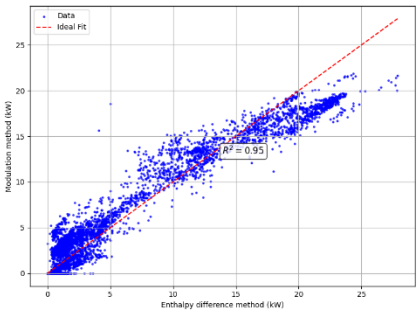

Figure 6. Enthalpy difference method vs modulation method for VAV box electric coils

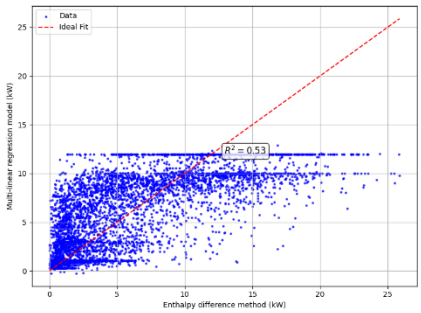

Figure 7. Enthalpy difference method vs. multi-linear regression model for perimeter units

For VAV box electric reheat coils, Fig. 6 compares estimates using the modulation method (Eq. (7)) and the enthalpy difference method (Eq. (6)), and demonstrates strong agreement between both methods, with an R^2 score of 0.95, indicating a high degree of similarity. This suggests that both methods are effective for estimating aggregate power consumption across all VAV boxes. However, when examining individual coils, the errors can be more significant, highlighting the need for further investigation into the sources of discrepancies. Understanding and addressing these errors will improve the reliability of the methods for more granular energy modelling.

Finally, Fig. 7 compares the results from Eq. (8) and Eq. (9) for perimeter units, revealing a weak correlation with an R^2 score of 0.53. It is worth reminding that Eq. (9) has been calibrated with Eq. (8). While the model demonstrated good performance in (Darwazeh et al., 2021), its practical application in this case study shows significant discrepancies. (Darwazeh et al., 2021) applied their method to 3-15 perimeter units but they acknowledged that the model performance rapidly declines with the number of perimeter units. This case study has 29 perimeter units, which may explain the loss of model accuracy. Furthermore, in (Markus et al., 2025), the assumption of linear relationship between perimeter unit power and valve position, may result in an overestimation of heat output, which is also observed here (MLR shows higher results 60% of the time). Finally, Eq. (8), which was used to calibrate Eq. (9), depends on six air-side and water-side variables, which also increase uncertainty. This comparison underscores the need for further model refinement or alternative approaches for such systems, especially in situations where there is a lack of instrumentation.

3.4 Opportunities highlighted by virtual energy meters

Through the case study presented, Virtual Energy Meters (VEMs) demonstrate significant potential for improving building energy performance and operational efficiency. During the morning peak on weekdays, 34% of the heating load comes from electrical reheat coils, a reliance that could be optimized through AHU heating coil supply temperature setpoints, particularly during demand response events and depending on the central heating plant equipment (boilers vs. heat pumps). For ventilation, VEMs reveal opportunities for energy savings by adjusting ventilation rates based on actual occupancy instead of nominal values. This adjustment could save 1.4-1.8 MWh/winter, equivalent to 80-103 $/winter (0.24-0.32 $/m^2), and 61-80 kg$CO_{2eq}$/winter

(0.18-0.24 $kgCO_{2eq}/m^2$), numbers rather low due to the heat recovery system. Additionally, VEMs allow to quantify the impact of heat recovery systems in reducing ventilation-related losses; savings of 188 \$/winter (0.56 $\$/m^2$), and 141 $kgCO_{2eq}$/winter (0.42 $kgCO_{2eq}/m^2$) are achieved in this case study. Furthermore, VEMs could play a critical role in fault detection and diagnostics by comparing outputs from different methods to identify sensor errors or equipment malfunctions. These insights highlight the potential of VEMs for making informed decisions, improving efficiency, and advancing sustainable building practices.

4. CONCLUSION AND FUTURE WORK

This work demonstrates the potential of applying virtual energy meters for typical heating systems in commercial and institutional buildings. Insights gained from virtual energy meters provide a comprehensive understanding of energy usage and losses within the building, which can be used for designing more efficient HVAC operations. These calculations help quantify energy-intensive components and identify opportunities for optimization, ensuring that energy usage aligns with actual occupancy and operational needs. Future work includes the improvement of existing models, the testing of new methods, extending the analysis to the whole building and replication to other buildings, equipped with different heating and cooling systems.

SUMMARY
Rapid urbanization has led to compact cities with vertical structures and complex configurations. The urban wind environment (UWE), shaped by urban morphology, influences building energy consumption, yet current building energy simulation (BES) tools cannot fully account for its impact. This study examines how urban configuration affects energy performance in a mid-rise district in Amman, Jordan. A target building was analysed within five sub regions, each with distinct physical characteristics. Computational Fluid Dynamics simulations measured wind velocity, pressure coefficients, and convective heat transfer coefficients (CHTC) around the building. These data were integrated into DesignBuilder 7.3 to assess UWE's impact on energy performance. The findings show a significant discrepancy in measured wind velocity (up to 1.73 m/s) and CHTC values across zones, demonstrating the built environment's effect on UWE. Comparing the base case (without CHTC) to scenarios with CHTC revealed discrepancies of up to 49%, emphasizing urban morphology's role in energy demand.

Keywords: Urban wind environment, Building energy performance, Urban configuration, Computational Fluid Dynamics (CFD).

1. INTRODUCTION

Rapid urbanization has transformed natural landscapes into densely built environments, creating compact cities with high-density buildings that significantly impact the urban microclimate (Bhalindar Singh, 2020). These dense cityscapes disrupt wind flows, reduce ventilation, and create turbulent air patterns, affecting pedestrian comfort, air quality, and pollutant dispersion (Al Labbad et al., 2022, Xia et al., 2015). Urban microclimates significantly influence building energy performance (BEP) by affecting ventilation, infiltration, and convective heat transfer across building surfaces (Pfafferott et al., 2021, Mirzaei, 2022). The convective heat transfer coefficient (CHTC), which measures the heat exchange between a building's exterior and the surrounding air, is shaped by factors such as wind speed, direction, and temperature differences air (Xue et al.,

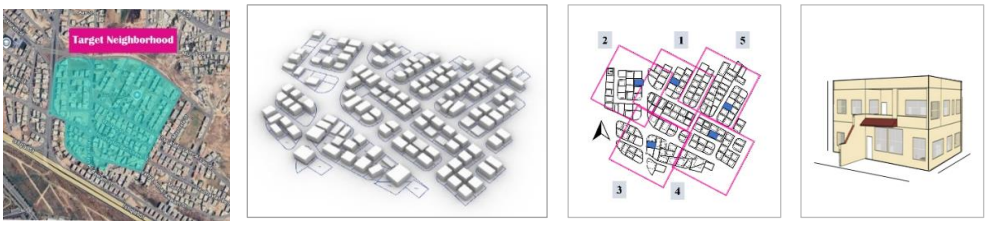
2022; Yang et al., 2017). Additionally, variations in wind pressure influence infiltration and natural ventilation, which in turn affect heating and cooling demands (Cóstola et al., 2009; Younes et al., 2012). Other microclimate elements, including the urban heat island effect, greenery, wind-driven rain, and pedestrian wind comfort, also contribute to energy consumption in buildings (Kubilay et al., 2018; Li et al., 2019; Priya & Senthil, 2021). Although the influence of microclimate on BEP is well-documented, current Building Performance Simulation (BPS) tools typically rely on generic meteorological data, often overlooking localized urban conditions, resulting in significant inaccuracies in energy assessments (Hadavi & Pasdarshahri, 2021b, Pei et al., 2023). A promising approach to integrating urban microclimate into BEP analysis is the coupling of computational fluid dynamics (CFD) with BPS tools (Bouyer et al., 2011). This integration can be performed through one-way coupling, where either BPS data informs CFD simulations (Type A) (Hadavi & Pasdarshahri, 2021b) or vice versa (Type B) (Brozovsky et al., 2022), or through two-way dynamic coupling (Type C) (Zhang & Mirzaei, 2021b, Zhang & Mirzaei, 2021a), which provides higher accuracy but is computationally intensive. Several studies have successfully used CFD-BPS coupling to enhance urban energy simulations (Shirzadi et al., 2019b, Gobakis & Kolokotsa, 2017). Other studies have used CFD to compare standard weather data with localized microclimate data, highlighting substantial variations in energy consumption predictions (Kyriakodis et al., 2019). Additionally, research has examined how urban form influences microclimate and energy demand, showing that factors like urban density, building orientation, and vegetation can mitigate cooling loads (Brozovsky et al., 2022; Javanroodi & Nik, 2019). Despite advances in CFD-BPS coupling, challenges remain, including high computational costs, complex modelling requirements, and limited experimental validation datasets (Mirzaei, 2021). Many studies rely on simplified models that fail to capture the full complexity of urban environments, and large-scale research integrating CFD-based microclimate data into BPS remains limited. This research aims to systematically address the building energy performance gap related to their surrounding wind environment. A densely populated neighbourhood in Amman, subdivided into five distinct zones, serves as the case study. By situating an identical reference building in each zone, the research investigates how urban morphology shapes microclimatic conditions and energy consumption. Validated CFD simulations will be employed to evaluate wind flow patterns and surface pressure coefficients, which will then be incorporated into Design Builder for energy modelling.

2. METHODOLOGY

This study examines a high-density urban district in Amman, subdivided into five zones with distinct morphological characteristics, including variations in density, block arrangement, height-to-width ratios, and occupied area. A representative building, reflecting the district's predominant typology, was placed at the center of each zone to assess the impact of urban form on wind behavior and energy performance. CFD simulations were conducted for eight wind directions and three wind speeds (maximum, minimum, and median) based on Amman's meteorological data. Wind velocity was measured at 256 points along four logging axes positioned two meters from the building façades, while additional parameters such as Cp and CHTCs were recorded. The results were integrated into Design Builder Version 7.3 for BPS, quantifying the impact of urban wind environments on energy performance by evaluating how urban configurations influence local wind conditions and building energy consumption.

2.1. Case Study Area

This study focuses on Basman, a densely populated district in central Amman, located about 5 km from the city's official meteorological station in Marka. Positioned at latitude 31.96° N and longitude 35.95° E, Amman experiences high solar radiation, with around 320 sunny days annually (Alrwashdeh, 2021). The city's climate is characterized by hot, dry summers (28–32°C) and cool winters with occasional snowfall (UN-Habitat, 2022). The case study area is Basman, spans 141,424 m, and has a predominantly northeast orientation. It consists of 132 residential blocks with building heights ranging from 4 to 16 meters. Buildings range from those built in the 1980s to recent constructions in 2024, with stone as the main material. The study area was divided into 200×200 meter zones to analyze the impact of urban morphology on wind dynamics and building performance. These zones were selected to minimize overlap while capturing key physical variations (Fig. 1).



(a) (b) (c) (d)

Figure 1. a) The map of target neighbourhood, b) perspective of target district, c) location of five sub regions, d) two-story target building

A representative building, reflecting the district's common architectural features, was placed in each zone to assess how different urban configurations influence wind behavior and energy performance. One the buildings in each zone was selected randomly and replaced by representative building. Building configurations and simulation settings are presented in Table 1.

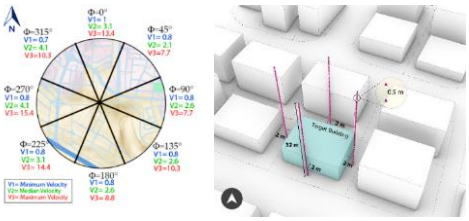
Table 1. Building energy simulation settings

Building characteristics	Location	Function	Building Area (m^2)	Occupancy density ($People/M^2$)
	$N31°58'23.28$, $E35°56'28.78$		450	9 persons, 0.0156
Envelope Properties	Infiltration (ac/h)	R ($m^2\,K/W$)-Wall	U (W/m^2K)-Wall	U (W/m^2K)-Roof
	1.2	0.473	2.11	1.02
Systems & Operations	HVAC Systems	Heating set point-set back (℃)	Cooling set point/ set back (℃)	Internal Heat Gains (w)
	Direct Expansion (DX) systems	21/12	25- 27	2,897

2.2. CFD-BPS Coupling

This study adopts a one-way coupling approach (Type B) to examine how urban microclimate affects building energy performance by integrating CFD (ANSYS Fluent 2022 R1) with Design Builder Version 7.3. The CFD outputs serve as inputs for Design Builder Version 7.3 to assess the energy demand of the target building in the hottest day. Simulations were conducted for eight wind directions and three wind speeds, determined from meteorological data spanning the past decade. Additionally, steady-state simulations were performed for the four prevailing wind directions. Microclimate conditions were recorded along vertical lines positioned near the building façades, with logging points capturing wind speed variations (Fig. 2). The collected data were used to

generate weather files for energy simulations. Key parameters, including pressure coefficients (Cp) and convective heat transfer coefficients (CHTC) for all façades and the roof, were analyzed, and floor-by-floor pressure distributions were calculated. These results were then integrated into Design Builder for a comprehensive energy performance evaluation.



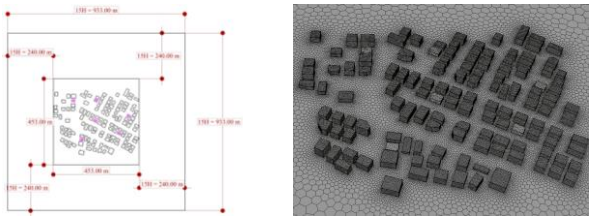
(a) (b)

Figure 2. (a) Minimum, median and maximum windspeed from eight directions in Amman city, and (b) location of logging points around the target building

3. CFD SIMULATION SETTINGS

3.1. Computational Domain and Grid

Fluid flow characteristics were analyzed across various scenarios, ensuring residual errors remained below the threshold. Average pressure coefficients and convective heat transfer rates were determined for each building surface under four wind directions. The urban district was modeled at Level of Detail 1.0 within a 453m × 453m grid. Following COST and AIJ guidelines, the CFD domain extended 15 times the tallest building (H = 16m) on each side, resulting in a 933m × 933m × 255m domain. The polyhedral grid contained 1,190,976 cells, with skewness and non-orthogonality below 0.5 (Fig. 3).



(a) (b)

Figure 3. (a) Case study domain size, b) grid of case study area

3.2. Grid Sensitivity Analysis

A grid independence study with three mesh sets was performed using the Grid Convergence Index (GCI). According to the results, the GCI results for the level 2 refinement grid were below 5%, aligning with previous research recommendations. A wind speed ratio comparison across different mesh refinement levels revealed significant differences between level 1 and levels 2 and 3. However, the discrepancy between levels 2 and 3 was minimal, indicating that further refinement would provide only marginal improvements. Consequently, level 2 mesh settings were selected for data generation (Table 2).

Table 2. CGI value for different mesh refinement levels

level of refinement	Number of Cells	r value	CGI For pressure field	CGI For velocity field
1	606,901	1.25	1.80%	6.00%

2	1,190,976	1.25	1.40%	4.43%
3	2,346,433	-	-	-

4. RESULTS

The research results are divided into two phases. The first phase presents CFD simulation outcomes, including wind velocities, wind speed at building height, CHTC, and Cp for the main facades across five urban zones. The second phase focuses on the energy simulation results for the target building.

4.1. Wind Behavior Comparison

Wind speed was measured at 7.11m on five 7m buildings to evaluate urban impacts on wind flow. Figure 4 shows the significant influence of surrounding structures, with notable velocity differences across wind directions. For example, in the North wind direction (D1), wind speeds at the West logging point ranged from 1.83 m/s to 0.10 m/s, a discrepancy of 1.73 m/s (1730% difference). Likewise, at the South logging point, wind speeds ranged from 0.15 m/s to 0.92 m/s, showing a discrepancy of 0.70 m/s (513.33% difference). In the East wind direction (D2), the South logging point exhibited the greatest difference of 0.72 m/s, ranging from 0.81 m/s to 0.09 m/s. For the South wind direction (D3), wind velocities at the South logging point varied significantly, with a maximum of 1.61 m/s and a minimum of 0.18 m/s, yielding a discrepancy of 1.43 m/s (794% difference), while the East logging point displayed a 0.44 m/s difference. Lastly, in the West wind direction (D4), the East logging point showed wind speeds between 0.22 m/s and 0.56 m/s, with a discrepancy of 0.34 m/s (154% difference), while the West logging point ranged from 0.15 m/s to 0.63 m/s, showing a 0.48 m/s discrepancy (320% difference). These findings emphasize the considerable influence of urban form on wind behavior, with some discrepancies exceeding 1700%, highlighting the critical importance of considering the urban context in wind flow analyses.

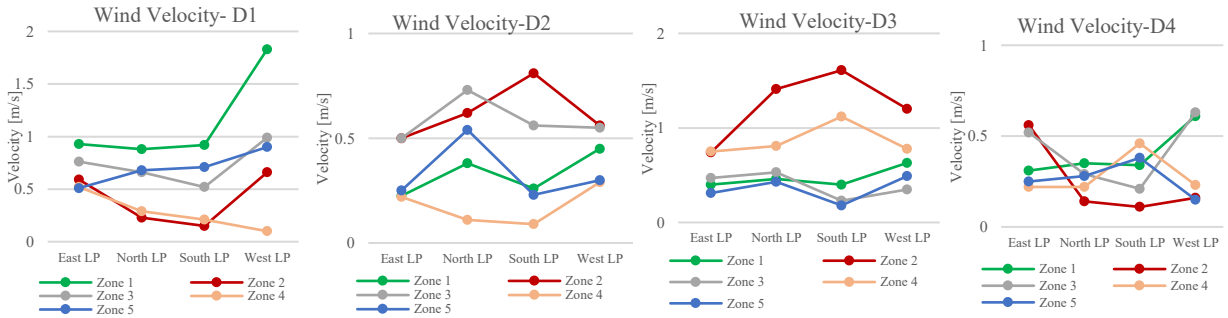


Figure 4. Velocity at logging points at the height of target buildings in five zones for four wind directions

4.2. CHTC and Cp Variations Across Facades

Measured values of CHTC on the facades are illustrated in Figure 5. These results indicate that across all wind directions and for each of the five facades, the "Isolated" scenario persistently exhibits the highest CHTC values. This pattern arises due to the absence of adjacent structures, which allows uninterrupted wind flow around the building. Consequently, elevated wind velocities enhance convective heat transfer rates across all surfaces. The magnitude of this effect is particularly striking in certain cases. For instance, under the north wind condition (D4), the western facade experiences the most pronounced discrepancy, with a CHTC of 16.63 W/m²·K in the "Isolated" case, compared to just 5.12 W/m²·K in Zone 5—an increase of 224.80%. Even within the urban setting, disparities in CHTC values across various zones highlight the crucial role of

environmental parameters. For example, under the west wind direction (D4), the western facade exhibits CHTC values ranging from 5.12 W/m²·K to 11.60 W/m²·K, reflecting a variation of 126.56%. These discrepancies stem from factors such as urban configuration, building density, and the spatial distribution of adjacent structures, all of which modulate local wind patterns and, in turn, surface heat dissipation. Examining the influence of facade orientation in relation to the prevailing wind direction within each urban zone indicates that the degree of exposure to wind currents dictates the extent of convective heat transfer. Windward facades, directly confronting the airflow, experience heightened wind pressures, leading to intensified heat transfer rates. In contrast, leeward facades and those aligned perpendicular to the wind direction are more sheltered, resulting in diminished wind velocities and consequently lower CHTC values. Additionally, the roof consistently registers higher CHTC values than vertical facades, as it remains fully exposed to wind flow across all wind conditions, thereby facilitating greater thermal exchange. These findings emphasize that, beyond the influence of urban morphology, facade orientation is a fundamental determinant in the spatial distribution of CHTC across the building envelope (Fig. 5).

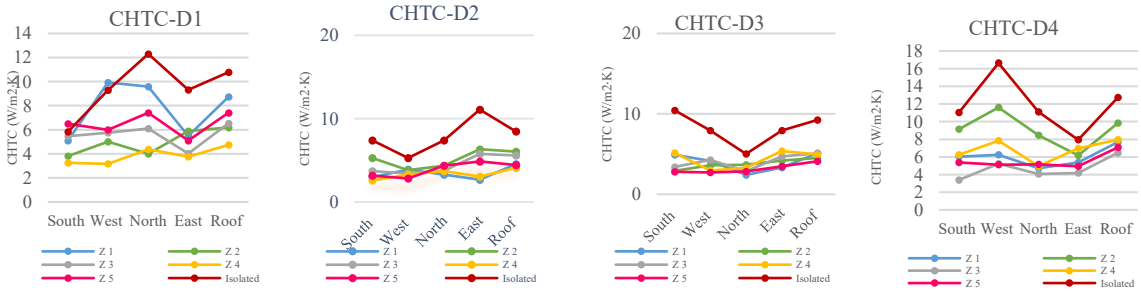

Figure 5. CHTC values on the four facades of the target building across five zones for four wind directions

4.3. Building Energy Consumption

It has been demonstrated that the built environment and urban configurations influence wind conditions, leading to variations in CHTC and Cp. These variations affect the heat exchange rate and natural ventilation potential of buildings, ultimately impacting overall building energy consumption. To assess the impact of urban context on building energy consumption, CHTC and Cp values obtained from CFD simulations are integrated into energy simulations in Design Builder, and the results are compared. The target building is a two-story residential building.

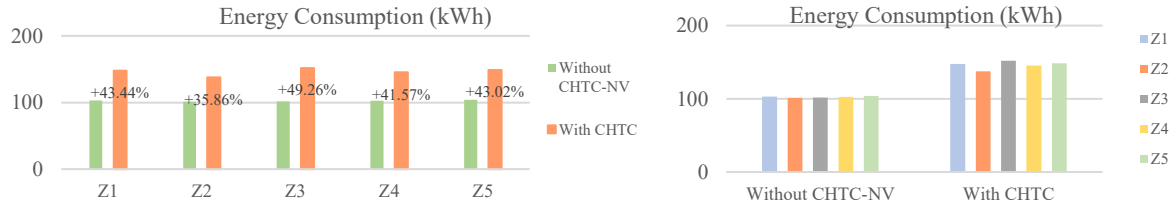

Figure 6. Energy consumption of the target building in July 28, 2016

The above chart illustrates energy consumption over a 12-hour period (8 AM to 8 PM) on the hottest day of the year, July 28, 2016. In these simulations, CHTC obtained from CFD wind simulations were applied to all five building façades within Design Builder. The results demonstrate a significant difference in energy consumption when CHTC values are considered compared to when they are ignored. In conventional energy simulations that do not account for the surrounding environment, the predicted energy consumption is considerably lower. However, incorporating the urban context and CFD-derived CHTC values leads to a substantial shift in

simulation results. Notably, the scenario where only ventilation heat exchange with the environment (CHTC) is accounted for exhibits the highest energy consumption. In some cases, the discrepancy between this scenario and the baseline reaches up to 49%. Furthermore, when comparing energy consumption among target buildings located in five different zones under similar conditions (with and without CHTC), notable differences emerge. In the absence of CHTC, variations in energy consumption are minimal and primarily influenced by differences in building orientation and rotational angles relative to geographic north and south. However, when CHTC is considered, the same buildings with identical characteristics exhibit significant differences in energy consumption due to variations in their surrounding urban configurations. A comparison of different zones reveals that the target building in Zone 2 experiences the lowest energy consumption, while the target building in Zone 3 shows the highest energy demand.

5. CONCLUAION

In conclusion, this study highlights the significant impact of urban morphology on the UWE and building energy performance, particularly in densely populated, high-rise urban areas. Through a comprehensive analysis of various urban configurations in a case study from Amman, Jordan, this research underscores the need for a more nuanced approach to urban design that incorporates the effects of UWE on energy consumption. The CFD with BPS tools, such as Design Builder, has provided valuable insights into how urban form, including building density, block proportions, and spatial layout, influences wind behavior and natural ventilation. The findings demonstrate that modifications in urban design, such as changes in building proportions and configurations, can significantly alter convective heat transfer, wind pressure, and ventilation patterns, leading to variations in heating and cooling demands. The results indicate that urban microclimate factors, often overlooked in conventional energy performance simulations, play a crucial role in shaping energy consumption patterns. This study reveals that localized microclimate data, when incorporated into building energy simulations, can significantly improve the accuracy of energy performance assessments. The coupling of CFD and BPS tools, though computationally intensive, offers a promising pathway to more accurate, site-specific energy simulations.

SUMMARY
Energy disaggregation is a critical tool for improving energy efficiency in building management, yet most current methods focus on single buildings with submeter data, leaving a gap in scalable solutions for large building portfolios using only bulk meter data. This research addresses that gap by developing a model to disaggregate electricity consumption across a portfolio of buildings. Using the ASHRAE Kaggle dataset, which includes extensive building metadata (e.g., primary use, square footage, year built, floor count) and weather features (e.g., air temperature, wind speed, cloud coverage), we incorporate time-series features data and explore eXtreme Gradient Boosting (XGBRegressor) to enhance the model's ability to generalize to unseen building portfolios. Submeter data will be used for evaluation, ensuring accuracy and robustness in disaggregation. This approach aims to provide actionable insights for energy optimization at scale, paving the way for better-informed policy decisions and improved energy management practices.

Keywords: Energy disaggregation, Building Portfolio, Submetering, Regression-based model.

1. INTRODUCTION

In the quest for sustainability, enhancing energy efficiency in buildings has become a critical objective for both policymakers and facility managers. A key strategy in achieving this goal is energy disaggregation, which involves breaking down total energy consumption into its components. This allows for targeted interventions that can significantly reduce energy waste. However, the current methods for energy disaggregation primarily focus on individual buildings with detailed sub-meter data, leaving a substantial gap when it comes to applying these techniques across larger portfolios of buildings that rely solely on bulk meter data.

Non-intrusive load monitoring (NILM) methods have become increasingly popular for their capability to break down energy consumption by specific appliances, promoting better energy management and possible cost reductions. These techniques have primarily been applied within residential buildings, mainly because household appliance data is easily accessible and there are several public datasets available. Although NILM has been effective in residential areas, implementing these techniques in large office buildings is notably challenging. This is due to restricted access to data

and the significant differences between residential, office, and industrial sites (Adabi et al., 2015; Yaniv and Beck, 2025).

The potential benefits of implementing disaggregation techniques in large buildings are significant, both economically and environmentally. Many buildings spend thousands of dollars or more annually on electricity and are often required by regulations in various countries to reduce their energy consumption. Beyond financial savings, large buildings represent a major share of global energy use, so even small gains in energy efficiency facilitated by disaggregation insights can lead to considerable reductions in carbon emissions. This underscores the importance of industries in sustainable development and environmental protection (Calvo et al., 2021).

The behavior of heating/cooling systems, lighting plug loads, and appliances is quite different from that of household devices. Large office and commercial buildings host a wide array of equipment, while household appliances typically fall into a few standard categories such as ovens, toasters, and air conditioners. Additionally, the operation of some industrial machines can be highly complex compared to the relatively simple functions of most home appliances. The operational schedules in this sector are distinct as well; while residential electricity usage follows predictable patterns based on time of day, weekends, seasons, and holidays, industrial operations often adhere to specific shift schedules, requiring coordination with shift managers to understand each facility's timetable.

Federal buildings, which often lack comprehensive sub-metering systems, highlight the challenges associated with bulk meter data. These buildings frequently have either no sub-meter data or data that is riddled with gaps and inaccuracies. Even when available, sub-meter data typically spans only a limited timeframe, such as a year or less, which impedes effective long-term energy management. This lack of detailed data prevents energy managers from accurately identifying inefficiencies and implementing improvements on a broader scale.

Disaggregation techniques play an important role in optimizing energy consumption in buildings. These methods, categorized into supervised and unsupervised approaches, offer valuable alternatives for different data availability scenarios. In supervised methods, optimization algorithms are utilized, but their main drawback is the requirement of a labeled dataset (e.g., refrigerator, air conditioner, washing machine). Acquiring labeled data can increase the setup costs of NILM systems, making unsupervised methods more favorable in some cases (García et al., 2018). Using an unsupervised disaggregation method, García et al., 2018, presented an interactive web tool for exploring NILM results. Using non-negative matrix factorization (NMF) methods, it analyzes power demand data from a hospital complex. The tool integrates user knowledge through visual analytics, allowing expert users to interpret NMF components and identify demand patterns and inefficiencies. In a previous study presented by Brucke et al., 2020, a fully unsupervised approach using particle swarm optimization was introduced for energy disaggregation. However, its application was limited to power data from two industrial consumers, making comparisons with other research challenging.

Zaeri, Ashouri, et al., 2022, proposed a regression-based approach using BAS trend data to disaggregate heating and electricity consumption in commercial buildings. This method, which employs genetic algorithms and least-square solvers, demonstrated its accuracy using data from an

academic office building in Ottawa, Canada. Additionally, A. A. Narges Zaeri Esfahani B. G. and Rizvi, 2023; Zaeri, Gunay, et al., 2022 investigated the impact of submeter density and configuration on disaggregation accuracy, highlighting critical factors for optimizing submeter deployment in commercial buildings. Moreover, H. B. G. Narges Zaeri Esfahani A. A. and Bahiraei, 2024 proposed a time-series decomposition-based method for unsupervised energy disaggregation, which was validated using submeter data from ten office buildings. This method provides insight into lighting and thermal scheduling variations at different temporal scales.

The limitation of current energy disaggregation methods in addressing large-scale applications creates a significant knowledge gap. Traditional models require granular data inputs that bulk meters do not provide, making it difficult to derive actionable insights for large building portfolios. This gap underscores the need for innovative approaches that can leverage existing bulk meter data to provide meaningful energy usage breakdowns.

Driven by these challenges, our research seeks to bridge this gap by developing a scalable model capable of disaggregating electricity consumption across multiple buildings. Using the ASHRAE Kaggle dataset, which includes extensive metadata and weather features, we employ eXtreme Gradient Boosting (XGBRegressor) to enhance the model's generalization to unseen building portfolios. By evaluating the model against available sub-meter data, we ensure its accuracy and robustness, providing a reliable tool for energy optimization. Our approach not only addresses the immediate data availability issues but also aims to transform how energy consumption is managed across large building portfolios. By providing more precise insights, this model supports better-informed policy decisions and improved energy management practices, contributing to the overarching goal of sustainability in the built environment.

Through visual representations, users can easily spot anomalous values, detect malfunctioning or poorly commissioned systems, and observe energy consumption patterns. This visualization-based approach enhances the ability to analyze and interpret energy data, enabling more effective decision-making and interventions to optimize energy usage within buildings (Meyers et al., 1996).

2. METHODOLOGY

In this paper, we developed five separate XGBoost regressors, one for each building use portfolio, leveraging bulk meter data, weather data, and time-series characteristics of the bulk meters. Each model is trained on a complete year of data for a given building, and subsequently, the models can be saved and used to predict missing or faulty submeter data during other time periods. Additionally, we performed feature importance analysis to identify the most correlated predictors, helping to understand the key variables influencing the model's predictions.

2.1. Portfolio disaggregation model

2.2. XGBRegressor

We selected the XGBoost model due to its capability to handle complex, non-linear relationships and its robustness against overfitting. XGBoost provides insights into feature importance, which is valuable for understanding the factors influencing energy consumption. XGBoost is an ensemble learning method based on decision tree algorithms. It utilizes gradient boosting to optimize the predictive power. The model iteratively improves by minimizing the objective function, which is

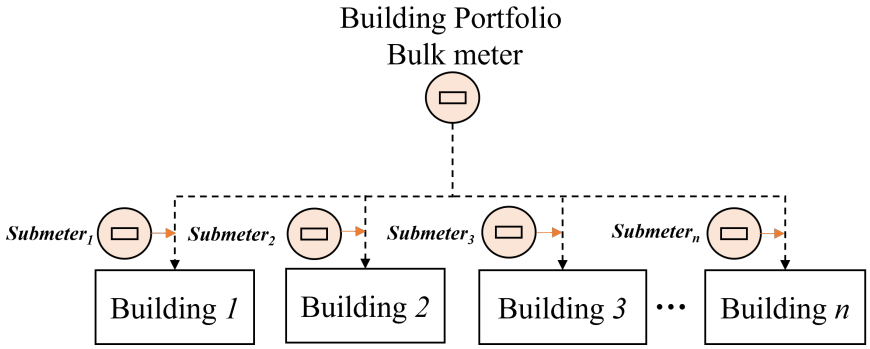

Figure 1. Example of figure.

composed of a differentiable loss function and a regularization term. The model can be mathematically described as follows:

$$L(\phi) = \sum_{i=1}^{n} l(y_i, \hat{y}i) + \sum k = 1^{K} \Omega(f_k) \tag{1}$$

where $L\phi$ is the overall objective function, l is a differentiable loss function measuring the difference between the prediction $\hat{y}_i$ and the true value y_i, and $\Omega(f_k)$ is a regularization term that penalizes the complexity of the model. The regularization term can be expressed as:

$$\Omega(f) = \gamma T + \frac{1}{2}\lambda \sum_{j=1}^{T} w_j^2 \tag{2}$$

where γ and λ are hyperparameters controlling the model complexity, T is the number of leaves in the tree, and w_j is the weight of leaf j.

The model was implemented using the XGBoost library in Python. We conducted extensive hyperparameter tuning to optimize performance, focusing on parameters such as the learning rate, maximum tree depth, and number of estimators. The input data was preprocessed to handle missing values and normalize features.

2.3. Case study and dataset

The ASHRAE Great Energy Predictor III competition dataset is a comprehensive collection used to advance machine learning methodologies for predicting energy usage in buildings. It includes over 20 million data points from 2,380 energy meters across 1,448 buildings, collected from diverse sites worldwide (Miller et al., 2020). The dataset provides three years of hourly meter readings and is instrumental in developing counterfactual models that predict energy consumption without retrofits. This allows for the calculation of energy savings post-retrofit, supporting better market incentives and reducing financing costs by demonstrating the value of energy efficiency improvements. For this study, we focused on a case study involving five buildings from this dataset, all

located at site_id 14. By selecting buildings within the same region, we ensured similar weather conditions, which aids in creating consistent and reliable models. These buildings, categorized as either office or education facilities, serve as a practical example of how the dataset can be utilized to develop models that disaggregate electricity consumption. This approach demonstrates the scalability of the models across building portfolios and their potential impact on energy management practices.

2.4. Exploratory data analysis

The analysis of feature importance across various buildings shows that '*total_Elec*' consistently stands out as a significant predictor of electricity consumption. It emerges as the most crucial feature for Buildings 1260, 1251, and 1287, underscoring its role in capturing historical consumption patterns that aid in future predictions. Temporal features such as '*week_of_year*', '*hour*', and '*day_of_week*' also prove important across different buildings, indicating the impact of time-based patterns on energy usage. For instance, '*week_of_year*' is the leading feature for Building 1296, while '*hour*' is vital for Building 1242. Weather-related features, like '*dew_temperature*' and '*air_temperature*', although less dominant compared to temporal or historical consumption data, modestly enhance the model's predictive power, particularly for Building 1251, where '*dew_temperature*' holds a significant importance score.

To improve model performance, we refined the feature set by removing those with negligible importance, such as *is_weekend*', which consistently show zero importance across all buildings. This simplification can lead to a more efficient model without compromising accuracy, by focusing on the most impactful predictors for energy disaggregation across the portfolio. as in Table 2

Table 1. Selected building portfolio.

building_id	site_id	Primary_use	Square_feet
1242	14	Office	23,871
1251	14	Education	104,604
1260	14	Office	86,455
1287	14	Education	60,582
1296	14	Office	8,836

2.5. Portfolio disaggregation model validation and error calculation

To assess the performance of the energy disaggregation model, we employed two key evaluation metrics: the coefficient of determination R^2 and the Coefficient of Variation of the Root Mean Square Error (CV-RMSE). These metrics provide a comprehensive understanding of the model's accuracy and predictive capability.

The coefficient of determination, R^2, measures the proportion of variance in the observed data that is predictable from the model. It is defined as: $R^2 = 1 - \frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{N}(y_i - \bar{y}_i)^2}$ where y_i is the actual value, $\hat{y}_i$ is the predicted value, and $\bar{y}$ is the mean of the observed values. An R^2 value close to 1 indicates a high degree of correlation between the predicted and actual values. The CV-RMSE quantifies the ratio of the root mean square error to the mean of the observed values, providing a normalized measure of prediction error. It is calculated as: $\text{CV-RMSE} = \frac{\text{RMSE}}{\bar{y}} \times 100\%$ where $\text{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(\hat{y}i - yi)^2}$ and $\bar{y}$ is the mean of the observed values. According to ASHRAE Guideline 14, a CV-RMSE value below 30% is considered acceptable for engineering applications. These metrics were selected for

their ability to provide insight into both the accuracy and reliability of the model's predictions, ensuring a robust evaluation of its performance across different scenarios.

3. RESULTS AND DISCUSSION

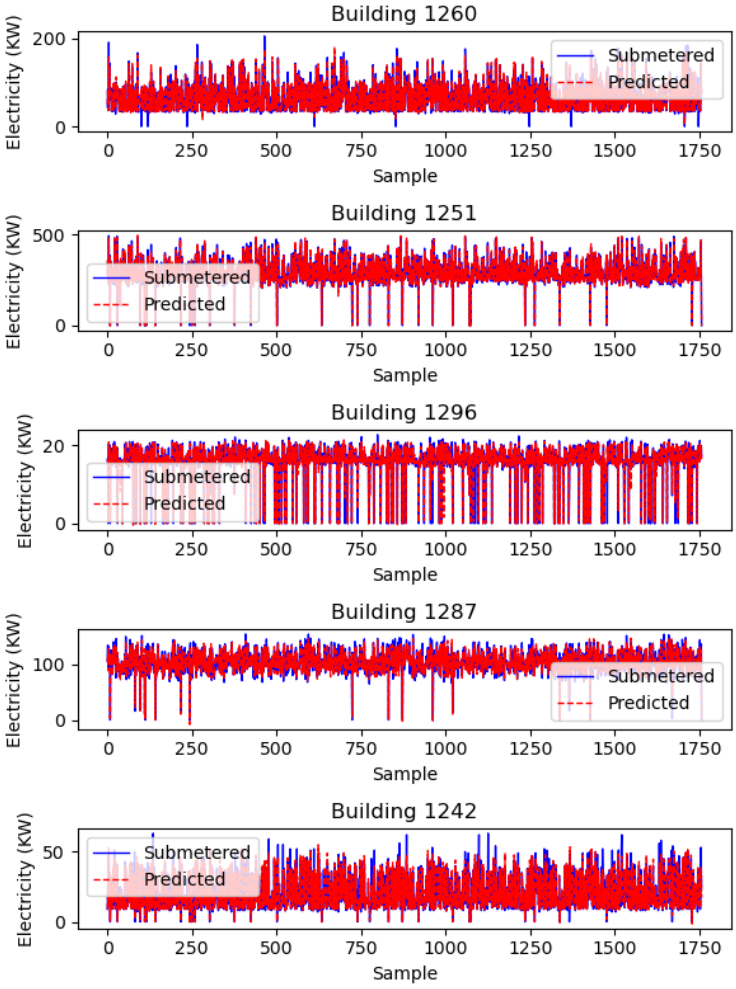

Figure 2. Comparison of submetered and predicted data by models trained with hourly data for electricity.

The XGBoost regressor models were developed and evaluated for five buildings using the features detailed in the methodology section. The performance was assessed using the coefficient of determination R^2 and the Coefficient of Variation of the Root Mean Square Error $CV-RMSE$. These metrics provide a comprehensive evaluation of model accuracy and reliability, consistent with ASHRAE Guideline 14 standards (Guideline, 2014). For Building 1260, the model achieved an impressive $R^2 = 0.94$, indicating a strong ability to capture the variability in electricity consumption. The $CV-RMSE$ was 0.11, well below the ASHRAE threshold, demonstrating excellent predictive accuracy. Feature importance analysis revealed that '$total_Elec$' was the most influential feature, followed by '$week_of_year$' and '$month$'.

In Building 1251, the model showed exceptional predictive capability with an $R^2 = 0.98$. A CV-

Table 2. Performance of the proposed regression models for electricity demand in hourly resolution.

building_id	CV-RMSE	R^2
1242	0.18	0.90
1251	0.03	0.98
1260	0.11	0.94
1287	0.07	0.88
1296	0.09	0.93

RMSE of 0.03 indicates the model's predictions are highly reliable. The model's performance was primarily driven by '$total_Elec$' and '$dew_temperature$', reflecting the impact of both historical consumption and weather conditions on energy use. For Building 1296, the $R^2 = 0.93$ suggests a robust model fit. The CV-RMSE at 0.09 confirms the model's practical applicability. The dominance of '$week_of_year$' highlights temporal patterns as key predictors, with 'day_of_month' and '$total_Elec$' also contributing significantly. The model for Building 1287 showed good performance with an $R^2 = 0.88$ and a CV-RMSE of 0.07, underscoring its accuracy. Here, '$total_Elec$' and '*hour*' were the most significant features, emphasizing the importance of both historical and daily patterns in predicting energy consumption. In Building 1242, the $R^2 = 0.90$ indicates a strong correlation between predicted and actual values. A CV-RMSE of 0.18, although within acceptable limits, suggests potential for further model enhancement. '*hour*' emerged as the predominant feature, signifying the critical role of time-of-day in energy usage predictions.

4. CONCLUSION AND FUTURE WORK

This research represents an improvement in addressing the complexities of energy disaggregation within building portfolios, which often suffer from a lack of comprehensive submetering systems. By utilizing XGBRegressor and the metadata and weather features from the ASHRAE Kaggle dataset, we have developed a model that effectively uses bulk meter data to provide detailed insights into electricity consumption across a portfolio of five buildings. A key achievement of this study is the creation of a robust tool that empowers energy managers with the capacity to identify inefficiencies and make informed decisions, even when granular sub-meter data is lacking. This model bridges a crucial knowledge gap in large-scale energy management and supports the broader goal of sustainability within the built environment. The availability of disaggregated energy data opens up numerous avenues for further analysis. This breakdown allows for enhanced applications such as fault detection and energy anomaly detection using Building Automation Systems (BAS) data. It also facilitates the identification of energy flow disaggregation for each end-use within buildings, providing a foundation for more targeted energy management strategies. Looking ahead, our future work will focus on expanding the model's application to scenarios where sub-meter data is either unavailable or inconsistently available across different portfolios of buildings. We plan to explore the integration of unsupervised learning techniques to further refine the model's ability to disaggregate energy usage at the individual building level. This will enhance the model's flexibility and scalability, making it a valuable asset in diverse energy management contexts. Through these efforts, we aim to not only improve the model's performance but also broaden its utility, contributing to more sustainable and efficient energy management strategies across various building portfolios.

Extraction of carbon emission factors for buildings at meso-scale

Yuanyuan Liu [1], Yan Wu [1,*], Bingyang Zhang [1], Tianle Chen [1]

[1] *Tongji University, Shanghai, China, 2430419@tongji.edu.cn*

SUMMARY
Localized carbon emission factors are crucial for the accurate formulation of carbon emission reduction policies. Aiming at the lack of building carbon emission factors at meso-scale in China, this paper proposes a method for extracting and calibrating the carbon emission factors of building materials and operation applicable to urban meso-scale and building micro-scale, and calculates them with case data. The results of the study show that: (1) the distribution of carbon emission factors of building materials in Chinese provinces and cities is concentrated in the range of 649.56-1317.48 $kgCO_2/m^2$ (2011-2020); (2) electricity consumption (indirect emission) accounts for the highest proportion of carbon emission in operation, and there is a significant difference in the regional differences, e.g., the intensity of indirect carbon emission of healthcare buildings spans from 5.52 to 163.71 $kgCO_2/m^2$; (3) economic level, energy structure and urbanization rate are the main drivers of building carbon emissions.

Keywords: *Carbon emission factor, Meso-scale, Building*.

1. INTRODUCTION

Buildings are an essential component of human social production and life, and are also major consumers of natural resources and contributors to environmental pollution. As the largest construction market in the world, China's carbon emissions from the construction industry account for more than a third of the country's total carbon emissions (Wang et al., 2024; Luo et al., 2016). Carbon emission factor unit of greenhouse gas emissions released by the use of a certain emission source, the extraction of building carbon emission factors can provide scientific support for energy saving and carbon reduction policymaking. Defining the boundary of carbon emission accounting is the first step to start the extraction of carbon emission factors. Currently, scholars have different definitions of the measurement scope for carbon emissions. Zhang and Wang divide the building lifecycle into three phases: materialization, operation, and demolition (Zhang & Wang, 2015). Some researchers split the materialization phase into two stages — production and construction (Cho et al., 2016). Additionally, some studies include the design phase of buildings in the calculation scope (Cui et al., 2019; Shen et al., 2018). In building carbon emission calculations, most researchers focus on measuring the carbon emissions of individual or multiple buildings to identify their main influencing factors (Chastas et al., 2018) or calculate carbon emission factors for building materials (Wang et al., 2024). However, research on carbon emission factors at scales larger than the micro-scale is relatively scarce. Studies have shown that carbon emission factors with localized and regional characteristics are more reflective of a region's carbon emission levels and are more suitable for national contexts. This study divides building carbon emission accounting into building materials, construction, and operation. Given that the carbon emissions during the construction process account for only about 1% (CABEE & Chongqing University, 2023), this study primarily focuses on the carbon emissions from building materials and operations. Based on existing research results, this study proposes a

method for calculating the carbon emission factors of building materials and operations applicable to the urban meso-scale and building micro-scale. It calculates carbon emission factors for building materials and operations that are more localized characteristic, using available data. The composition and distribution characteristics are analyzed to identify the causes of the emissions and to summarize the influencing factors.

2. METHOD

2.1 Carbon Emission Factors for Building Materials

Considering that the current carbon emission factors for building materials are generally micro-product level building materials factors that cannot measure the carbon emissions generated by the production and transport of building materials in a region, this study proposes a method for calculating the building materials factors at the city level, which is also applicable to the micro-architectural level.

The carbon emissions from building materials should include the production and transportation stages. The carbon emission factor calculation formula is shown in Eq. (1).

$$C_{jc} = \frac{\sum_{i=1}^{n} (EF_{i,m} M_i + M_i D_i T_i)}{A} \quad (1)$$

Here, C_{jc} represents the carbon emission factor of the building material; $EF_{i,m}$ represents the carbon emission factor of the i-th material; M_i represents the quantity of the i-th material; Di represents the average transportation distance of the i-th material; Ti represents the carbon emission factor for transportation per unit weight of the i-th material; A represents the building area; i represents the material type.

In light of the difficulty in obtaining meso-scale city-level statistics on construction material transport distances and conveyance modes, this study draws on standard documents, industry reports, and carbon-emission data from multiple engineering case studies to determine the proportional relationship between material production and transport emissions. The resulting ratios generally fall between 2 % and 7 %. Consequently, when transport data are unavailable, the transport-stage emissions may be estimated by applying a coefficient of 2 %–7 % of the production-stage material carbon emissions.

2.2 Operational Carbon Emission Factor

When calculating the carbon emission factor of building operations, this paper introduces the concept of "carbon emission intensity." The carbon emissions from building operations are divided into direct and indirect emissions, and the concept of "comprehensive carbon emission intensity" is introduced to better measure urban carbon emission levels. Direct carbon emissions are caused by energy consumption, such as natural gas, coal, etc.; indirect carbon emissions are caused by purchased electricity, heat, and cooling.

2.2.1. Comprehensive carbon emission intensity

The formula for calculating the comprehensive carbon emission intensity of building operations is constructed according to Eq. (2).

$$C_Z = \frac{C_M}{A} = C_d + C_{id} \quad (2)$$

Where C_Z represents the comprehensive carbon emission intensity of building operations; C_M represents the annual carbon emissions from building operations; C_d represents the direct carbon emission intensity from building operations; C_{id} represents the indirect carbon emission intensity from building operations.

2.2.2. Direct carbon emission intensity

The formula for calculating the direct carbon emission intensity of building operations is shown in Eq. (3) and Eq. (4).

$$C_d = \frac{\sum_{i=1}^{n}(EF_{i,e}E_i)}{A_h} \quad (3)$$

$$A_h = A_a \cdot m \quad (4)$$

Where $EF_{i,e}$ represents the carbon emission factor for the i-th energy type; E_i represents the quantity of the i-th non-renewable energy used in building operations, excluding electricity; A_h represents the residential building area; A_a represents the per capita residential building area; m represents the population number.

2.2.3. Indirect carbon emission intensity

The formula for calculating the direct carbon emission intensity of building operations is shown in Eq. (5).

$$C_{id} = EUI \cdot EF \quad (5)$$

Where *EUI* represents the annual electricity consumption intensity of the building; *EF* represents the electricity carbon emission factor of the region where the building is located.

2.3 Data Priority Levels

This study focuses on the extraction of meso-scale building carbon emission factors. Here, "meso-scale" is defined as the level of an individual city, a province, or an urban agglomeration composed of adjacent cities, rather than a sub-city district or a building complex. Accordingly, data published by authoritative national agencies are accorded the highest priority in the accounting process; secondary priority is assigned to limit values specified in relevant standards (for material accounting) or to operational data from energy-monitoring platforms (for operational accounting).

3. RESULTS AND DISCUSSION

3.1 Carbon Emission Factors for Building Materials

This study selects building material consumption data from 31 provinces and cities in China between 2011 and 2020 as the research sample. The data comes from the "China Building Industry Statistical Yearbook." Given the diversity of building materials and the incomplete building material factor database, this study, after considering the availability of data, selects the main carbon emission sources from building materials: steel, wood, aluminum, cement, and glass. The carbon emission factors for these materials are listed in Table 1.

Table 1. Carbon emission factors of building materials

	Steel (tCO_2/t)	Wood (tCO_2/m^3)	Cement (tCO_2/t)	Glass (tCO_2/m^2)	Aluminum (tCO_2/t)
Carbon emission factor	1.789	-0.843	0.822	0.047	2.600

Fig.1 shows the distribution of building material carbon emission factors across China's provinces and cities from 2011 to 2020. As observed in Fig.1, the majority of building material emission factors in Chinese provinces and cities range from 649.56 to 1317.48 $kgCO_2/m^2$.

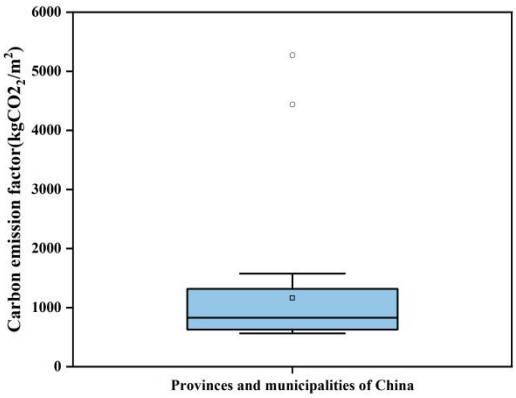

Figure 1. Distribution of building material emission factors across provinces and cities in China.

Fig.2 illustrates the composition of total building material carbon emissions in different provinces and cities of China in 2020. From Fig.2, it is evident that steel and cement are the main sources of carbon emissions among the five types of building materials. Moreover, it is clear that high-carbon-emission areas are clustered in the eastern provinces (e.g., Jiangsu, Zhejiang, Fujian), where economic development, technological capacity, and urbanization rates are generally higher. By contrast, low-carbon-emission regions are predominantly in the west (e.g., Qinghai, Ningxia, Tibet), where mountainous and plateau terrain has historically constrained early urban growth.This suggests that natural resources, geographical location, and climate conditions are also significant factors affecting building carbon emissions.

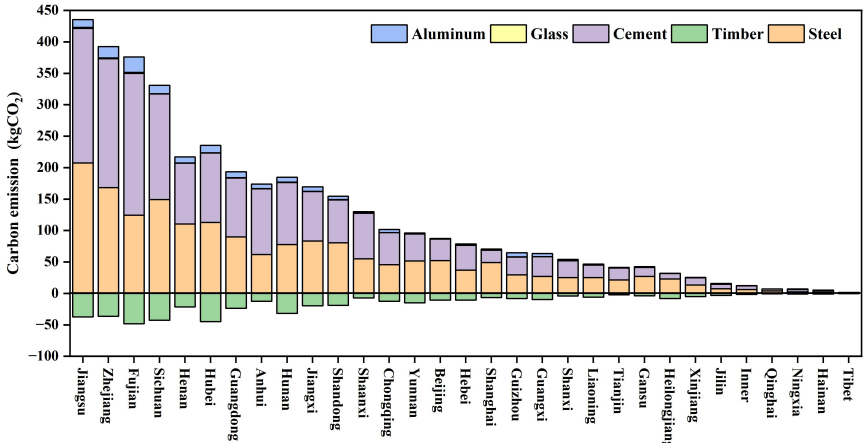

Figure 2. Composition of Building Material Carbon Emissions in Provinces and Cities of China (2020).

The year-on-year trend of carbon emission factors of building materials at the macro-country level tends to reflect the trend of policy orientation and market demand, and the driving factors behind them often significantly affect the change of meso-factors, so analysing the trend of their change can provide important references and bases for the study of meso-factors.

Fig.3 reflects the trends in China's building material carbon emissions and carbon emission factors from 2011 to 2020. Fig.4 shows the annual changes in China's building construction area from 2011 to 2020. From Fig.3, it can be observed that the carbon emission factors for building materials in China follow a similar trend to that of carbon emissions, with the highest carbon emission factor recorded in 2013 at 1286.18 $kgCO_2/m^2$. From 2015 to 2029, the carbon emission factors for building materials showed a gradually increasing trend, albeit at a slower rate. Notably, from 2012 to 2013, the building material carbon emission factor decreased significantly, despite an increase in the construction area (Fig.4). This is likely due to the implementation of policies promoting the use of green materials. Combining Fig.3 and Fig.4, from 2016 to 2029, the construction area and carbon emissions were inversely proportional, likely related to changes in the structure of its consumption of building materials.

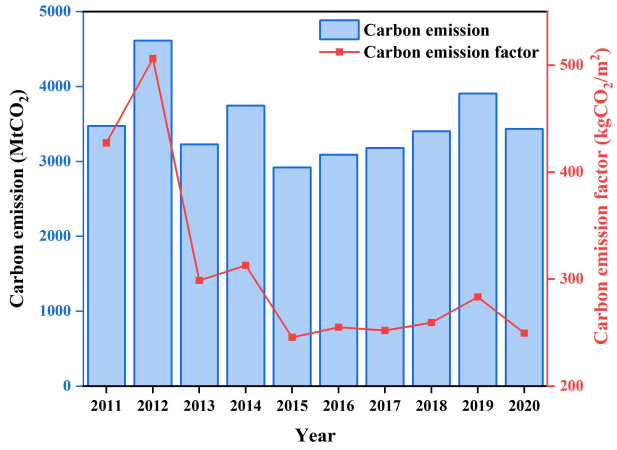

Figure 3. Carbon Emission Factors (2011-2020).

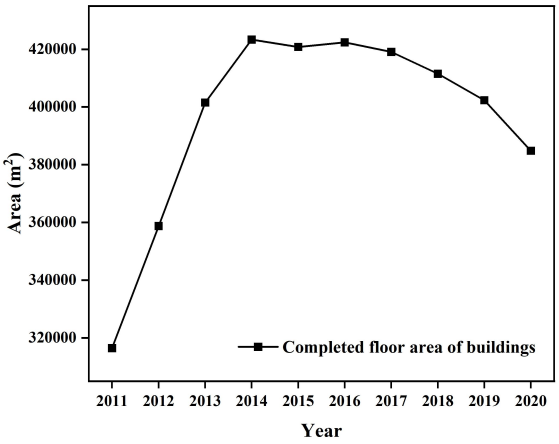

Figure 4. Changes in Construction Area (2011-2020).

3.2 Operational Carbon Emission Factor

Quantifying the carbon intensity of building operations in first-tier cities, which are highly concentrated in terms of economic and population density, and second- and third-tier cities, which are more densely distributed in China, can reveal the characteristics of carbon emissions at different stages of development in China. Considering the availability of data, Beijing, Shanghai, Shenzhen and Bozhou are selected as typical cities for this study.

3.2.1. Comprehensive carbon emission intensity

This study calculates the direct carbon emission intensity, indirect carbon emission intensity, and comprehensive carbon emission intensity of building operations in Shanghai for the years 2022 and 2023, using data from the Shanghai energy consumption monitoring report. The calculation results are shown in Table.2. From Table.2, it is clear that indirect carbon emissions, primarily

resulting from electricity consumption, make up the largest portion of building operational carbon emissions..

Table 2. Calculation results comprehensive carbon emission intensity

Year	direct carbon emission intensity ($kgCO_2/m^2$)	indirect carbon emission intensity ($kgCO_2/m^2$)	comprehensive carbon emission intensity ($kgCO_2/m^2$)
2022	5.2	35.4	40.6
2023	6.7	41.4	48.1

3.2.2. Direct carbon emission intensity

This study analyzes the direct carbon emission intensity of energy consumption from residential buildings in Bozhou, China, from 2019 to 2022. The data comes from the "Bozhou Statistical Yearbook." The energy consumption mainly considers natural gas and liquefied petroleum gas. The carbon emission factors for natural gas and liquefied petroleum gas are taken from "Building Carbon Emission Calculation Standard," which are 1.566 tCO_2/t standard coal and 3.1013 $kgCO_2/kg$, respectively.

Table.3 shows the calculation results of direct carbon emission intensity in Bozhou from 2019 to 2022. From the table, it can be seen that the direct carbon emission intensity in Bozhou has been increasing year by year, primarily due to the increase in urbanization rate, which leads to a higher population and thus an increase in energy consumption. Comparing the results of this calculation with the direct carbon emission intensity of Shanghai in Table 2, it is easy to find that Shanghai is significantly higher than Bozhou, which shows that the economic level significantly affects urban carbon emissions.

Table 3. Calculation results of direct carbon emission intensity

Year	Carbon emissions (10000 $kgCO_2$)		Per capita housing area (m^2)	Population (10000)	Housing area (m^2)	Direct carbon emission intensity ($kgCO_2/m^2$)
	Natural gas	LPG				
2019	5433.49	948.72	51	207.40	10577.40	0.603
2020	6789.25	925.93	57	212.40	12106.80	0.637
2021	7810.77	940.17	57	215.40	12277.53	0.713
2022	8525.21	1806.84	54.3	218.50	11864.55	0.871

3.2.3. Indirect carbon emission intensity

Residential buildings are a significant component of social production and life, and studying the indirect carbon emission intensity of residential building operations is of great importance. This study calculates the indirect carbon emission intensity of residential buildings across 30 provinces and cities in China, using energy consumption data as the sample. The data covers the years 2014 to 2024.

Fig.5 shows the distribution of indirect carbon emission intensities for various types of buildings, classified by function. It can be seen that the data for hotel buildings shows the least fluctuation among the various building types, with indirect carbon emission intensity remaining relatively stable across different regions. On the other hand, the indirect carbon emission intensity for many other buildings, such as healthcare buildings, shows a wide fluctuation range, with intensities varying from 5.52 $kgCO_2/m^2$ to 163.71 $kgCO_2/m^2$. This indicates that there are

significant regional differences in the indirect carbon emission intensity of building operations, primarily due to variations in regional economic scale, industrial structure, energy structure, and urbanization rate. This underscores the importance of localized, region-specific carbon emission factors.

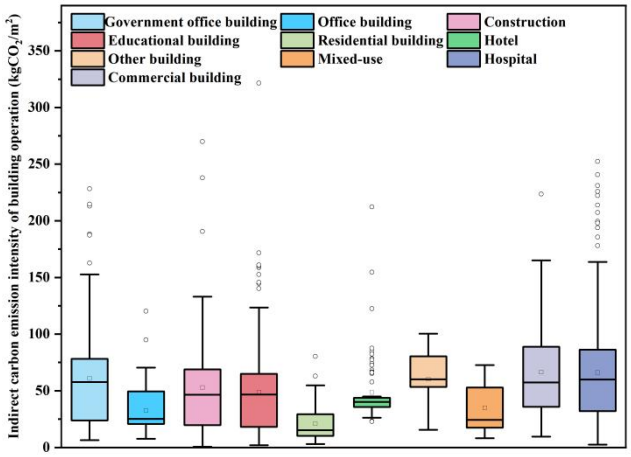

Figure 5. Distribution of indirect carbon emission intensity for various building types.

In order to examine more broadly the differences in the indirect carbon intensity of building operations in different regions, typical cities in the south, east, and north, namely Shenzhen, Shanghai, and Beijing, were selected for comparison. Fig.6 compares the indirect carbon emission intensities of different types of buildings in the cities of Beijing, Shanghai, and Shenzhen for 2023.

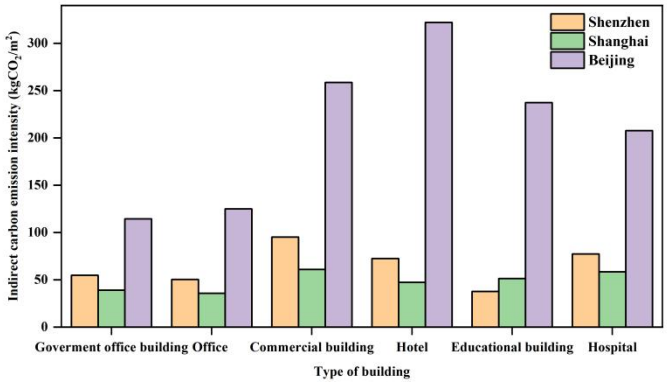

Figure 6. Indirect carbon emission intensity for various building types in first-tier cities.

As shown in Fig.6, the differences in indirect carbon emission intensity between Shanghai and Shenzhen are minimal, while Beijing's building operational indirect carbon emission intensity is significantly higher than the other two cities, mainly due to the heating energy consumption in Beijing. This also highlights the urgency of optimizing the regional energy mix.

4. Conclusions

Buildings are one of the main sources of urban carbon emissions, and the study of localised building carbon emission factors can provide a scientific basis for the formulation of efficient energy-saving and carbon reduction policies. In this paper, we propose a method for extracting building carbon emission factors applicable to urban mesoscale and building microscale, and calculate them with corresponding case data, and the conclusions are as follows:

The carbon emissions from building materials are primarily derived from steel and cement. From 2011 to 2020, China's macro building material carbon emission factors fluctuated, but the fluctuations became slower after 2016. Due to various factors such as policies and resource endowment, the building material consumption structure in different provinces and cities varies. The building material emission factors are mainly distributed between 649.56 $kgCO_2/m^2$ and 1317.48 $kgCO_2/m^2$.

Indirect carbon emissions are the primary component of building operational carbon emissions. The indirect carbon emission intensity for different types of buildings varies greatly across regions. For example, the indirect carbon emission intensity for healthcare buildings ranges from 5.52 $kgCO_2/m^2$ to 163.71 $kgCO_2/m^2$. Building operational carbon emission intensity is influenced by multiple factors, such as GDP, urbanization rate, and energy structure. This highlights the importance of considering regional and localized building carbon emission factors in order to accurately reflect the carbon emission levels of different regions.

SUMMARY
This study explores the potential of large language models (LLMs) for facilitating data collection in home energy audits by comparing a baseline GPT-4 with a knowledge-augmented GPT that integrates multimodal retrieval-augmented generation (RAG) and prompt engineering. Using a ceiling insulation case study, we evaluate performance across task definition, execution instructions, insulation identification, and R-value estimation. Preliminary findings suggest that the knowledge-augmented GPT may offer more focused, reference-aligned guidance, potentially reducing user confusion and mitigating safety risks. Future work includes integrating multi-agent oversight to strengthen reliability and broaden applicability. By leveraging advanced LLM capabilities, the knowledge-augmented GPT demonstrates a promising pathway toward cost-effective, user-friendly, and widely accessible energy audits.

Keywords: home energy audit, language models, retrieval-augmented generation, prompt engineering

1. INTRODUCTION

Buildings are major contributors to global greenhouse gas emissions, with the residential sector alone accounting for approximately 11% (World Resources Institute, 2024). Previous studies suggest retrofitting existing residential stock is crucial for mitigating climate change (Haley & Torrie, 2021). The first step in a residential retrofit is a home energy audit, which involves the evaluation of home energy performance. However, the limited availability of experienced energy auditors, along with the high costs and lengthy evaluation times, have been bottlenecks. While automated approaches for home energy audits have been developed (Alanezi et al., 2021), gathering and inputting data remain challenging.

Large language models (LLMs), such as GPT-4 (OpenAI et al., 2023), have shown promise in bridging knowledge and resource gaps in fields traditionally reliant on professional expertise, partially through advanced conversational interaction, context-based referencing, and multimodal comprehension (Chu et al., 2024). Building on these LLM capabilities, our long-term goal is to develop an AI agent that can assist homeowners and energy auditors in conducting home energy

audits. The agent aims to make home energy audits more user-tailored, reliable, and accessible, ultimately encouraging broader adoption of home energy retrofits.

In this exploratory work, we investigate the potential of LLMs in facilitating efficient data collection in home energy audits—one of the key challenges impeding broader retrofitting efforts. Specifically, we compare the performance of the baseline GPT-4 against a knowledge-augmented GPT that incorporates multimodal retrieval-augmented generation (RAG) and prompt engineering.

2. METHODOLOGY

2.1. Native GPT-4: OpenAI Playground

As a baseline, we employ GPT-4 natively via the OpenAI Playground. The GPT-4 model is configured with a temperature of 0 for deterministic outputs, while all other settings remain at their defaults. We then provide the model with a series of queries simulating a homeowner's perspective—aligned with our case study's scenario—to evaluate its capabilities.

2.2. Knowledge-augmented GPT with Multimodal RAG and Prompt Engineering

We build a knowledge-augmented GPT based on GPT-4 (Fig. 1). Specifically, it leverages multimodal RAG (Zhao et al., 2023) to incorporate relevant references. To preserve context, references are loaded and partitioned by modality and section into "chunks"—representing original documents—which are then saved in a document store. To facilitate optimal semantic retrieval, GPT-4 generates text-based summaries of these original documents, which are stored in a paired vector database. Together, these interconnected databases form a multi-vector retriever. Upon receiving a homeowner's query, the retrieval system identifies the most relevant text-based summaries and then retrieves the corresponding original document chunks across various modalities, enabling reference-grounded responses.

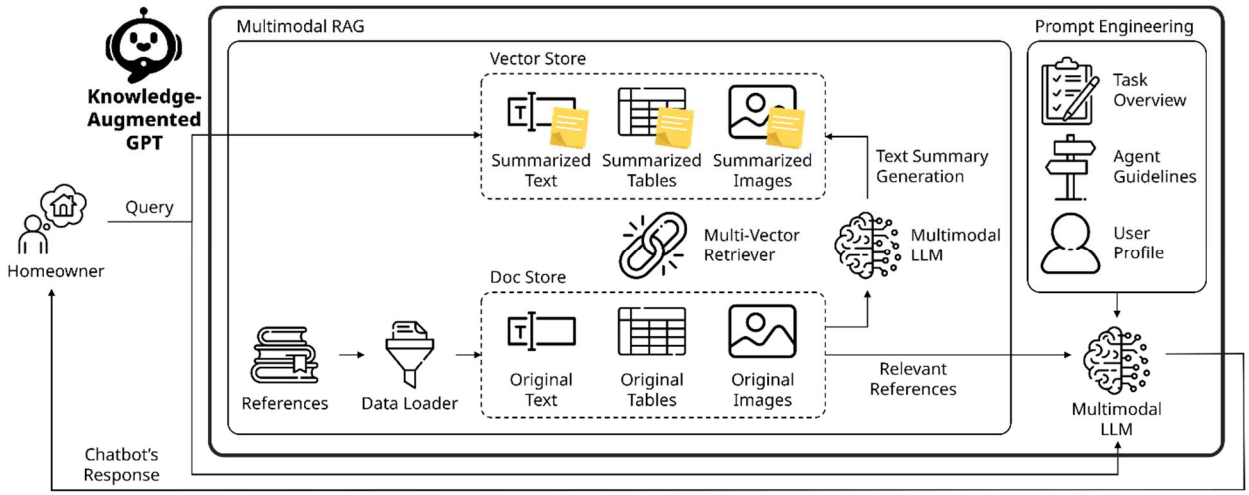

Figure 1. Knowledge-augmented GPT integrating multimodal RAG and prompt engineering.

Additionally, the knowledge-augmented GPT employs prompt engineering (Sahoo et al., 2024) to incorporate contextual information across three sections: (1) Task Overview, defining the role and responsibilities of the knowledge-augmented GPT; (2) Agent Guidelines, requiring consultation of relevant references before resorting to general knowledge, while providing proactive, concise

guidance and supporting image interpretation in a friendly tone; and (3) User Profile, reflecting the homeowner's limited background and preference for plain language. This structured approach fosters context-aware interactions. The knowledge-augmented GPT is then presented with the same series of queries as the native GPT-4, enabling a direct comparison.

3. RESULTS AND DISCUSSION

3.1. Case Study: Ceiling Insulation Data Collection

Ceiling insulation data collection is selected as the representative task. In this case study, we examine whether our knowledge-augmented GPT can provide the necessary guidance—referencing the EnerGuide Rating System (ERS) (Natural Resources Canada, 2023)—to help homeowners gather key information, such as insulation type and R-value. We assume a typical scenario where the homeowner has basic household tools (e.g., ladder, tape measure) but limited ERS familiarity, and a detached home with an accessible attic lacking a finished floor, leaving the joists and insulation in between them exposed for inspection.

3.2. Response Comparison: Native GPT-4 versus Knowledge-Augmented GPT

For task definition and execution instructions (Fig. 2), the native GPT-4 showed unwarranted generalities—such as advising homeowners to step only on joists—which might initially seem acceptable but conflicted with ERS's explicit warning against stepping off the ladder into the attic, posing potential safety risks. In contrast, the knowledge-augmented GPT—using multimodal RAG—generally appeared more aligned with ERS guidance. Its steps and details were more focused and actionable, and prompt engineering further refined these instructions to be more concise yet engaging (e.g., interpreting images).

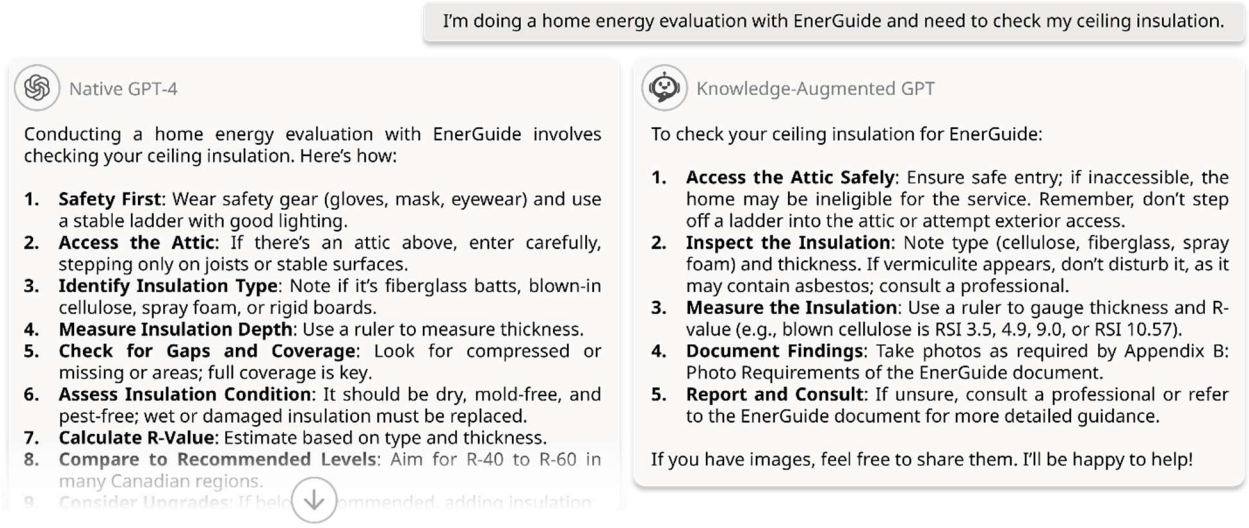

Figure 2. Native GPT-4 versus knowledge-augmented GPT: Task definition and execution instructions.

In the subsequent conversation about insulation identification and R-value estimation (Fig. 3), the native GPT-4 provided a range-based estimate that, while reasonable, could introduce unnecessary cognitive burden. In contrast, the knowledge-augmented GPT first presented a more deterministic, table-referenced R-value, potentially reducing guesswork. It also offered predefined response options aligned with the identified ceiling insulation, which may support more informed decision-

making. The knowledge-augmented GPT remained encouraging, guided by prompt engineering.

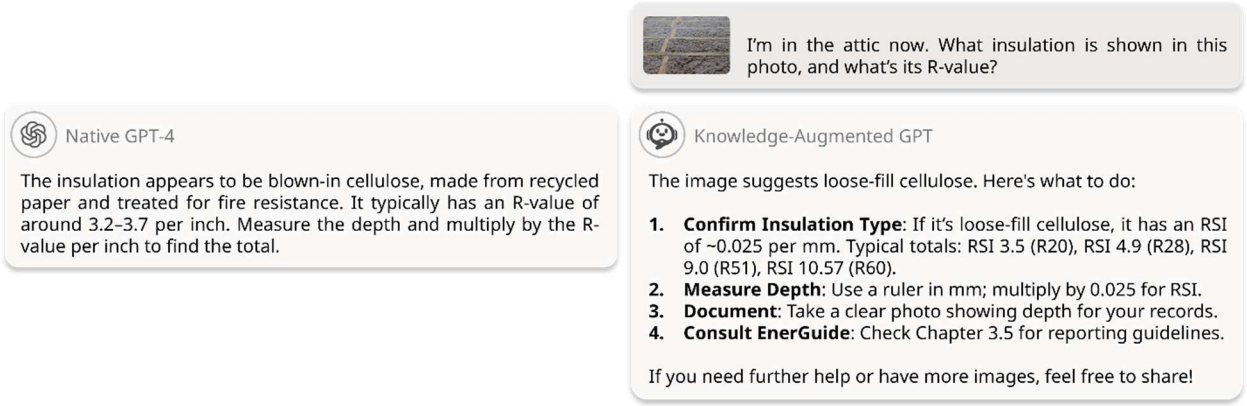

Figure 3. Native GPT-4 versus knowledge-augmented GPT: Insulation identification and R-value estimation.

While these initial findings appear promising, broad generalization remains challenging due to the volume and diversity of the required data and possible scenarios. Predefined workflows for complex tasks, supplemented by representative examples, could help improve the consistency of our knowledge-augmented GPT. Additionally, a multi-agent, LLM-based framework to oversee dialogue development may further enhance its robustness.

4. CONCLUSIONS

In this study, we explored LLMs for efficient data collection in home energy audits. Using a representative case, we compared native GPT-4 with a knowledge-augmented GPT integrating multimodal RAG and prompt engineering. Preliminary findings suggest that the knowledge-augmented GPT delivers more targeted, ERS-aligned guidance, highlighting a promising LLM-driven solution. Future work will extend into a multi-agent framework for broader applications.

SUMMARY
Climate change metrics have increased in recent years, and it is important for wind engineering to enhance the understanding of the complex interactions of wind in urban environments to mitigate the associated environmental and structural risks. Wind tunnel experiments can help to some limited extent due to the length restrictions and data availability. Computational fluid dynamics (CFD) has the potential to give valuable information regarding mean flow properties, but reliable fluctuating values are still an issue in the state-of-the-art. Research should work towards generalized tools that can give reliable data regarding mean and fluctuating properties of wind speed and temperature during extreme or regular wind events. In the present work, a hybrid approach is followed to overcome the current problems. This approach utilises CFD (LES-DT and CityFFD) and Localized Fourier Neural Operator (Local-FNO) to measure mean wind speed and turbulence properties in urban environment of Montreal. Practical applicability, efficiency and future targets of each method are highlighted.

Keywords: CityFFD, Large Eddy Simulation, Dynamic Terrain, urban microclimate, artificial neural networks, building energy, wind power, wind-induced loads

1. INTRODUCTION

Understanding the interaction of wind flow, temperature, humans and buildings in urban regions is vital for both environmental and structural applications. The former relates to climate change, pollutant dispersion, urban wind energy, while the latter deals with wind load estimation for safe and economical design. The complex nature of this interaction due to high turbulence in the lower atmospheric boundary layer, creates difficulties in the modelling techniques used in the state-of-the-art. This is especially the case for fluctuating properties such as turbulence.

This study utilises a hybrid approach in order to estimate the turbulence in a dense urban environment, based on Computational Fluid Dynamics (CFD) and data-driven based models. In the following section these methodologies are thoroughly discussed. In Section 3 aa case study is presented and, finally, in Section 4 the paper summarises and concludes.

2. METHODOLOGIES

CFD has been utilised for urban microclimate modelling extensively during the last decades, by means of RANS models that can capture mean properties. The need to expand the ability of these models to fluctuating properties as well, as to better understand and mitigate the risks of extreme weather conditions in urban settings, has evolved the research to LES modelling (Potsis et al., 2023, Tominaga et al., 2023). In the present study, two different LES approaches that have been recently developed by this working group are used.

First, a method based on CPU modelling, introducing fluctuations at the inflow wind based on the Dynamic Terrain approach (LES-DT). This methodology has proven capable of modelling fluctuating wind flow and structural loads (peaks) in urban environments (Potsis and Stathopoulos, 2024, Potsis et al., 2024). The other CFD method is based on GPU modelling and refers to the CityFFD approach that uses the semi Langrangian approach to model fluctuating wind flow and temperature properties in urban environments (Mortezazadeh and Wang, 2020, Mortezazadeh et al., 2022). It is highly efficient due to the GPU-based code and has been validated regarding mean wind flow and temperature metrics in urban configurations.

Data-driven methods have captured the attention of the wind engineering community recently, mainly due to the fast development of hardware and knowledge in similar engineering fields. In the present study, a Localized Fourier Neural operator (Local-FNO) method has been utilised. This approach has been applied recently in predicting accurately wind velocity and temperature in urban settings (Peng et al., 2024, Qin et al., 2025). Local-FNO is a localized variant of the Fourier Neural Operator designed to enhance data efficiency and deliver sharper prediction quality. The dataset consists of 30 3D CityFFD simulations, divided into 24 for training, 3 for validation, and 3 for testing. During training, each simulation is partitioned into small 3D patches via random sampling, effectively increasing the number of training samples. The model inputs include a building occupancy grid, the corresponding signed distance field (SDF), and a multi-directional distance feature that encodes geometry information beyond the scale of individual patches. The model is trained using the Root Mean Squared Error (RMSE) loss function. Early stopping is employed on the validation set to prevent overfitting.

3. CASE STUDY

In order to present each of the aforementioned methods applicability, efficiency and accuracy, a case study of downtown Montreal is selected. It consists of around 50 buildings, with various heights in an area of 985 m x 1204 m, as seen in Fig. 1(a). The reason that this particular cluster of buildings was selected is that both high rise buildings and mid-rise buildings are included. The two CFD approaches used are based on different settings, proven accurate through various validation studies (Mortezazadeh and Wang, 2020, Potsis et al., 2024). For example, CityFFD can utilise larger computatioonal domains and more finite volumes (23 million) as seen in Fig. 1(b), compared to LES-DT in Fig. 1(c) (7 million). CityFFD model has a length scale 1:1 (full-scale) and LES-DT 1:800.

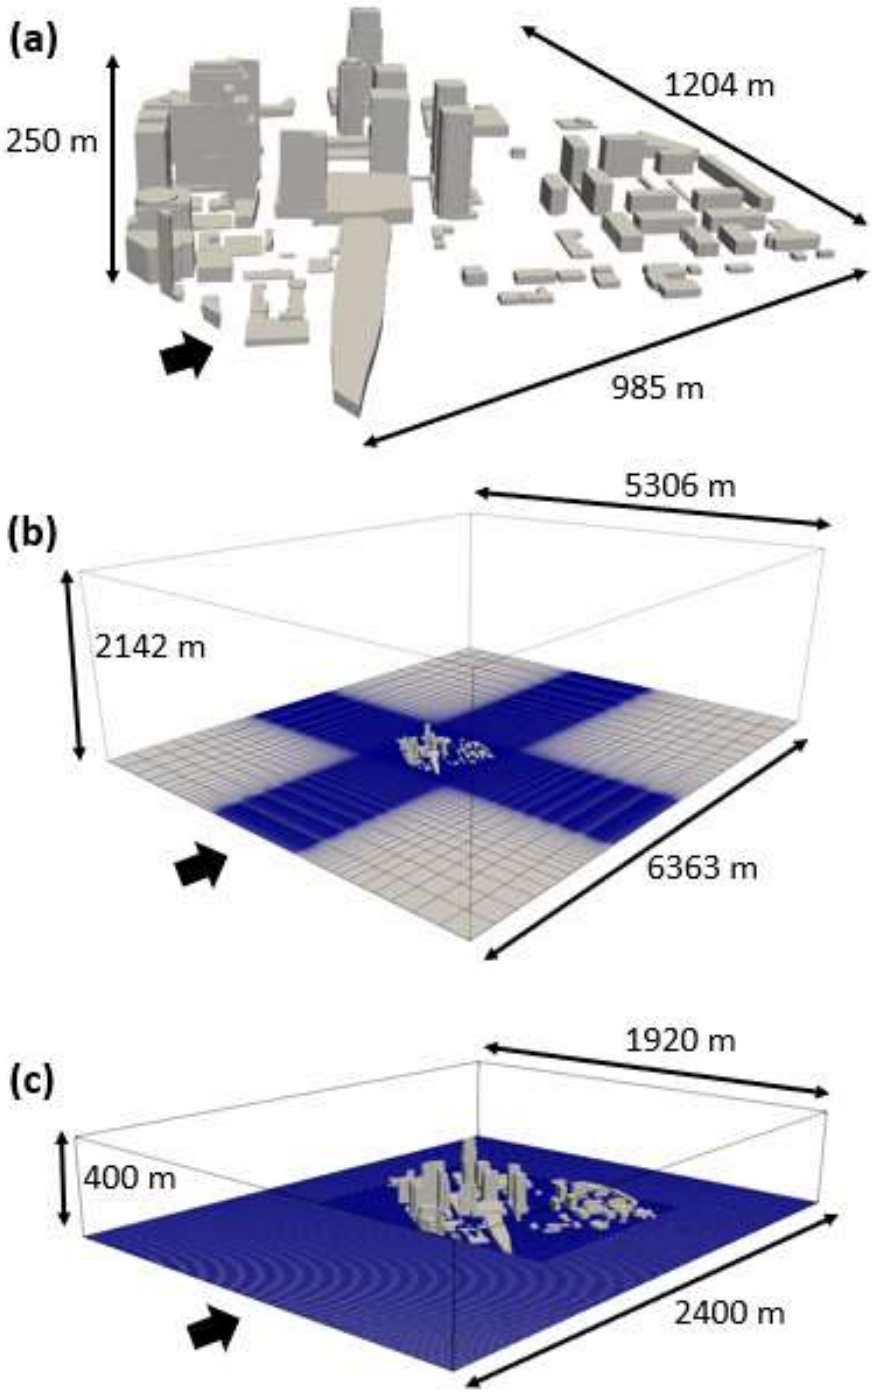

Figure 1. (a) Geometry of building clusters of case study, (b) computational domain setup in CityFFD, (c) computational domain setup in LES-DT.

3.1. Incident flow

A vital aspect as to understand the differences in the computational strategies and training procedure of the FNO, is an overview of the incident flow in the computational domain – that is the flow characteristic at the location exactly before the building cluster is placed. These profiles

are presented in Fig. 2 and extracted from analysis with empty computational domain. Fig. 1a presents the mean streamwise velocity normalized, based on the provisions of ASCE 49-21. As seen, the mean and longitudinal turbulence intensity profiles have good agreements with the experiments in Fig. 2a and Fig. 2b, where z_{ref} was selected as 10 m, based on provisions of ASCE 49-21. These profiles represent a suburban exposure B.

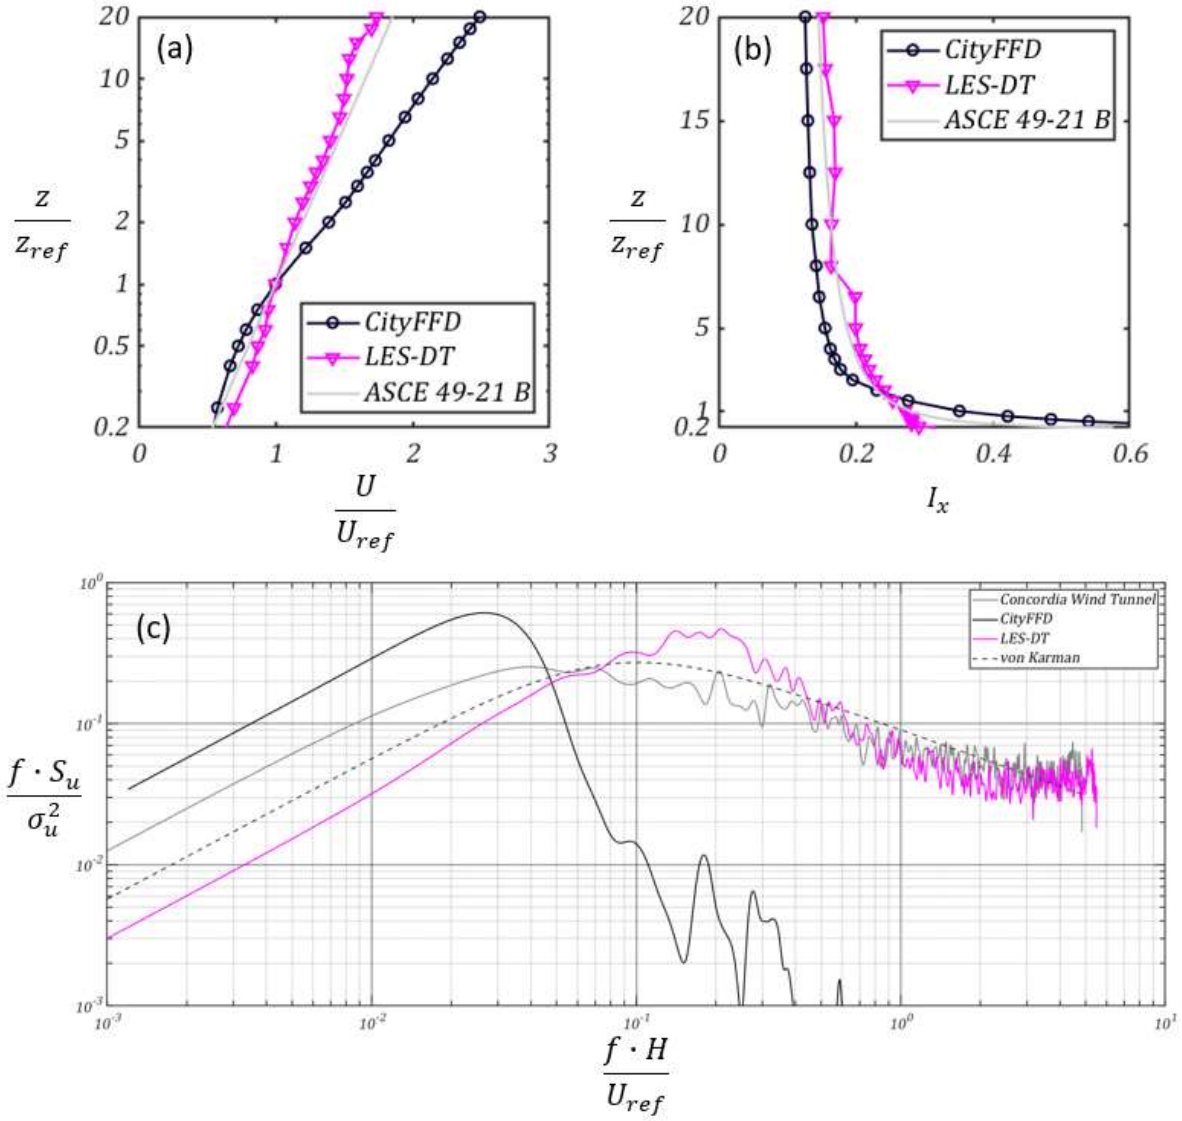

Figure 2. (a) Mean incident profile, (b) turbulence intensity incident profile, (c) spectrum at h = 64 m at incident location based on CityFFD, LES-DT, ASCE 49-21, Concordia Wind Tunnel and von Karman.

Another aspect that needs attention is also the spectrum of the longitudinal velocity at the incident location, that is presented for a height of 64 meters (full scale) in Fig. 2c. Similar results are achieved for other heights of the ABL. As discussed previously (Potsis and Stathopoulos, 2024 and Potsis et al., 2024), LES-DT is capable of reproducing the energy of these fluctuations with great accuracy, even after the cut-off frequency of LES. As shown, there is good correlation of

LES-DT with experimental results from Concordia Wind Tunnel and the theoretical von Karman Spectrum. Similar data from the CityFFD lack this capability, due to the combination of steady inflow properties and Fast Fluid Dynamics concept (Mortezazadeh and Wang, 2020), as also seen in Fig. 2c. Various techniques in the state-of-the-art reproduce similar results as the CityFFD regarding the spectrum (Potsis et al., 2023) – a limitation which is furhter explored in this work by comapring flow field metrics inside the urban canyons.

3.2. Flow field metrics inside urban canyons

Fig. 3 presents the normalized longitudinal mean wind flow at a plane of z = 30 m. Clearly, results by LES-DT and CityFFD have great similarity, except maybe the length of the detached eddies behind some of the buildings. As a next step this discrepancy will be further scrutinized and discussed in the conference presentation. The Local-FNO is able to reproduce the mean flow field with good accuracy, especially given the fact that the training was conducted in different cases resembling urban environments, and not the urban configuration presented in Fig. 1.

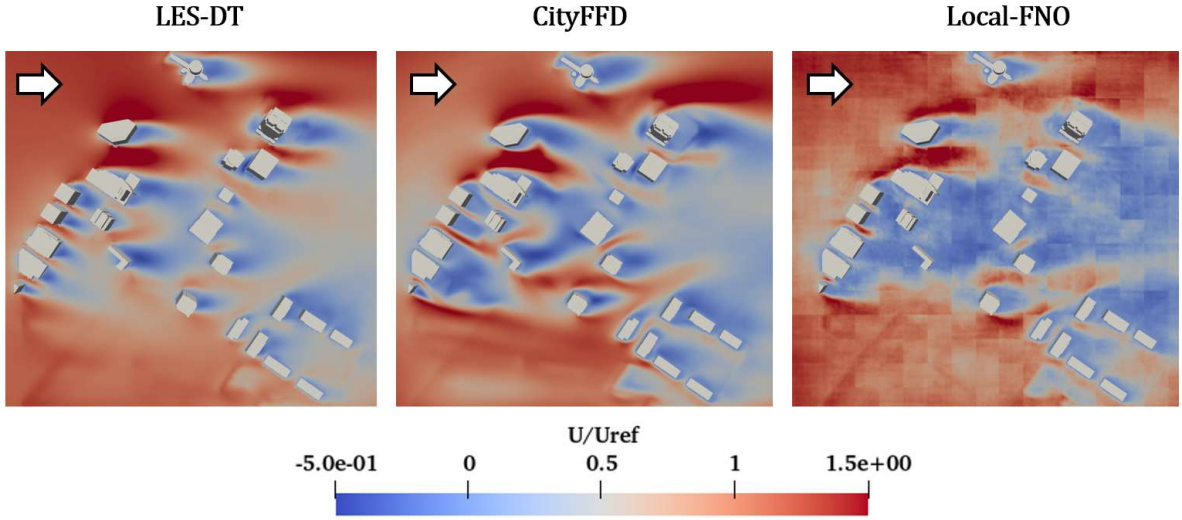

Figure 3. Mean normalised streamwise wind velocity at z = 30 m height form LES-DT (left), CityFFD (middle) and Local-FNO (right)

Furthermore, turbulence features in urban environments need to be modelled properly as to conduct meaningful environmental applications. These are also a prerequisite for structural applications, since these peak values relate closely with the gusts of the wind flow. In Figure 4, similar results are presented regarding the normalized time averaged turbulence kinetic energy distribution at the z = 30 m plane. As can be seen, LES-DT introduces more turbulence features in the computational domain, which has proven helpful for design applications resembling more gust winds for peak pressure estimation. CityFFD results agree to a great extent with LES-DT, although the turbulence kinetic energy near walls is not modelled very well. This is expected according to the modelling targets of this tool. Finally, Local-FNO captures the general character of the fluctuations, but more detailed comparisons are necessary to improve the training of the model.

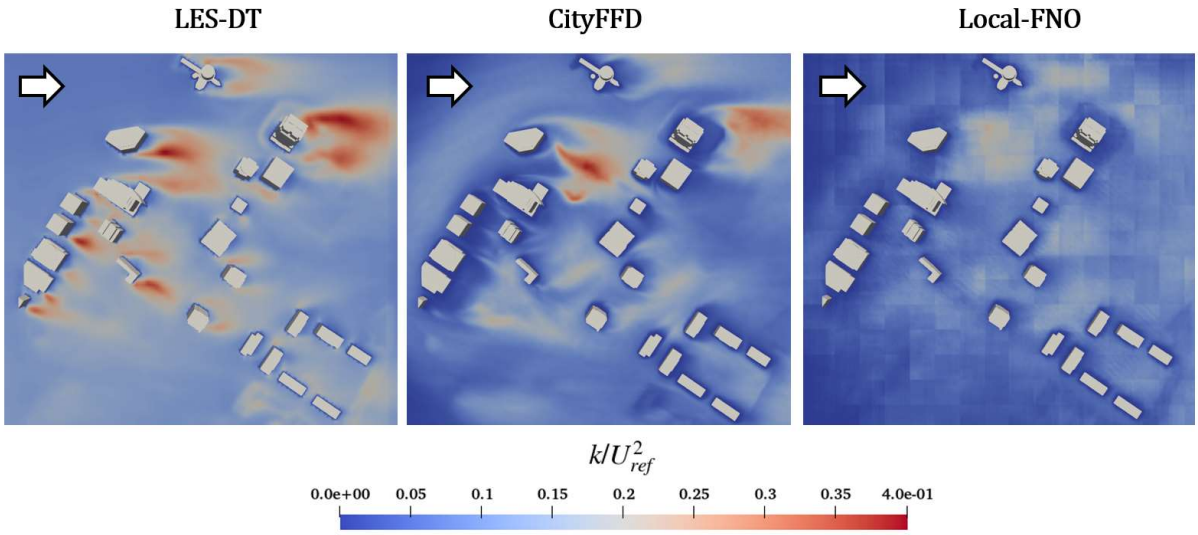

Figure 4. Time averaged turbulence kinetic energy of wind velocity at z = 30 m height form LES-DT (left), CityFFD (middle) and Local-FNO (right)

3.4. Efficiency and practical applicability

The target of this work is to discuss engineering-based solutions aiding various environmental or structural applications. For this purpose, Table 1 shows important aspects of each method. Environmental applications can be applied with each method at the moment, since they mainly refer to mean flow properties. Regarding environmental applications where turbulence features are needed LES-DT and CityFFD seem to be capable to predict turbulence features with similar accuracy. Aspects of further improvement of Local-FNO to capture fluctuating properties will be reported and discussed in detail in the conference presentation. Regarding structural applications, LES-DT is the only methodology tested capable of reproducing peak wind induced pressures as well. Additional results will be further communicated during the conference.

Table 1. Applicability and Efficiency of LES-DT, CityFFD and FNO

Method	Application		Efficiency
	Environmental	Structural	
CityFFD	X		23 million elements/6 hours on GPU
LES-DT	X	X	7 million elements/40 hours on 640 CPUs
Local-FNO	X		12 hours for training /1 minute for testing

4. SUMMARY - CONCLUSION

A hybrid approach based on two CFD methodologies (CPU-based and GPU-based) and Local-FNO have been utilised to model mean and turbulence wind flow in a dense urban environment in Montreal. Given the great potential in terms of calculation time of GPU-based tools (such as CityFFD), this work encompasses to create efficient engineering-based solutions for urban microclimate modelling. Details of the selected case study were presented and some results regarding the incident flow properties and flow field metrics inside urban canyons. Good accuracy is achieved between the three methods regarding mean flow properties, but some differences are highlighted for turbulence kinetic energy. The tremendous efficiency of Local-FNO constitutes it as an ideal tool for further development.

SUMMARY
The configuration of surrounding structures significantly affects pedestrian-level wind comfort in urban areas. This study assesses wind comfort on the UTCB campus using CFD simulations for ten relevant wind directions and respective meteorological data gathered from a nearby weather station. The building geometry was modeled by taking into account only critical features, while mesh generation used polygonal and hex-core cells. Simulations were performed using the Realizable k-ε turbulence model implemented in Ansys Fluent, with boundary velocity profiles adjusted for terrain roughness and exposure factors.
Dimensionless velocity fields were analyzed at 1.5 meters above ground, and site-specific data were used to calculate the probability of exceeding a 5 m/s wind speed. Results show that the campus meets the highest comfort class (Class A) year-round based on the Dutch Wind Nuisance Standard NEN 8100. This research validates the applicability of NEN 8100 for improving pedestrian wind conditions in complex urban environments.

Keywords: Pedestrian wind comfort, CFD simulation, building aerodynamics.

1. INTRODUCTION

Over the past decade, European cities have experienced a trend toward redensification, driven by population growth due to immigration and a decline in urban sprawl (Cortinovis et al., 2022). While Romania remains the European country with the highest rate of land occupation growth — primarily due to the conversion of agricultural land into urban functional areas (European Environment Agency, 2023) — the European Union set a "no-net-land-take" goal for 2050 in its Soil Strategy (2021). Consequently, further intensification of urban densification trends, including in Romania, is expected in the coming decades.

The past decade has brought numerous real estate developments, both residential and commercial, to Bucharest. These developments often feature high-rise buildings and increased density. Driven by a focus on maximizing profitability and sometimes possibly inadequate regulation enforcement, the new architectural landscapes are characterized by narrow spaces between buildings, which encourages the formation of air currents.

In this context, at the Technical University of Civil Engineering in Bucharest (UTCB), a method for evaluating pedestrian wind comfort is being developed, encompassing CFD (Computational Fluid Dynamics) simulations and wind tunnel experiments. Pedestrian comfort studies integrate meteorological data, aerodynamic information, and comfort and safety criteria (Blocken et al., 2007). Meteorological data can be obtained from weather stations near the study area and correlated with the site using terrain roughness, distance, and site type (Du et al., 2017).

Aerodynamic data can be acquired through experimental testing in boundary-layer wind tunnels and/or through CFD simulations (Blocken and Persoon, 2009), (Janssen et al., 2013), (Adamek et al., 2013), (Du et al., 2017). Although the Lawson (2001) and Davenport (Janssen et al., 2013) criteria are still commonly used regarding pedestrian comfort criteria, apart from the Dutch NEN 8100 standard (2006), there are currently no global regulations standardizing the evaluation of these parameters.

2. METEOROLOGICAL DATA

Velocity data was collected using an anemometer placed under standard conditions, specifically 10 meters above the ground near the meteorological station at Baloteşti, near OTP Airport, 15 km from the UCTB campus. Measurements were conducted over 5 years, from January 1, 2016, to March 5, 2020, with an hourly frequency. After filtering out irrelevant recordings, 42912 hours remained, providing a substantial dataset for statistical analysis. The highest recorded wind velocity was 20.6 m/s, while the calm period accounted for only 0.12% of the total duration. Figure 1 plots the wind rose at Baloteşti meteorological station.

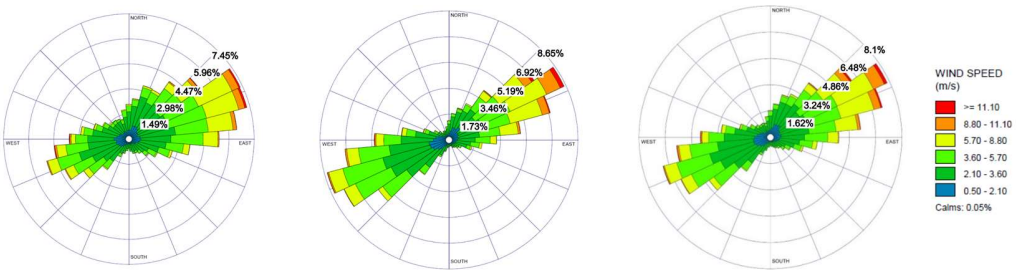

Figure 1. The wind rose at the Baloteşti meteorological site. Spring-summer (left), Autumn-Winter (middle), and whole period (right)

3. THE INVESTIGATED SITE

The UTCB campus was selected as a case study for a pedestrian wind comfort analysis. An extended area with a radius of approximately 350 meters was considered to quantify the influence of building geometry and other nearby obstacles. Figure 1 provides an overview of the entire area studied.

Figure 2. Satellite view of the area surrounding the modeled site (left) and Site sketch showing building footprint and layout details (right)

4. NUMERICAL INVESTIGATION METHOD

CFD isothermal simulations were carried out using Ansys Fluent 2023 for 10 wind directions, including cardinal, intercardinal, and 67.5° and 247.5°. A pressure-based solver was employed with the COUPLED algorithm to link pressure and velocity fields. Turbulence was modeled using the Realizable k-ε two-equation model, and all equations used second-order discretization schemes. The computational domain was cuboid-shaped, with the flow aligned to the longer side. A velocity profile was imposed at the inlet based on exposure factors, with 5 m/s at 10 m height. The outlet had a zero-gauge static pressure condition; the ground was modeled as a no-slip wall, while lateral surfaces were slip walls.

Each simulation used a different hybrid mesh with approximately 12.1 million cells, combining polygonal cells near boundaries and hex cells in the core flow. The minimum cell size near buildings was 0.5 m, while the largest cells reached 10 m at the outer edges. Size functions with a 10% growth rate were applied. Polyhedral cell layers were added between adjacent zones with different cell sizes to prevent abrupt transitions (greater than 1:8) in the hex-core regions.

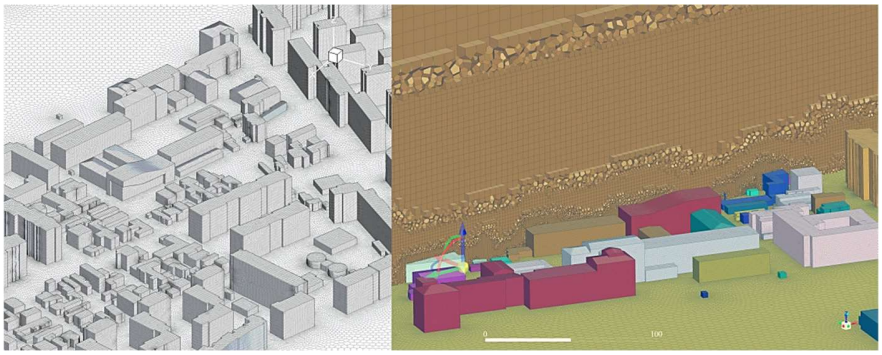

Figure 3. Detail of the fluid domain. Surface mesh (left) and volume mesh (right)

5. RESULTS

Dimensionless velocity fields U/U_{60} were evaluated in horizontal planes 1.5 meters above the ground, where U_{60} is the velocity at the blending height (60 m).

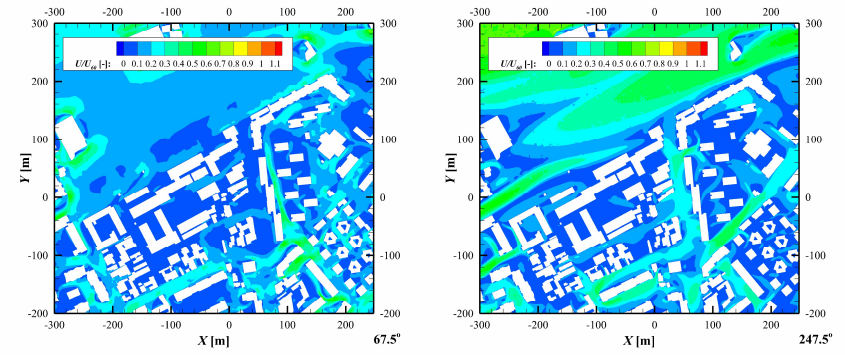

Figure 4. Nondimensional velocity contours U/U_{60} in a horizontal plane placed at 1.5 m above the ground. Wind direction 67.5° and 247.5°

Site-specific wind data were then used to calculate the probability of exceeding a wind speed threshold of 5 m/s at this height. This serves as the reference for determining pedestrian comfort class following the Dutch Wind Nuisance Standard NEN 8100. The results indicate that the entire UTCB campus meets the requirements for the highest comfort class (Class A) under both summer and winter conditions. This classification is achieved through a comprehensive analysis of the interaction between the wind and the built environment, factoring in site-specific contributions to wind speed variations.

5. CONCLUSIONS

Wind comfort at the pedestrian level in urban areas is greatly influenced by buildings' shape, size, placement, and orientation. Wind comfort criteria outlined by the Dutch Wind Nuisance Standard NEN 8100 were applied to the UTCB campus site. The combination of CFD simulation results for ten wind directions and statistical meteorological data indicates good wind quality for the campus area, meeting the requirements for comfort class A for pedestrian wind comfort.

SUMMARY

Predicting wind fields in urban environments requires capturing complex interactions between buildings and airflow, particularly long-range wake effects influenced by directional geometry. Traditional methods relying on computational fluid dynamics (CFD) are prohibitively expensive for large-scale simulations, while data-driven approaches struggle with limited training data and the need to model both local and far-field dependencies. In response, we propose a novel framework that leverages a multi-directional distance feature (MDDF) combined with localized training to achieve effective wind field predictions with minimal CFD data. By reducing the problem's dimensionality, localized training effectively increases the number of training samples, while MDDF encodes the surrounding geometric information to accurately model wake dynamics and flow redirection. Trained on only 24 CFD simulations, our localized Fourier neural operator (Local-FNO) model generates full 3D wind velocity and temperature predictions in under one minute, yielding a 500-fold speedup over conventional CFD methods. With mean absolute errors of 0.3 m/s for wind speed and 0.3 °C for temperature on unseen urban configurations, our method demonstrates strong generalization capabilities and significant potential for practical urban applications.

Keywords: Urban microclimate, wind engineering, deep learning, neural networks

1. INTRODUCTION

Modern urban planning demands a comprehensive analysis of the interplay between urban design and local environmental conditions (Yahia et al., 2018). Urban areas exhibit complex microclimates that are shaped by variations in building density, geometry, and the configuration of open spaces. These microclimatic variations can affect energy consumption for heating and cooling, the distribution of pollutants, and the overall comfort of residents. In this context, efficient and accurate predictive modeling provides urban planners with the necessary insights to design cities that optimize natural ventilation and thermal regulation. By capturing the intricate dynamics of airflow and temperature distribution, planners can better position buildings, tailor materials selection, and design public spaces that foster energy efficiency while enhancing human comfort and well-being.

Conventional CFD methods are highly detailed and accurate but come with substantial computational burdens that restrict their practical application in fast-paced urban planning contexts. These traditional simulations demand extensive processing time to capture the complex interactions of wind and temperature around intricate building configurations. The requirement for high-resolution meshes and long simulation runtimes makes it nearly impossible to perform real-time assessments or iterative design modifications. As a result, while CFD offers valuable insights into urban microclimate, its slow performance makes it impractical for the responsive and flexible analysis needed in modern urban development.

Recent advances in deep learning have shown significant promise in directly approximating CFD solutions from boundary conditions (Hao et al., 2023; Z. Li, N. Kovachki, et al., 2023). Once trained, models such as convolution neural networks, neural operators, and transformers can deliver orders-of-magnitude speedups compared to traditional, fine-grained CFD solvers, enabling real-time simulation of urban microclimate. This computational efficiency is pivotal for dynamic urban planning and design. However, these models require extensive, high-quality CFD simulation data to generalize effectively across diverse and complex urban geometries. It often necessitates no fewer than thousands of cases, even for relatively simple scenarios (Wang et al., 2025). This substantial training data requirement remains one of the key challenges in scaling these techniques for broader applications.

In this work, our proposed method leverages localized training combined with a novel geometry encoding scheme to achieve efficient and scalable urban wind field predictions with a remarkably small CFD dataset with only 24 simulations. The approach is based on the assumption that the wind behavior in a complex urban setting is largely dictated by the local building geometries, with distant influences playing a secondary role. By partitioning the overall simulation domain into smaller 3D patches, we effectively reduce the problem's dimensionality and augment the available training data. Within each patch, surrounding geometric information is encoded using a multi-directional distance feature (MDDF), providing detailed context about the nearby urban structures. Our strategy not only enhances the model's ability to predict localized wind phenomena but also benefits from parallel computations, ensuring scalability to large CFD domains with constrained computational resources.

Our experimental results reveal a significant advancement in generalizable urban wind field prediction. By training the localized Fourier neural operator (Local-FNO) model (Qin et al., 2025) on just 24 CFD simulations, with each covering a 1.2 km urban area with a 14.4-million-cell grid at a 4 m horizontal resolution, the model can generate full 3D predictions, including three-dimensional wind velocity and temperature fields, in under one minute. This constitutes an approximate 500-fold speedup over traditional CFD methods that typically require around eight hours for a similar simulation. The model achieves a wind speed mean absolute error (MAE) of 0.3 m/s and a temperature MAE of 0.3 °C, with correlation coefficients reaching 0.98 for both variables. These results highlight the potential of localized training for efficiently modeling wind field under complex urban boundary conditions. Furthermore, as a data-efficient approach, it stands to benefit further from additional training data, promising even more accurate predictions in the future.

2. METHODOLOGY

2.1. Urban Location Selection

We selected 30 urban locations to serve as the training, validation, and testing sets for our deep learning model, focusing on environments with high-rise buildings and complex layouts, the most challenging scenarios for urban wind field prediction. The selection process was based on comprehensive urban morphology indicators. Using the GBMI Tool (Biljecki and Chow, 2022), we extracted key three-dimensional morphological features such as building footprint area, height, and volume, as well as shape complexity metrics (e.g., compactness, equivalent rectangular index) and spatial configuration parameters. These indicators were chosen for their ability to capture the physical attributes and spatial arrangements that significantly influence urban microclimate, wind flow patterns, and energy performance, as demonstrated in prior studies (Hu et al., 2024; Kaseb et al., 2020). Through Euclidean distance analysis of standardized indicators, considering their mean, median, and standard deviation, we identified an initial pool of candidate locations from our database. It should be noted that the final selection of the 30 cities from this pool was not entirely based on these rules. Rather, they were manually chosen by referencing these rules to ensure their suitability for CFD simulation. Figure 1 illustrates the height maps for several selected sites. The dataset was then partitioned into 24 locations for model training, 3 for validation, and 3 for testing.

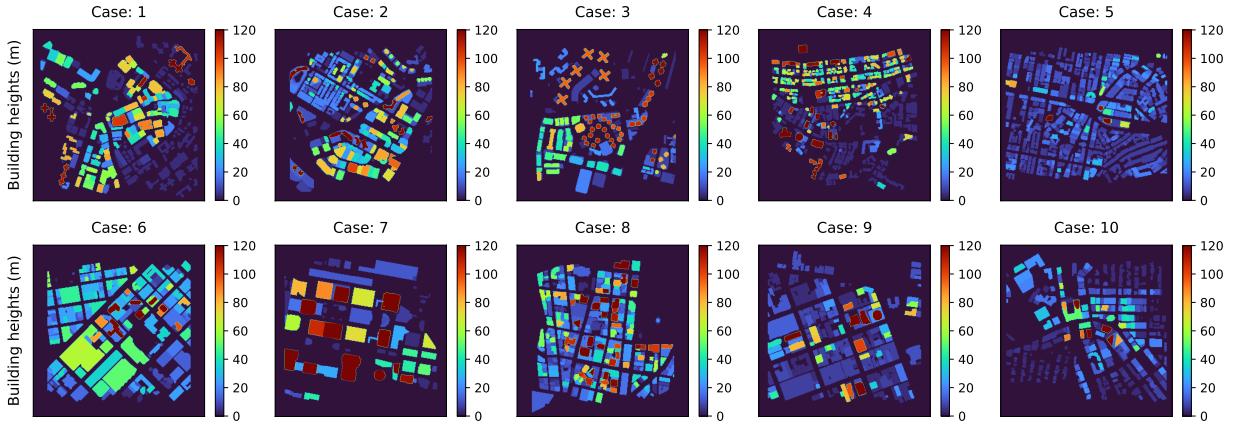

Figure 1. Building height maps for 10 cases in the dataset, covering a 1.2 km $\times$ 1.2 km domain.

2.2. Localized Fourier Neural Operator

The Fourier neural operator (FNO) has garnered attention in solving partial differential equations (PDEs) for its capacity to learn resolution-invariant mappings (Z. Li, N. B. Kovachki, et al., 2021). By operating predominantly in the Fourier domain, FNO efficiently extracts low-frequency global features, which are particularly useful in capturing the overall dynamics of fluid flow. FNO has been successfully applied to predict time-dependent urban wind velocity fields (Peng et al., 2024). However, FNO faces challenges in more complex, high-resolution scenarios, often producing blurry outputs, demanding high GPU memory, and requiring extensive data. The localized Fourier neural operator (Local-FNO) has been introduced to address these issues (Qin et al., 2025). Local-FNO enhances the traditional FNO framework by integrating local training strategies and patch

overlapping techniques, improving prediction quality and data efficiency and boosting generalization for multiscale turbulent flows.

Previous studies on FNO and Local-FNO for microclimate prediction have primarily focused on time-dependent forecasting, where the model takes an instantaneous flow field as input and predicts its future state. This requirement poses a limitation, as it restricts the model's use to scenarios where such input data are readily available. In our work, we extend the capabilities of Local-FNO by directly predicting the time-averaged flow field solely from building geometry. This method is inherently more challenging due to the lack of an input flow field for reference, yet it offers enhanced versatility and applicability, particularly in urban design and planning contexts where only the structural layout is available.

2.3. Multi-directional Distance Feature

The Multi-directional Distance Feature (MDDF) is a novel approach for encoding building geometry, designed to overcome the limitations of traditional signed distance functions (SDF) when applied to small local patches. SDF provides overall distance measurements but lacks the capacity to pinpoint the direction of obstacles within small, local patches, which is a critical shortcoming when predicting complex wind behaviors like the wake effect behind buildings. MDDF overcomes this limitation by calculating the distance to buildings at multiple fixed angles. In the horizontal plane, this is achieved by sampling distances at densely distributed angles over 360°, thereby furnishing every local patch with detailed directional information. For the vertical dimension, the MDDF is limited to a 180° span since the upward distance typically trends toward infinity and offers limited value. Moreover, MDDF's computational complexity scales linearly with the region's side length, in contrast to the SDF, whose complexity is proportional to the total number of grid cells (growing quadratically in 2D). This makes MDDF an efficient choice for encoding detailed urban geometries.

While MDDF employs a dense set of angular samples to ensure accurate encoding of building geometry, each angle's calculation is independent, which allows for effective parallel processing and significant reductions in computational time. In addition, the dense output of MDDF can be efficiently compressed using a Fourier transform, keeping only the essential low-frequency components. This selective retention not only maintains, but often enhances, model performance by filtering out high-frequency discretization noise. It ensures that the feature dimensionality presented to the deep learning model remains relatively low.

2.4. CFD Data Preparation

The CFD airflow and temperature data for training deep learning models are simulated from City Fast Fluid Dynamics (CityFFD) (Mortezazadeh et al., 2022). CityFFD uses a semi-Lagrangian approach and fractional stepping method to enhance accuracy while reducing computational costs. The built-in large eddy simulation (LES) model captures turbulence in the atmospheric boundary layer. A fourth-order interpolation scheme minimizes numerical errors, even on coarse grids. Developed with CUDA-C++ for GPU processing, CityFFD predicts local microclimate conditions and models urban aerodynamics. It has been validated against wind tunnel and real-world data, demonstrating reliability in airflow and temperature predictions (Yang, 2024). Additionally, CityFFD can integrate with WRF and building energy models for comprehensive urban climate

analysis (Zhan et al., 2023).

The CityFFD model numerically solves the governing equations for fluid dynamics, which include continuity, momentum, and energy conservation laws in Equation 1:

$$\begin{aligned} \nabla \cdot \vec{U} &= 0 \\ \frac{\partial \vec{U}}{\partial t} + (\vec{U} \cdot \nabla)\vec{U} &= -\nabla p + \left(\frac{1}{Re} + \nu_t\right)\nabla^2 \vec{U} - \frac{Gr}{Re^2}\,\theta \\ \frac{\partial \theta}{\partial t} + (\vec{U} \cdot \nabla)\theta &= \left(\frac{1}{Re \cdot Pr} + \alpha_t\right)\nabla^2 \theta \ , \end{aligned} \tag{1}$$

where $\vec{U}$, θ, and p denote velocity, temperature, and pressure, while Re, Gr, and Pr represent the Reynolds, Grashof, and Prandtl numbers. ν_t and α_t correspond to turbulent viscosity and thermal diffusivity.

Each of the 20 selected building clusters spans a 1.2 km $\times$ 1.2 km area, containing 200 to 600 buildings. The total computational domain covers 6 km $\times$ 5 km with a height of 2 km, containing 24 million grids. Near buildings, the grid resolution is 4 m $\times$ 4 m horizontally and 1.5 m vertically. The domain's vertical boundaries act as inlets or outlets based on wind direction, while the ground is a no-slip wall and the top is a symmetry plane. Simulations use an air temperature of 30 °C, a west wind at 4 m/s, and a building surface temperature of 40 °C. The wind profile follows a power-law equation:

$$u(z) = u_{\text{ref}} \left(\frac{z}{z_{\text{ref}}}\right)^{\alpha}, \tag{2}$$

where $u(z)$ is wind speed at height z, with $\alpha = 0.15$, $z_{\text{ref}} = 10$ m, and $u_{\text{ref}} = 4$ m/s. A time step of 0.5 s ensures a CFL number (Courant et al., 1928) of 0.5, calculated as $\text{CFL} = u \times \frac{\Delta t}{h_{\text{cell}}}$, where u is the local velocity and h_{cell} is the local cell size. Each simulation utilizes a single GPU and requires approximately 8 hours to achieve statistical stability. The final dataset includes the time-averaged wind field after convergence.

2.5. Model Training

The training leveraged wind field data from 30 cities, with the dataset partitioned into 24 cases for training, 3 for validation, and 3 for testing. To effectively increase the number of samples, each training instance was augmented by mirroring while preserving wind direction. The input data, with dimensions of $300 \times 300 \times 160$, is processed during training by randomly sampling local patches of size $46 \times 46 \times 48$ from the entire domain. For testing, these patches are arranged in a grid with overlapping regions so that only the central, more reliable areas contribute to the final prediction, thereby mitigating higher errors near patch boundaries. The input features include global coordinates, SDF, and MDDF.

Model training was conducted on a single 32GB GPU using the AdamW optimizer combined with a step learning rate scheduler and early stopping based on validation performance. The training comprised 100 epochs, with each epoch taking approximately 10 minutes, totaling around 16 hours. After training, the model is capable of predicting a full 3D wind field in 10 seconds. In

practical applications, when building geometry is provided as input, additional computation time is required for calculating SDF and MDDF. Nevertheless, the overall prediction time remains within one minute.

3. RESULTS

We demonstrate the performance of Local-FNO with MDDF on an unseen test case. Figures 2 and 3 show horizontal and vertical slices of the wind field's u, v, and w components, as well as temperature. The model effectively captures the overall flow pattern. Notably, the u component, which is aligned with the prevailing wind direction, achieves an MAE of 0.26 m/s and a correlation coefficient of 0.98, while temperature predictions reach an MAE of 0.27 °C with the same high correlation of 0.98. The v and w components exhibit lower correlations at 0.82, reflecting the greater complexity and sensitivity of these directions to building geometries. Although Local-FNO does not replicate every intrinsic small-scale flow feature within complex urban settings, it delivers fast and acceptable predictions in under one minute, despite being trained on only 24 CFD simulations. This high data efficiency suggests that performance can be further enhanced with additional training data. While localized training and testing result in visible discontinuities at patch boundaries, these artifacts can be mitigated using post-processing techniques such as smoothing.

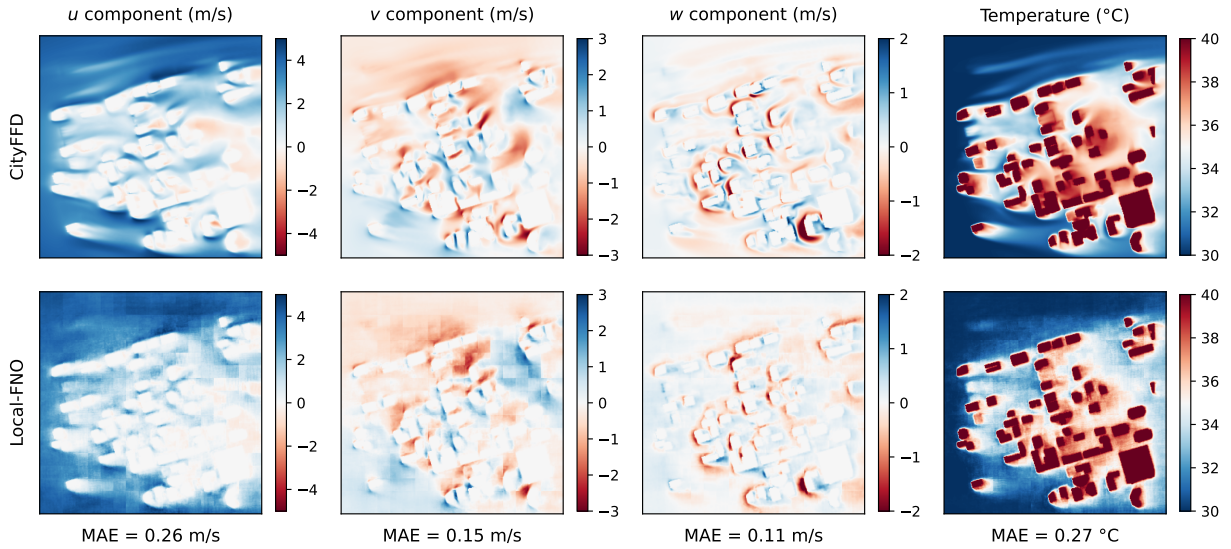

Figure 2. Visualization of wind speed and temperature for CityFFD and Local-FNO at a 30 m horizontal plane.

In Figure 4, we illustrate the flow stream as predicted by Local-FNO. The model effectively reproduces the general flow pattern, though discrepancies remain in the wake regions behind buildings relative to CityFFD.

4. CONCLUSIONS

This study presents a highly data-efficient deep learning framework that leverages localized training combined with a novel multi-directional distance feature encoding. Trained on just 24 CFD

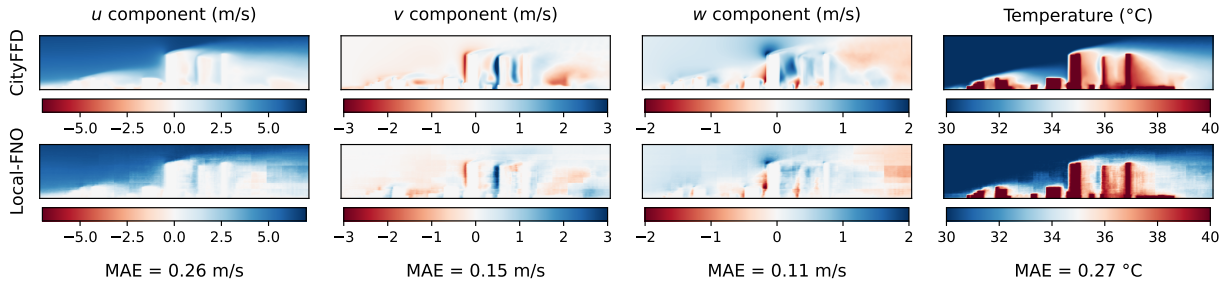

Figure 3. Visualization of wind speed and temperature for CityFFD and Local-FNO at a vertical plane.

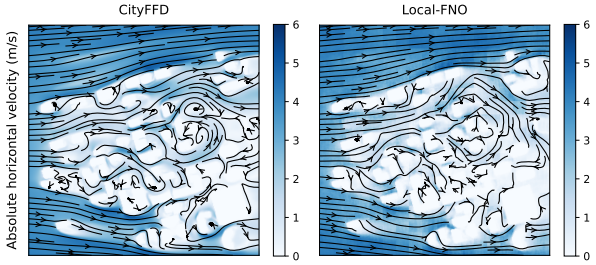

Figure 4. Visualization of flow stream for CityFFD and Local-FNO at a 30 m horizontal plane.

simulations, our approach successfully generalizes to new and complex urban geometries, delivering full 3D wind field predictions in under one minute. By directly leveraging building geometry to predict airflow and temperature, our approach holds substantial promise for enhancing applications in urban design and planning. Future work will focus on incorporating additional training data to further improve accuracy, refining post-processing techniques to smooth patch discontinuities, and exploring alternative model architectures beyond neural operators. These initiatives aim to further strengthen the accuracy and scalability of our framework for broader urban applications.

SUMMARY
The study examines the influence of grid resolution in large-eddy simulations (LES) on predicting low-occurring wind gust events around a single isolated building (1:1:2) at a pedestrian height. Four grid size configurations (H/30, H/40, H/60, H/80) were evaluated by comparing LES predictions of wind speed with wind tunnel experiment (WTE) data. The accuracy of LES in capturing low-occurring peak wind speeds was assessed using power spectral density and peak factor analysis. The peak factors were calculated at 5%, 1%, and 0.1% exceedance probability values. While finer grids improved predictions, this came at a significantly higher computational cost. Among the tested configurations, the H/60 grid achieved normalized mean square error convergence, capturing almost 80% of peak factor measurements within 20% deviation from WTE results at 0.1% exceedance probability. However, the H/40 grid offered the optimal balance between accuracy and cost.

Keywords: Low-occurring high wind speed, LES, Pedestrian wind, wind gust

1. INTRODUCTION

In computational wind engineering, pedestrian-level wind environments have traditionally been evaluated using Reynolds-averaged Navier-Stokes (RANS) equations due to their ability to predict high mean wind speed regions with reasonable accuracy (Tominaga et al., 2023). However, RANS simulations often underestimate turbulent kinetic energy (TKE), leading to poor predictions for high-speed wind events such as wind gusts (Shirzadi and Tominaga, 2022). Although the coefficient in RANS can be tuned for TKE prediction, with advancements in computational power, large eddy simulation (LES) has gained some popularity as it offers higher accuracy than RANS in predicting mean wind speed and turbulent intensity (Zhong et al., 2022). Nevertheless, a key advantage of LES is its generation of ample time-series data, enabling detailed studies of gusts and peak wind events. Such analyses are important for ensuring pedestrian and cyclist safety for ground-level wind, facilitating safe drone operations, and identifying suitable locations for rooftop wind turbines.

The accuracy of LES and the amount of turbulence fluctuation that LES captures depends on the filter width conceptually applied to the governing equations, usually based on the grid size. While larger turbulent scales are resolved, smaller scales are modeled, making grid resolution a critical parameter. Given the computational expense of LES, simulation must be conducted with best practices to save time and cost and utilize its benefits for evaluating details of flow fields (Tominaga, 2024). Therefore, to establish good practices for LES for pedestrian-level wind

environments, researchers have focused on the benchmark case of a single isolated building. Various sensitivity analyses have been conducted, including blending first-order and second-order schemes (Ikegaya et al., 2018), timestep discretization (Liu and Niu, 2016), subgrid-scale (SGS) modeling, convergence criteria, and grid sensitivity using orthogonal meshes (Okaze et al., 2021). For a single isolated building, dividing the width and height into 20 and 40 equal parts, respectively, has been shown to provide sufficient resolution to predict mean flow and second-order turbulent statistics.

While these studies on LES suggested a minimum grid size of H-40, where H represents the building height, they do not address the sensitivity of grid sizes to low-occurring peak wind predictions. Unresolved part of turbulence in LES can cause peak wind events at pedestrian levels, such as gusts, one of the concerns for elderly pedestrian and cyclist safety. This study aims to fill this research gap by investigating the influence of grid resolution on the accuracy of LES in capturing low-occurring peak wind events at the pedestrian level. By analyzing the grid sensitivity for predicting rare gust occurrences, this research seeks to suggest and find an optimal trade-off between computational cost and accuracy.

2. METHODOLOGY

The wind tunnel experiment (WTE) was conducted at Tokyo Polytechnic University, Japan, using an open-circuit wind tunnel and a 1:1:2 (length, width, and height) single isolated building block model (Okaze et al., 2021). The Reynolds number, based on the building height H (0.2 m) and mean wind speed, was approximately 4.3×10^4. The measurements were taken at a sampling frequency of 1000 Hz for 60 seconds. Fig. 1 illustrates the locations of 383 sampling points at pedestrian height ($z = \mathrm{H}/16$). Complete details of the WTE setup and dataset are available in the referenced literature (AIJ, 2020) case-H.

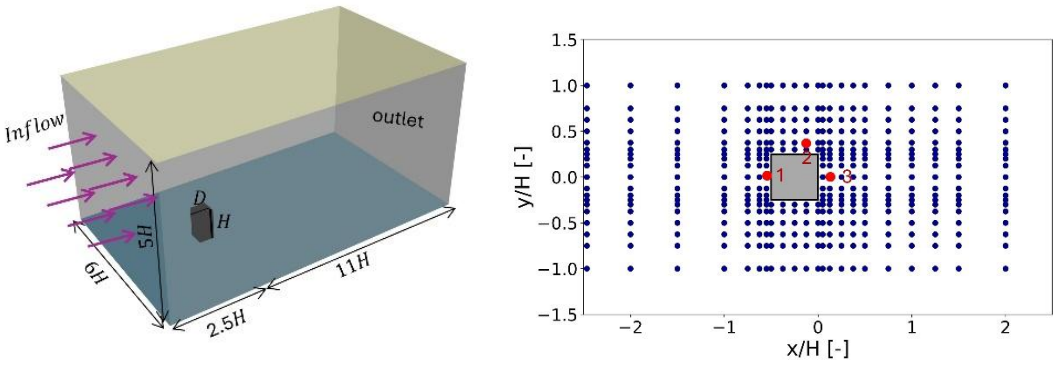

Figure 1. Shows the schematic of the WTE (left) and the location of points sampled on the pedestrian plane.

LES is performed on the same block model in OpenFOAM-v2206, replicating the WTE conditions. The computational domain extends 11 H(x) × 6 H(y) × 5 H(z) (streamwise, lateral, and vertical) following the computational wind engineering guidelines (Franke et al., 2011). The blockage ratio is about 1.67%. Fig. 1 presents a schematic of the LES domain setup, while Table 1 outlines the numerical conditions of the LES.

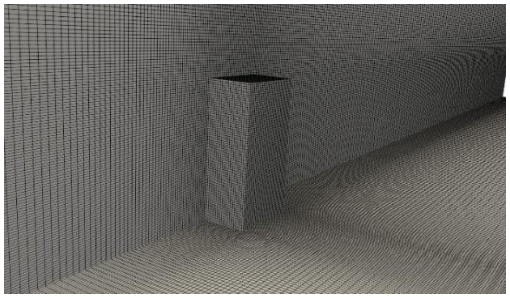

Figure 2. Grid illustration for grid cases. This figure represents the H-80 case.

For peak wind analysis, it is important to extract the simulation time-series data at the same sampling rate as the WTE. Accordingly, LES time-series velocities are sampled at a frequency of 1000 Hz for a duration of 40 s. All the analyses are non-dimensionalized using the building H and mean inlet velocity at the building height ($U_{\mathrm{H}} = 4.69\ m/s$).

Table 1. LES parameters setup

Settings	Details
Inflow	Precursor turbulence inflow data set obtained from the additional LES applied as time-varying mapped fixed boundary condition.
Wall B.C (top, building, sides and bottom)	Spalding wall function
Spatial discretization	Advection Filtered Linear 2V, and 2nd order central difference for remaining
Time step	1×10^{-4} s. maximum Courant number < 1
Time discretization	2nd order backward
Pressure-velocity coupling	PISO

2.1. Computational Grid

To investigate the impact of grid resolution on peak wind predictions, four grid configurations consisting entirely of hexahedral cells with building refinements (H/30, H/40, H/60, and H/80) are analyzed for sensitivity analysis. The cells near the building maintain an aspect ratio of one and are gradually stretched away from the building (stretching factor less than 1.04), as illustrated in Fig. 2. The time step was kept consistent across all grid refinement cases to ensure that any inaccuracies in wind predictions were solely attributed to grid resolution, thereby providing a clear evaluation of grid sensitivity on LES accuracy. The maximum Courant number was maintained below 0.7 for the finest grid case, resulting in even lower numbers for the coarser grid cases. The finest H-80 grid required 24 times more computational power than the coarse H-30 grid. Details of the refinement configurations are summarized in Table 2.

Table 2. Cases for grid sensitivity analysis.

Cases	Cell size building height	No of Cells (Millions)	Number of cells from ground to the pedestrian height	Average y^+ building block	Duration on 20 CPU (Wall clock hrs.)
H-30	H/30	0.65	1.9	58.98	34.6
H-40	H/40	1.49	2.5	46.97	68.4
H-60	H/60	4.3	3.75	31.58	162
H-80	H/80	9.7	5	23.82	824

2.2. Gust wind analysis

Accurately capturing peak gust wind velocities is crucial when assessing the safety of pedestrian wind environments (Hunt et al., 1975). Wind gust values are commonly evaluated in terms of mean μ_s and standard deviation (σ_s) at any exceedance probability as:

$$U_g = \mu_s + K(\sigma_s) \quad (1)$$

Where, K is the peak factor that quantifies the extremeness of gust wind speeds relative to the turbulence, expressed in terms of standard deviation. Low-fidelity models often assume a constant value of peak factor K, which can range between 0-3.5. However, there is no universal consensus on the appropriate value for pedestrian distress criteria (Vita et al., 2020). In this study, we calculated the peak factor (K_q) to better represent, low-occurring high wind speed events. The K_q is defined in terms of the probability of exceedance of the wind speed (s_q) as:

$$K_q = \frac{s_q - \mu_s}{\sigma_s} \quad (2)$$

Here, μ and σ are the mean and standard deviation of the wind speed s. Exceedance probabilities of 0.1%, 1%, and 5% indicate low-occurring high wind speed events at the pedestrian level. For example, a 0.1% exceedance probability corresponds to the 99.9th percentile wind speed, meaning only 0.1% of recorded samples surpass this threshold. With 40,000 samples collected over 40 s (1000 Hz sampling), this equates to 40 exceedances (0.04s). When scaled to the full 1.78-hour dataset, total exceedance reaches approximately 6.4 seconds.

3. RESULTS AND DISCUSSION

The results are presented in two parts: first, comparing LES wind speed spectra with WTE spectra and analyzing resolved TKE across grids; second, calculating and comparing the peak factor from Eq. (2) for LES and experiment.

3.1. Power spectra density and turbulence

Fig. 3 compares the power spectral density (PSD) of wind speed obtained from the WTE and LES across four grid refinements. This analysis is conducted for three probe points located at pedestrian height, z/H=1/16 (corresponding to 2 m in full scale). The probe locations are defined as follows: upstream of the building block where the horseshoe vortex forms (x/H = -0.55, y/H = 0), on the side of the building (x/H = -0.125, y/H=0.375), and downstream of the building (x/H= 0.125, y/H=0). These locations are marked in red in Fig. 1. Spectra are normalized with frequency and variance.

At point 1 (Fig. 3a), the spectral cutoff is observed at $f\mathrm{H}/U_{\mathrm{H}}$ = 1 for the H-30 grid, highlighting its limited resolution in capturing high-frequency turbulence in the inertial subrange, as indicated by the deviation from the −2/3 slope. With progressive grid refinement, the resolution of TKE improves, enabling the PSD to capture smaller-scale structures in the inertial subrange, with the normalized cutoff frequency extending to approximately 3-6 for the H-80 grid. At point 2 (Fig. 3b), the finest H-80 grid sustained the PSD at higher frequencies with more PSD spikes in the inertial subrange than observed in the experiment. This can be due to the numerical oscillation due to the 2nd-order central differencing scheme. At point 3 (Fig. 3c), all grid sizes adequately capture

the PSD peak. However, the downstream location is less susceptible to the numerical oscillation observed near sharp gradients or corners.

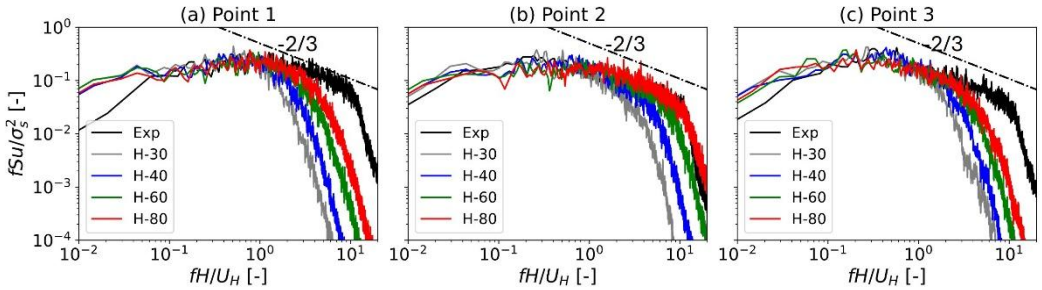

Figure 3. Wind speed power spectra density at three different locations of the pedestrian plane. Labels represent the grid refinement cases.

Fig. 4 illustrates iso-contours of the Q-criterion, highlighting vortical structures across four grid cases. As grid resolution increases (Fig. 4a–d), more flow structures are directly resolved by LES. While larger turbulence structures are captured on coarser grids, finer grids resolve smaller eddies, reducing subgrid-scale modeling. Notably, Fig. 4c and 4d show increased small-scale turbulence at pedestrian height, extending energy density spectra to higher frequencies (Fig. 3).

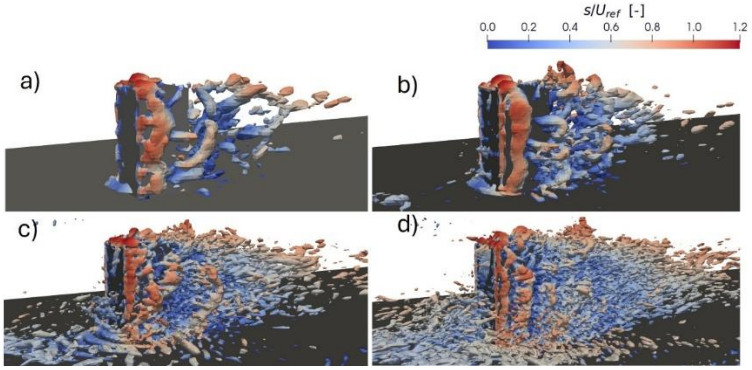

Figure 4. Comparison of iso-contours of the Q-criterion at $Q = 10000\ s^{-2}$ for four grid resolutions: a) H-30, b) H-40, c) H-60, and d) H-80.

The LES quality index proposed by (Celik et al., 2005) quantifies the ratio of resolved TKE to total TKE, which is defined as:

$$\mathrm{LES_{IQ}} = \frac{k_{res}}{k_{res}+k_{sgs}} = \frac{k_{res}}{k_{res}+a_k\Delta^p} \quad ,where\ k_{res} = \frac{1}{2}(\overline{u'u'} + \overline{v'v'} + \overline{w'w'}) \tag{3}$$

$$a_k\Delta^p = \frac{k_{res2}-k_{res1}}{\alpha^p-1} \quad ,where\ \alpha = \frac{\Delta_1}{\Delta_2} > 1 \tag{4}$$

Here, k_{res} is the resolved turbulent kinetic energy, Δ is the grid size, and $p = 2$ is the order of numerical accuracy. Fig. 5 presents a scatter plot illustrating the distribution of resolved TKE across different grids. The finer grid cases (H-40 and beyond) resolve more than 80% of the TKE, whereas the H-30 case resolves less than 80% of the TKE at pedestrian-level height, indicating a lower LES resolution in that region.

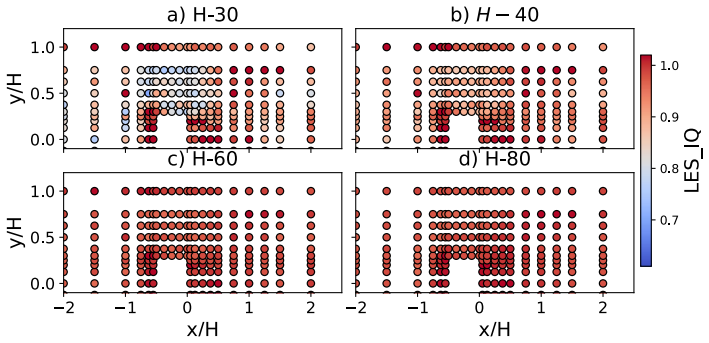

Figure 5. Scatter plot at pedestrian height colored by LES quality index for four grid refinement cases: a) H-30, b) H-40, c) H-60, and d) H-80.

3.2. Peak Factor

Fig. 6 presents a scatter plot comparing the peak factor at probabilities of exceedance of 5%, 1%, and 0.1%, representing high wind speed events of varying rarity, for four grid refinement cases in LES against WTE data. Two dotted lines indicate a ±20% deviation.

For the 5% exceedance probability (Fig. 6a), the peak factor values range from 1.5 to 2.3, with approximately 99% of the data points for all grid refinement cases falling within the ±20% deviation. At the 1% exceedance probability (Fig. 6b), which corresponds to rarer high-speed wind events, peak factor values range from 2 to 3.5. The data exhibits greater scatter compared to the 5% exceedance probability, though most points still lie within the ±20% accuracy range.

At the 0.1% exceedance probability (Fig. 6c), representing extremely rare high wind speeds, the peak factor values span from 3 to 5.5 across various locations. The scatter decreases progressively with finer grid refinement, indicating improved accuracy in predicting extreme wind phenomena. Overall, across all exceedance probabilities, LES predictions show a consistent overprediction of the peak factor compared to the WTE results.

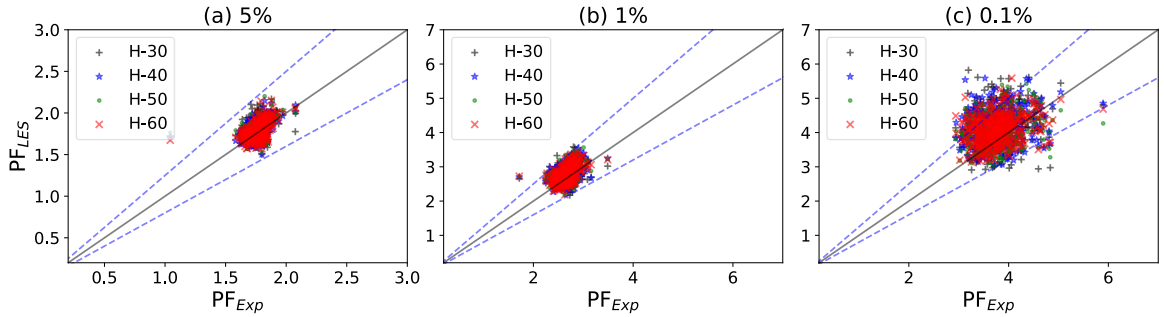

Figure 6. Scatter plot comparing peak factor values for 4 grid refinement cases with the experiment at 5%, 1%, and 0.1% probability of exceedance value. The blue line shows the 20% deviation.

The error metric for peak factor prediction is quantified in terms of normalized mean square error (NMSE), which represents the measure of scatter and, therefore, accounts for both systematic and random errors. It is defined as:

$$\text{NMSE} = \frac{\langle (O-P)^2 \rangle}{\langle O \rangle \langle P \rangle} \quad (5)$$

Here O is the observed peak factor and P is the predicted peak factor. For an ideal prediction, NMSE=0. The NMSE results, shown in Fig. 7a, are presented for the exceedance probability of 5%, 1%, and 0.1%. However, the NMSE results in Fig. 7b show the convergence of the grid as the O value in the NMSE equation is taken for the H-80 grid. Overall, the NMSE value increases as the exceedance probability decreases, indicating higher errors for lower-occurring high wind speed events. With successive grid refinements, the predictions improve as more high-frequency turbulence is resolved rather than modeled.

Although H-40 grid resolution resolves 80% of the turbulent kinetic energy at a 0.1% exceedance probability, the NMSE only converged for the H-60 (Fig. 7a) when compared to the experiment. However, in practicality, H-40 is an adequate resolution for sufficiently predicting very low-frequency extreme wind events. This grid resolution corresponds to the number of cells near 3 between ground and pedestrian height of 2 m, ensuring sufficient resolution for vortices resolution and reliable predictions.

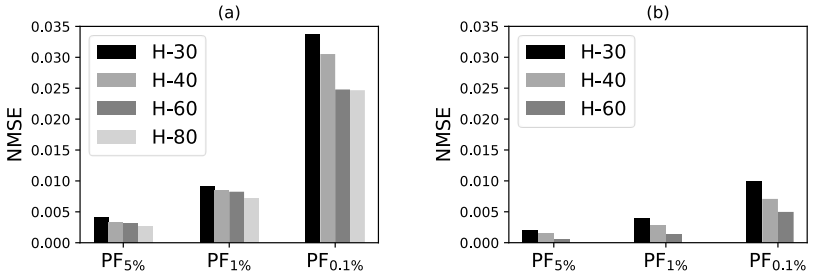

Figure 7. a) Bar graphs illustrate NMSE for four grid refinement cases at 5%, 1%, and 0.1% exceedance probabilities, comparing them with experimental data. b) shows the NMSE error of the coarser grid compared to the fine grid case. The bar color distinguishes grid refinement cases with each successive refinement.

CONCLUSION

This study examined the influence of grid resolution on low-occurring peak wind speed events at the pedestrian level, using a single isolated building block (1:1:2) as a benchmark case. Four grid resolutions (H/30, H/40, H/60, and H/80) were compared against WTE results. The findings demonstrated good overall predictions for peak factors for all the grid cases, with deviations within 20% for exceedance probabilities between 5% and 1%, representing high wind speed events. However, for a 0.1% exceedance probability, representing very rare high wind speed peaks, the grid resolution of H-60 achieved convergence for reliable prediction. This resolution included three cells from ground to pedestrian height and discretization of the building into 30 cells for width and 60 cells for height, resulting in nearly 80% of pedestrian regions being predicted within 20% deviation for 0.1% exceedance probability events. While grid refinement enhanced the accuracy of peak factor predictions, it came at an exponentially higher computational cost. Moreover, the grid resolution of H-40 and above was sufficient to resolve 80% of the TKE. Considering that H-60 grid resolution costs almost 3 times more computational power, the H-40 grid can still be used with reasonable accuracy for practical purposes.

Since this study is on a simplified benchmark case of a 1:1:2 building block with an impact on the surrounding flow at the pedestrian level, in real-world scenarios, the flow can be far more complex, with turbulence generated by smaller structures that can contribute to extreme peaks of wind speed. Therefore, further research efforts are needed to develop more complex benchmark cases that provide sufficient temporal resolution of velocity measurements for studying peak wind events and enabling meaningful comparison with the LES predictions.

SUMMARY
Thunderstorm outflows generate intense near-ground winds that can threaten urban safety. Previous studies have primarily focused on isolated outflows. As a result, the interaction between thunderstorm outflows, atmospheric boundary layer (ABL) winds, and urban geometries remains relatively underexplored. This study uses Computational Fluid Dynamics (CFD) to simulate outflow propagation within a street canyon in the presence of a background ABL wind. The CFD simulations closely reproduce wind tunnel measurements, highlighting the CFD's ability to complement experiments and provide detailed insights into urban wind dynamics. The low-Reynolds $k-\varepsilon$ turbulence model, with fine grids and low y^+ values, effectively resolves near-wall flow dynamics. The results show that street canyons amplify and sustain higher wind speeds, particularly at the pedestrian level, compared to open areas. This increases aerodynamic loads and makes urban infrastructure more vulnerable to wind damage, which highlights the critical role of urban geometry in determining outflow impacts.

Keywords: Thunderstorm outflow, CFD, Experiment, Street canyon.

1. INTRODUCTION

Thunderstorm outflows are characterized by intense winds near the ground and transient, localized flow conditions (Hjelmfelt, 1988), which differentiate them from typical atmospheric boundary layer (ABL) winds. These extreme wind events pose significant threats to urban infrastructure and public safety (Bélair et al., 2025; Solari et al., 2020). Research indicates that maximum radial outflow velocities typically occur between 50 and 120 m above ground level (Hjelmfelt, 1988) and cause substantial aerodynamic loads on structures (Solari, 2014).

The highly non-stationary and localized nature of thunderstorm outflows makes it difficult to capture these events with adequate spatiotemporal resolution, leading to limited full-scale data. Moreover, physical simulations in controlled facilities (i.e., wind tunnels) are costly (Hangan et al., 2017) and face limitations in rendering different configurations and scenarios. Computational Fluid Dynamics (CFD) is an effective approach to complement experiments by providing detailed insights into full-field flow characteristics. It also helps in interpreting complex flow dynamics that are often challenging to achieve through physical measurements alone.

Several techniques exist to simulate a thunderstorm outflow. One common approach is the impinging jet: a turbulent, axisymmetric air jet that impinges the ground perpendicularly and spreads radially. This method is widely acknowledged in wind engineering for its ability to replicate key dynamical features of an outflow, such as the primary and secondary vortices. The present research adopted the impinging jet approach.

Previous studies have thoroughly investigated the effects of ABL winds in urban environments (Blocken, 2014; Hadavi and Pasdarshahri, 2020). Similarly, the dynamics of an isolated thunderstorm outflow in an empty chamber is well-documented (Romanic et al., 2020a, Žužul et al., 2023). However, the interaction between thunderstorm outflows, background ABL winds, and urban geometries remains relatively underexplored—a critical gap given the projected increase in frequency and intensity of thunderstorms (Rädler et al., 2019). To address this research question, the present study numerically simulates the propagation of a thunderstorm outflow within a well-known urban configuration—a street canyon—in the presence of a background ABL flow.

2. METHODOLOGY

This research utilizes CFD to replicate the wind tunnel experiments conducted by Richter et al. (2018). They physically simulated a negatively buoyant gust using a jet impinging on a street canyon under the influence of a background ABL wind. Velocity fields within the canyon were measured using a two-dimensional Time-Resolved Particle Image Velocimetry system.

2.1. Scales

Figure 1 shows the computational domain and boundaries, with dimensions based on the experimental setup. The jet flow is ejected from a 10 mm diameter tube connected to pressurized air. The jet outlet is positioned 310 mm above the surface.

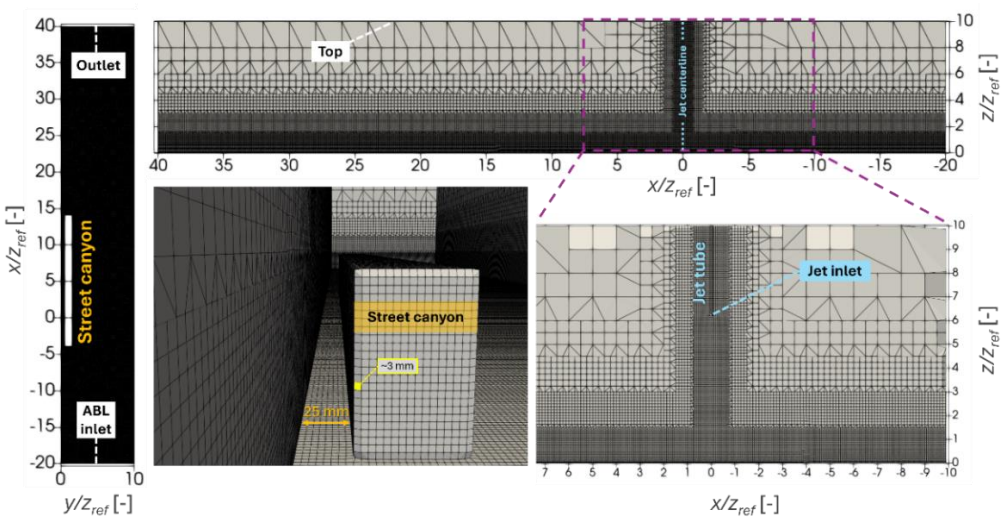

Figure 1. Computational domain with grid details and boundaries indications.

The street canyon model has dimensions of 75 mm in height, 50 mm in width, and 900 mm in length (Fig. 1). At a 1:200 scale, this represents a road width of 10 m and a low-rise building height of 15 m in reality. In addition to the original street canyon from Richter et al. (2018), the present study investigated a high-rise canyon with a height of 250 mm (equivalent to 50 m in reality), while maintaining the same width and length. For normalization, a reference height of 50 mm was selected, along with $U_{ref} = U(z_{ref})$, where U_{ref} represents the velocity of the background ABL flow in open terrain (i.e., without the canyon model).

2.2. CFD simulations

The steady-state and isothermal CFD simulations were performed using the simpleFoam solver from the OpenFOAM v2306 open-source CFD library. This solver employs the Semi-Implicit Method for Pressure-Linked Equations (SIMPLE) algorithm to solve the coupling between velocity and pressure in the Navier-Stokes equations. To save computational resources, half of the experimental setup was modeled (Fig. 1), assuming axisymmetric behavior. This approach is commonly used in CFD literature on flows that are symmetric along a plane (e.g., Žužul et al., 2023; Kim and Hangan, 2007). At the jet outlet face, a velocity of 45 m s^{-1} was prescribed, with the downward flow being perpendicular to the ABL flow. The developed ABL profile from an empty chamber was imposed to represent the background ABL flow. A zero-gauge pressure condition was applied at the outlet face. The near-wall flow was modeled using the atmWallFunction class for smooth surfaces.

The snappyHexMesh utility was used to generate a hexahedron-based unstructured mesh from a background grid created using the blockMesh tool. As shown in Fig. 1, the grid was significantly refined in critical regions, including the downdraft zone and the area where the outflow interacts with the street canyon. The grid sensitivity analysis was conducted by constructing three computational grids. The grid refinement factor is approximately 3.3 between the coarse (1.5 million cells) and medium (5 million cells) grids, and 1.9 between the medium and fine (9.4 million cells) grids. To quantify the error of the medium mesh compared to the fine mesh, the Grid Convergence Index (GCI) method is employed (Roache, 1994):

$$GCI = \frac{F_s|\epsilon|}{r^p - 1} \tag{1}$$

where F_s is the safety factor equals to 1.25, ϵ is the velocity relative error between the medium and fine mesh, r is the grid refinement factor, and p is the order of accuracy of the computation.

The first cell layer near the bottom surface was refined to 3 mm, yielding about 25 cells across the canyon height. Additionally, five cell layers with a growth ratio of 1.25 were added to the solid surfaces of the ground and canyon to maintain y^+ values within the desired range while minimizing computational cost.

The Reynolds-Averaged Navier-Stokes (RANS) approach was adopted to model turbulence. Four $k-\varepsilon$ and two $k-\omega$ turbulence models were tested: the standard $k-\varepsilon$, the realizable $k-\varepsilon$, the re-normalized group (RNG) $k-\varepsilon$, Launder and Sharma low-Reynolds $k-\varepsilon$, the standard $k-\omega$, and the shear stress transport (SST) $k-\omega$. Here, k is the turbulent kinetic energy, ε is the turbulent kinetic energy dissipation rate, and ω is the specific dissipation rate.

3. RESULTS

The comparison of turbulence models demonstrates the superior performance of the low-Reynolds $k-\varepsilon$ model, particularly when the canyon is present (not shown here due to the space limitation). For the case of open terrain (ABL+Jet), the performance of the standard $k-\varepsilon$ model is nearly equivalent to that of the low-Reynolds $k-\varepsilon$ model. The low-Reynolds $k-\varepsilon$ model is particularly effective in capturing near-wall flow characteristics. It resolves flow through the

viscous sublayer by utilizing thin cell layers with low y^+ values. Table 1 presents the y^+ values for each of the three simulated scenarios. The low y^+ values highlight the effective near-wall resolution achieved in this study. Table 1 also includes the GCI values for the medium-to-fine grid comparison. Given the low values of GCI on the two considered lines, it can be concluded that the medium grid successfully provides grid-independent results.

Table 1. y^+ values for each scenario in the form of [minimum, average, maximum]. GCI values for the medium-to-fine grid comparison are also reported; GCI_X: along a horizontal line (-6 < x/z_{ref} < 20) at y=0 and z=z_{ref}; GCI_Z: along a vertical line (0 < z/z_{ref} < 1.2) at y=0 and x/z_{ref}=5.7.

Scenario	y^+ Ground	y^+ Canyon	GCI_X $_{medium/fine}$	GCI_Z $_{medium/fine}$
ABL + Canyon	[2.2, 2.7, 3.0]	[0.1, 2.2, 4.2]	0.32%	0.16%
ABL + Jet	[1.1, 3.1, 5.9]	NA	1.11%	0.78%
ABL + Jet + Canyon	[2.1, 2.7, 3.1]	[0.2, 3.2, 8.8]	1.65%	1.06%

Figure 2 compares CFD and wind tunnel measurements for open terrain and street canyon scenarios via vertical profiles of horizontal velocity. To ensure consistency with the experimental study, the background ABL profile is subtracted. Overall, the CFD simulations accurately replicate the physical experiments, as evidenced by the Root Mean Square Error (RMSE) values (Fig. 2). The peak velocity reproduced in the CFD results cannot be fully confirmed due to absence of measurement data near the bottom surface, thereby highlighting the supplementary nature of CFD simulations to physical experiments. There is a trend of increasing error downstream from the downdraft, particularly in the canyon case. The CFD simulations become less accurate as the flow develops within the canyon after impingement, likely due to the turbulent eddies being modelled rather than resolved in the RANS turbulence models. Additionally, Fig. 2 shows that the horizontal velocity within the street canyon is higher at all heights compared to the open terrain case.

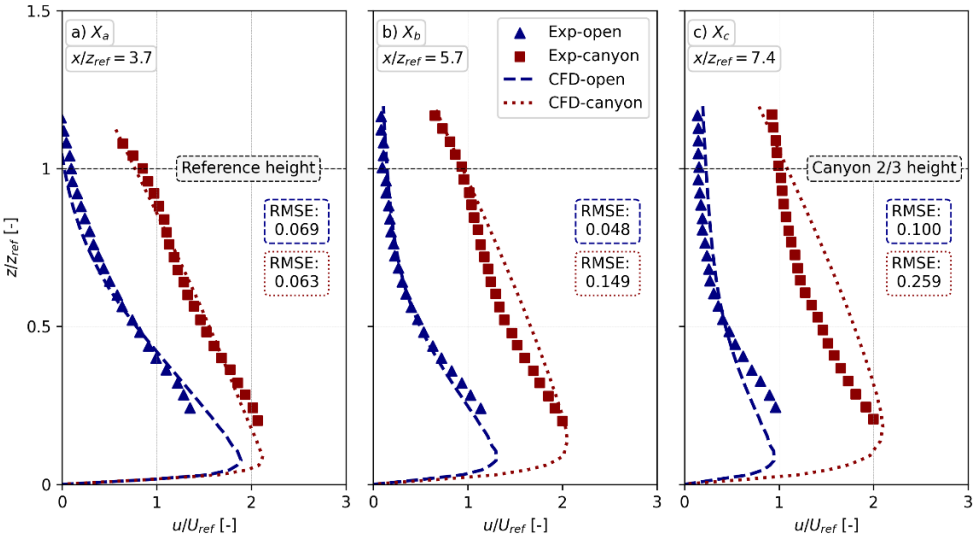

Figure 2. (a-c) Vertical profiles of normalized horizontal velocity at three streamwise positions downstream of the jet with y=0, comparing thunderstorm outflow propagation in open terrain and within a street canyon. The background ABL profile is subtracted. RMSE values quantify the difference between CFD and physical measurements in each case.

Figure 3 illustrates the development of horizontal wind along a horizontal line at z/z_{ref}=0.5, 1, 1.5, 2. This figure compares three background ABL velocities of ~2.3, 4.5, and 9.0 m s^{-1} at canyon height, corresponding to U_{Jet}/U_{ABL} ratios of 20, 10, and 5, respectively. The jet flow is entirely dissipated at the highest ABL velocity, with no peak observed. A slight velocity increase is noted for U_{Jet}/U_{ABL}=10 at x/z_{ref} ≅10, indicating that the touchdown point is advected downstream compared to U_{Jet}/U_{ABL}=20. Interestingly, near the ground in the canyon scenario (Fig. 3h), the lowest ABL case shows a velocity peak exceeding the other two cases. This demonstrates the nonlinear interaction between ABL and outflow winds. The combined flow is influenced by complex flow dynamics, such as turbulence, shear, and mixing, which prevent the velocities from simply adding up. This result aligns with Moeini and Romanic (2023), who proposed an analytical solution of the interaction between the ABL wind and isolated outflow.

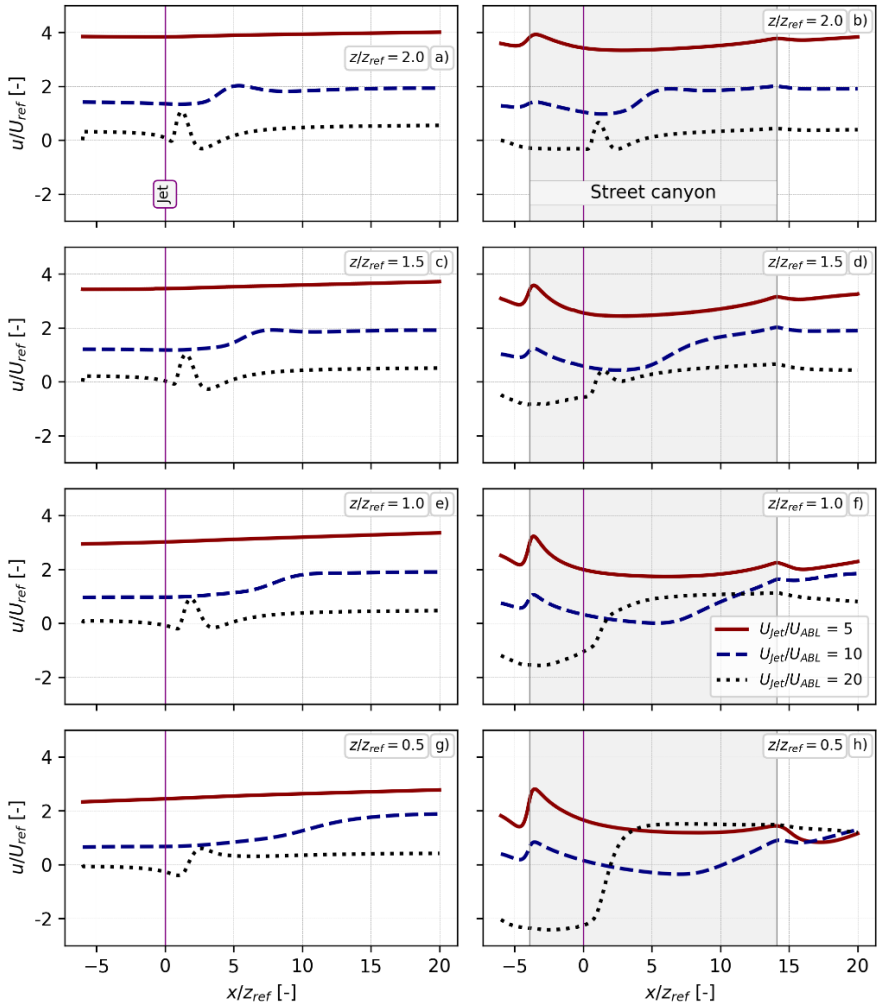

Figure 3. Horizontal wind speed development along the canyon centerline (y=0) at four different heights: (a-b) z/z_{ref}=2; (c-d) z/z_{ref}=1.5; (e-f) z/z_{ref}=1; (g-h) z/z_{ref}=0.5. The left column represents the open terrain scenario (ABL + Jet), while the right column shows the street canyon scenario (ABL + Jet + Canyon), with the canyon location shaded. The jet centerline is marked by a purple line at x=0 in all panels. Results are presented for U_{Jet}/U_{ABL} ratios of 20, 10, and 5, corresponding to three different background ABL velocities.

When the ABL is weak (i.e., U_{Jet}/U_{ABL}=20), the high velocities at approximately $x/z_{ref} = 2.5$ in the open terrain start to decrease soon after the downdraft region (Fig. 3a, c, e, g), which is a narrow region due to the small jet diameter. In contrast, velocity decay is less pronounced within the street canyon. As shown in the velocity contours (Fig. 4), the background ABL wind quickly weakens the jet in the open terrain, whereas the street canyon retains higher velocities after jet impingement by restricting the flow from spreading out. This flow dynamics results in maintaining the high wind intensity throughout the canyon (Fig. 4b). Noticeably, the canyon intensifies the negative impact of the outflow on the built environment. With the increased vertical distance from the canyon, the flow becomes similar to the open terrain (Fig. 3a-b and Fig. 4a-b).

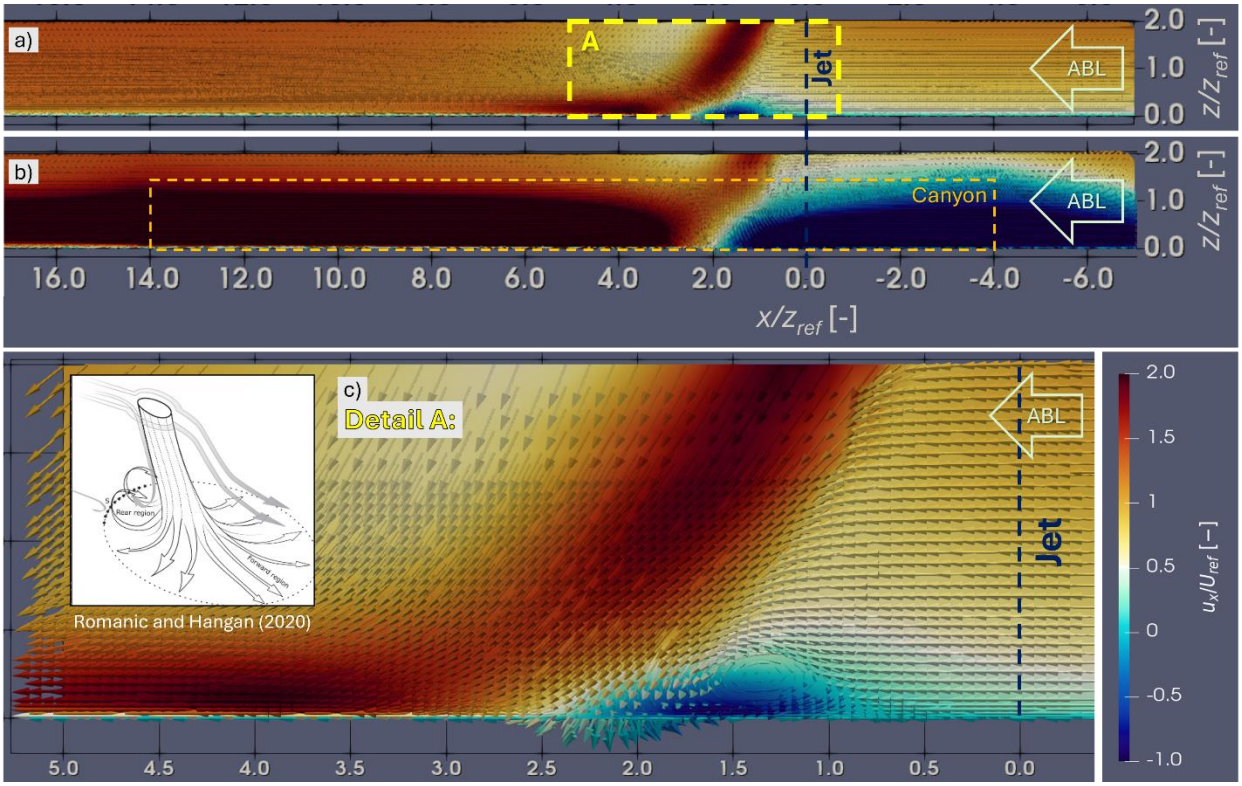

Figure 4. Sideview of the velocity contours and arrows of normalized horizontal velocity at y=0 for the scenarios of a) open terrain and b) street canyon. c) A zoom-in view of the touchdown area in the open terrain case, demonstrating agreement with the model proposed by Romanic and Hangan (2020b).

If we zoom in on the touchdown area in the open terrain scenario (Fig. 4c), a recirculation area can be observed just behind the stagnation point. The interaction between the radial outflow and opposing ABL wind generates a strong shear and convergence upwind of the impingement. This flow interaction forms a quasi-stationary recirculating vortex near the surface. In contrast, in the downwind region, the background wind aligns with and reinforces the radial outflow, flattening the outflow propagation. This observation is consistent with the conceptual model proposed by Romanic and Hangan (2020b) for outflow and ABL interaction.

Finally, Fig. 5 compares the results of the original canyon with those of a high-rise one. In the high-rise street canyon, the peak velocity is ~30% higher and conserved over a larger radial

distance. The peak velocity occurs at a slightly higher elevation in the high-rise canyon. Interestingly, despite the low-rise and high-rise canyons having heights of $1.5z_{ref}$ and $5z_{ref}$, respectively, the main difference in velocity magnitude remains confined to the pedestrian level below $0.5z_{ref}$. The velocity magnitudes between the two canyon cases approach each other above z_{ref}, particularly farther downstream from the jet impingement (Fig. 5c-d).

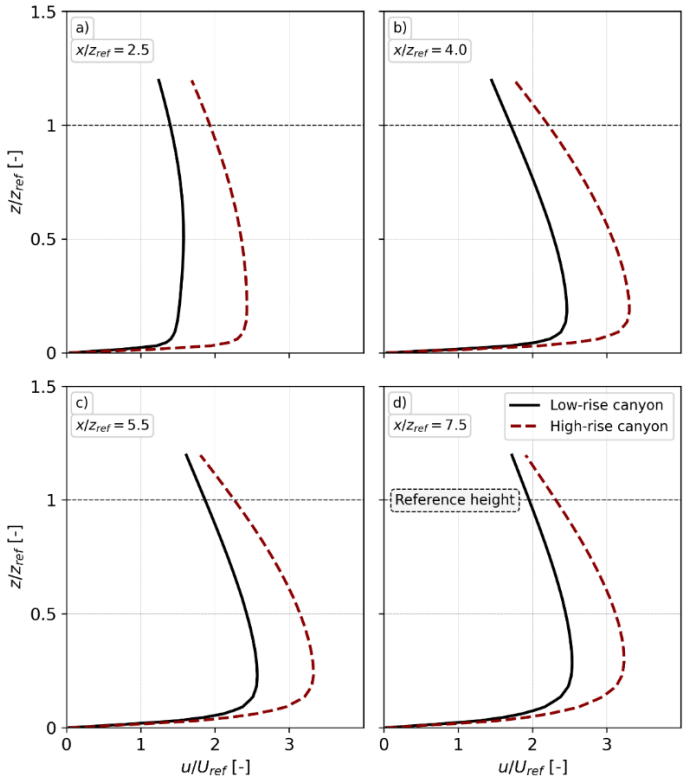

Figure 5. (a-d) Vertical profiles of normalized horizontal velocity at four streamwise positions downstream of the jet with y=0, comparing thunderstorm outflow propagation within a low-rise ($1.5z_{ref}$) and a high-rise ($5z_{ref}$) street canyon.

4. CONCLUSION

Thunderstorm outflows generate intense near-ground winds that pose significant risks to urban structures. This study addresses a gap in understanding the interaction between thunderstorm outflows, background atmospheric boundary layer (ABL) winds, and urban street canyons. Computational Fluid Dynamics (CFD) is used to reproduce wind tunnel measurements performed by Richter et al. (2018).

The study has two main objectives: 1) to evaluate CFD's ability in providing accurate insights into urban wind dynamics during outflow propagation, and 2) to investigate the influences of urban geometries, such as a street canyon, on outflow behaviour.

The results demonstrate that a low-Reynolds $k-\varepsilon$ turbulence model, combined with a highly refined mesh (y^+ primarily below 5), effectively resolves near-wall flow dynamics and acceptably

replicates wind tunnel measurements. This highlights CFD's value in complementing experiments and enhancing future experimental designs.

Findings also reveal that street canyons confine outflow propagation, amplify high wind velocities, and retain them over larger radial and vertical distances compared to open terrain. This escalates aerodynamic loads and the vulnerability of urban infrastructure, underscoring the significant influence of urban geometry on outflow behaviour.

ACKNOWLEDGEMENTS

The authors thank the Digital Research Alliance of Canada for providing access to supercomputer clusters used for running the CFD simulations. We acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada (NSERC) through Discovery Grant RGPIN-2021-02651. We appreciate the funding provided by the Fonds de recherche du Québec – Nature et technologies (FRQNT) through a Doctoral Research Scholarship. We also extend our gratitude to McGill University for their support through a Lorne Trottier Science Accelerator Fellowship.

Local and whole-body PBPK model to investigate the organ disposition concentration of di (2-Ethyhexyl) phthalate (DEHP) following inhalation exposure

SUMMARY
This study employed a hybrid model of Computational fluid dynamics (CFD) and Whole-body physiologically-based pharmacokinetics (PBPK) to elucidate the systematic disposition of DEHP and its metabolites in human organs via inhalation exposure. The reliability of this hybrid approach was validated through the use of experimental data. The local diffusive absorption of DEHP was found to be dependent on the airway compartment. In light of these findings, the results obtained from the whole-body PBPK indicate varied time-course concentrations in different organs based on the effects of physiological and biochemical parameters. The results are expected to consolidate the current technique as a reliable tool to link indoor contaminant exposure to organ concentration.

Keywords: Computational Fluid Dynamics, Whole-body PBPK, Inhalation exposure, DEHP

1. INTRODUCTION

Di (2-Ethyhexyl) phthalate (DEHP) is the most pervasive phthalate in the environment, and it can be detected in various furniture, building materials, cosmetics, and food packaging products. Furthermore, its presence has been confirmed in soil, water, and ambient air (Rowdhwal & Chen, 2018). The respiratory system is recognized as an intermediary conduit, which acts as the pathway for indoor DEHP to enter the body. It has been demonstrated that DEHP can act as an endocrine disrupter, which has the potential to induce disorders in multiple internal tissues, including the testis, renal system, liver, heart, and brain (Wang et al., 2024). In this context, an advanced numerical approach has been employed to elucidate the systematic disposition of DEHP so-called whole-body PBPK model (Li et al., 2022). Nevertheless, this model is less comprehensive in linking indoor contaminant exposure and the health effects of breathing activities. Therefore, the present study aims to quantitatively reveal DEHP behaviors in the internal organs using the CFD and whole-body PBPK hybrid technique.

2. METHODOLOGY

2.1. Numerical domain and grid design

A human respiratory tract down to the 16th generation was integrated with a computer-simulated person (CSP) placed in an indoor space with dimensions of 3×3×3 m^3. The numerical domain was discretized using poly-hex core elements with 10 prism layers adjacent to the respiratory wall. The total cell count reached nearly 25 million.

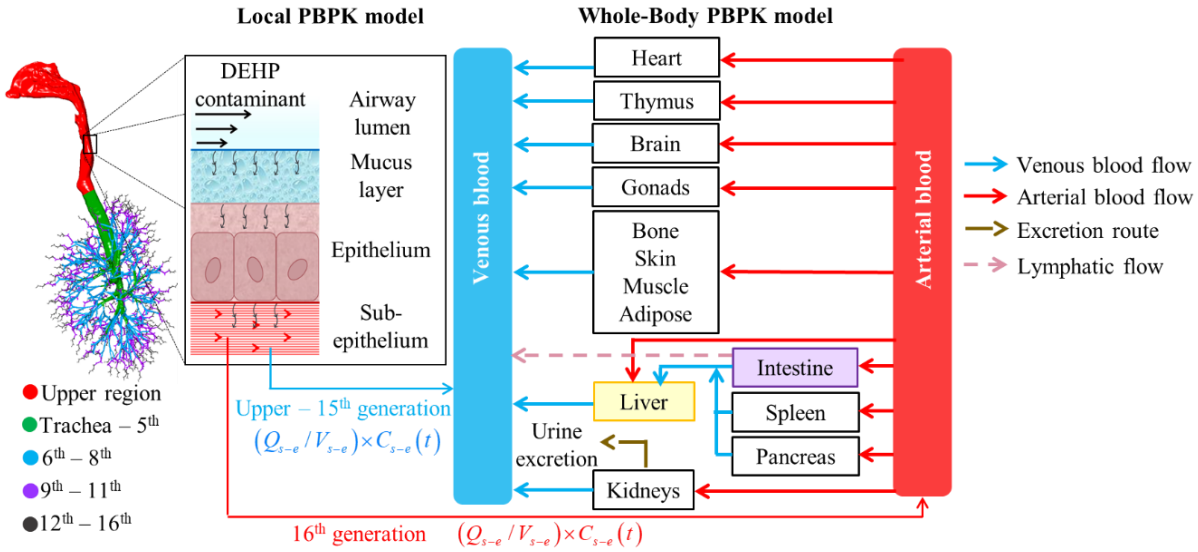

Figure 1. Diagram of the local and whole-body PBPK

2.2. Computational fluid dynamics method for airflow patterns and local PBPK

Incompressible, isothermal, and transient fluid flow was simulated by solving the Reynolds-averaged Navier-Stokes equations. The Low Reynolds type *k-ε* (Abe-Kondoh-Nagano) turbulent model was selected. This analysis applied the transient breathing flow profile retrieved from the experiment (Gupta et al., 2010). Six breathing cycles were simulated with a time step size of 0.005 s. Diffusion and transportation terms of DEHP in the respiratory tract were predicted using the scalar transport equation (Eq. (1)). For local PBPK, the absorption, diffusion, metabolic clearance, and blood perfusion occurred inside the respiratory tissue (Fig. 1) were simulated by Eq. (2) – (4).

$$\frac{\partial \overline{C_a}}{\partial t}+\frac{\partial \overline{U_i C_a}}{\partial x_i}=\frac{\partial}{\partial x_i}\left[\left(D_a+\frac{\nu_T}{\sigma}\right)\frac{\partial \overline{C_a}}{\partial x_i}\right] \tag{1}$$

$$\frac{\partial C_m(x,t)}{\partial t}=D_m\frac{\partial^2 C_m(x,t)}{\partial x^2} \tag{2}$$

$$\frac{\partial C_e(x,t)}{\partial t}=D_e\frac{\partial^2 C_e(x,t)}{\partial x^2} \tag{3}$$

$$\frac{\partial C_{s-e}(x,t)}{\partial t}=D_{s-e}\frac{\partial^2 C_{s-e}(x,t)}{\partial x^2}-\frac{Q_{s-e}}{V_{s-e}}C_{s-e}(x,t) \tag{4}$$

where U_i is the mean flow velocity, C_a is the ensemble mean contaminant concentration, D_a is the diffusion coefficient of DEHP in air, and σ is the turbulent Schmidt number. C_m, C_e, C_{s-e} and D_m, D_e, D_{s-e} are the contaminant concentrations and the diffusion coefficient in mucus, epithelium, and sub-epithelium, respectively. Q_{s-e} and V_{s-e} indicate the plasma flow rate and the volume in the sub-epithelium layer, respectively. The local PBPK model was simultaneously enabled with the transient breathing to predict the time-course concentration. During exhalation, airway outlets were set to zero concentration, assuming all DEHP absorption beyond the outlets. An exposure condition of 100 μg/m^3 in 3 hours were used following the experiment (Andersen et al., 2018).

2.3. Whole-body PBPK

After the local PBPK simulation, the uptake DEHP amount via the upper – 15th generation was administrated to venous blood and that of 16th generation was specified as arterial blood dose (Fig.1). In liver and gut, DEHP is primarily metabolized into byproducts including the mono(2-ethylhexyl) phthalate (MEHP), mono(2-ethyl-5-oxohexyl) phthalate, mono(2-ethyl-5-hydroxyhexyl) phthalate, and mono(2-ethyl-5-carbo) phthalate. The systematic distribution, metabolism, and clearance of DEHP and its metabolites are described by a set of ordinary differential equations involving the physiological and biomedical parameters.

3. RESULTS AND DISCUSSIONS

The local PBPK results indicate the discrete DEHP absorption percentage along the airway. Absorption was highest in the upper (~34%, Fig. 2a) and dropped close to 20% in the trachea – 5th generation and the 6th – 8th generation. For the 9th – 11th generation, the absorption percentage quickly declined to approximately 10% and even less than 1% in the 12th – 16th generation. Approximately 77% of inhaled DEHP was absorbed into the respiratory wall during one breathing cycle. These phenomena can be attributed to the employed parameters, such as the diffusion and partition coefficients, and the lack of geometry in the 8th – 16th generation. Then, DEHP was continuously diffused through airway tissue (Fig. 2b). Precisely, mucus concentration developed during inhalation – I and reached nearly zero during exhalation – E across all airway compartments. Similar fluctuations occurred in the epithelium and sub-epithelium, though an increment is observed, especially in the upper – 8th generation. Besides, the mucus concentration profiles remained lower value (around 3.6–5.0×10^3 μg/m^3) compared to the epithelium (roughly 45–1.2×10^5 μg/m^3) and sub-epithelium (about 10–2.8×10^4 μg/m^3) due to the partition coefficients.

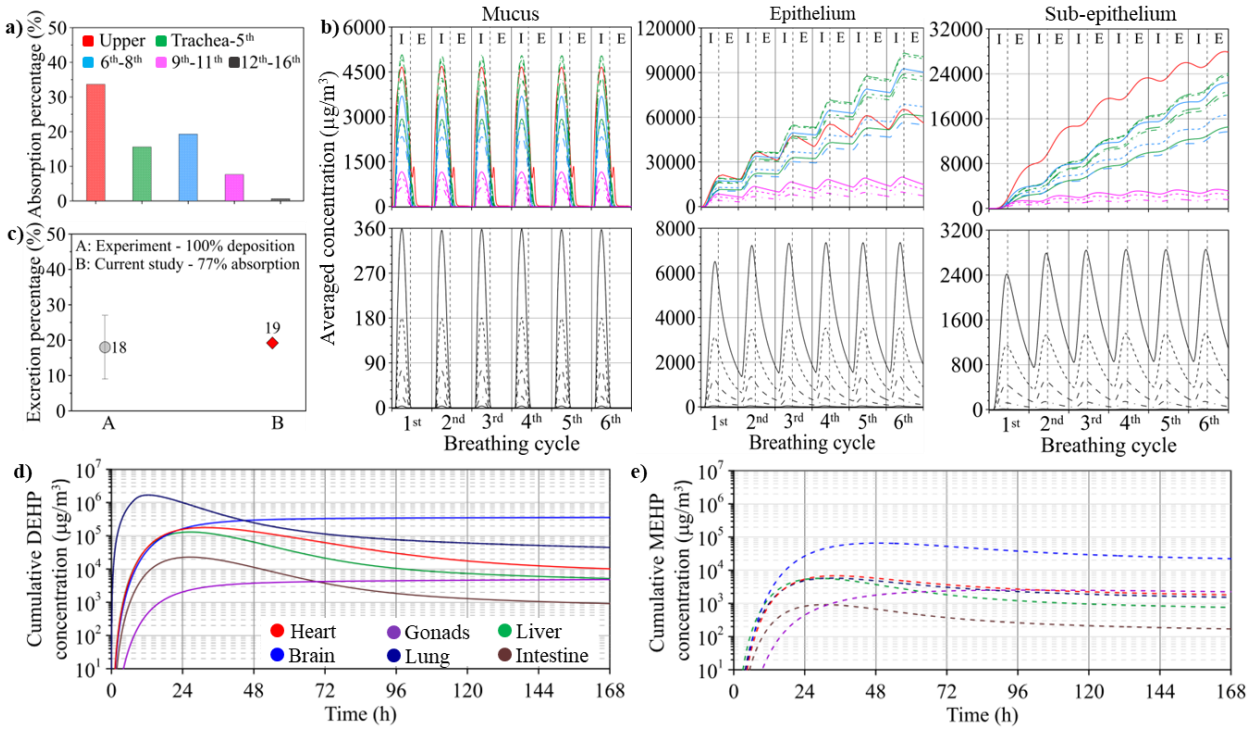

Figure 2. (a) DEHP absorption percentage onto the airway wall. (b) Averaged DEHP concentration in airway tissue. (c) Validation works against the experimental data. (d) DEHP and (e) MEHP transient concentration in organs.

Upon the local PBPK results, the venous and arterial blood doses up to 2,667 breathing cycles (corresponding to 3-hour exposure) were estimated based on the six breathing cycles using the logarithmic regression. Then, the whole-body PBPK simulation was launched to record DEHP's metabolites' total cumulative urine mass. The credibility of the hybrid model was verified based on the excretion factor, calculated by normalizing the total cumulative mass with the total absorption percentage and total DEHP inhaled amount. Notably, our simulation underpredicted the excretion factor (Fig. 2c); however, it is inevitable due to the foreseen uncertainties related to the biochemical and physiological parameters.

The time-course concentration in the organs was obtained via an 8-hour exposure case study (0 denoting the start of exposure) with an examined duration of 168 hours (7 days). As a result, the time-dependent of DEHP and MEHP significantly varied between organs (Figs. 2d and 2e). Specifically, DEHP concentration in the lung continuously progressed and reached its apex at 8 hours with a value of around 1.9×10^{6} μg/m^3, followed by a stiff decrement to around 5.0×10^{4} μg/m^3 at 168 hours (Fig. 2d). This evolutionary trend is also observed in the heart, liver, and intestine with different peak concentration time and value. Meanwhile, DEHP concentrations in the brain and gonads still continuously remained with the value of around 3.0×10^{5} μg/m^3 and 5.0×10^{3} μg/m^3, respectively, and required more time to be cleared. For MEHP (Fig. 2e), the time-course concentration in all organs experienced a downward trend after 48 hours, except for gonads, which delayed up to 120 hours. The peak concentration was found in the brain at approximately 7.0×10^{4} μg/m^3, and the lowest concentration of 9.0×10^{2} μg/m^3 occurred in the intestine. For other organs, the peak concentration ranged from 6.0×10^{3} to 7.0×10^{3} μg/m^3.

4. CONCLUSIONS

Development of the current whole-body PBPK coupling with the CFD analysis (local PBPK) offered a potential forecasting tool to monitor the time-dependent effects of exposure to DEHP. To precisely simulate the systematic disposition of DEHP and MEHP in the human body, it is essential to utilize the appropriate biochemical and physiological parameters. However, limitations include subject variability, parameter sensitivity, and limited validation data should be noted.

SUMMARY
In general, the range of construction noise is from 80 dBA to 120 dBA, which causes construction workers to have health problems such as noise-induced hearing loss (NIHL). This study proposes a framework capable of assessing construction noise using a generative pre-trained transformer (GPT) model and supporting field managers' decision-making. This framework is intended to evaluate whether to exceed the standard of a time-weighted average (TWA) and assess the human health impact of noise-induced hearing loss (HHIN). The case study confirms that the proposed framework can be used to calculate the TWA level and HHIN of occupational noise in construction, based on which an occupational noise assessment report can be generated. The results of this study are expected to support field managers' decision-making, manage workers' safety on construction sites, and contribute to reducing the incidence of NIHL.

Keywords: Construction worker, Occupational noise exposure, Noise-induced hearing loss, Generative pre-trained transformer

1. INTRODUCTION

Construction noise levels range from 80 dBA to 120 dBA, which are higher on average than the occupational noise exposure standard (i.e., 90dBA) according to the Occupational Safety and Health Administration (OSHA) (Lee et al., 2019). When workers are continually exposed to noise above the occupational noise exposure standard, they are at risk of developing noise-induced hearing loss (NIHL) (Burella et al., 2021). NIHL is a hearing impairment that occurs due to continuous exposure to sources of loud noise. In 2022, workers' health examinations were conducted in South Korea, and the results showed that NIHL accounted for 98.2% of occupational diseases (Ministry of Employment and Labor, 2022). Moreover, since NIHL causes permanent hearing loss, precautionary measures need to be taken. However, most previous studies on construction noise focused on noise assessments and analyses of noise impacts on workers (Hong et al., 2022; Hong et al., 2023). Therefore, study is needed to reduce workers' health impacts through the practical management of construction sites.

Recently, various studies using a generative pre-trained transformer (GPT) model developed by OpenAI have been conducted in the construction industry. Saka et al.(2024) suggested that the GPT model be used to evaluate compliance with construction-related regulations (i.e., safety procedure, design guidelines) and generate a report from the results to simplify field managers' decision-making process. In this regard, this study seeks to propose a framework for assessing construction noise using the GPT model and supporting field managers' decision-making based on the assessment results.

2. GPT-BASED OCCUPATIONAL NOISE ASSESSMENT MODEL DEVELOPMENT

The GPT-based model proposed in this study is designed to analyze noise at a construction site and assess compliance with legal regulations and workers' health impacts. Accordingly, it aims to automatically perform the following tasks: (i) assessment of whether to exceed the time-weighted average (TWA) standard; and (ii) human health impacts of noise-induced hearing loss (HHIN) assessments. Finally, an assessment report, which includes measures to reduce workers' health impacts, can be automatically generated based on the derived TWA level and HHIN results.

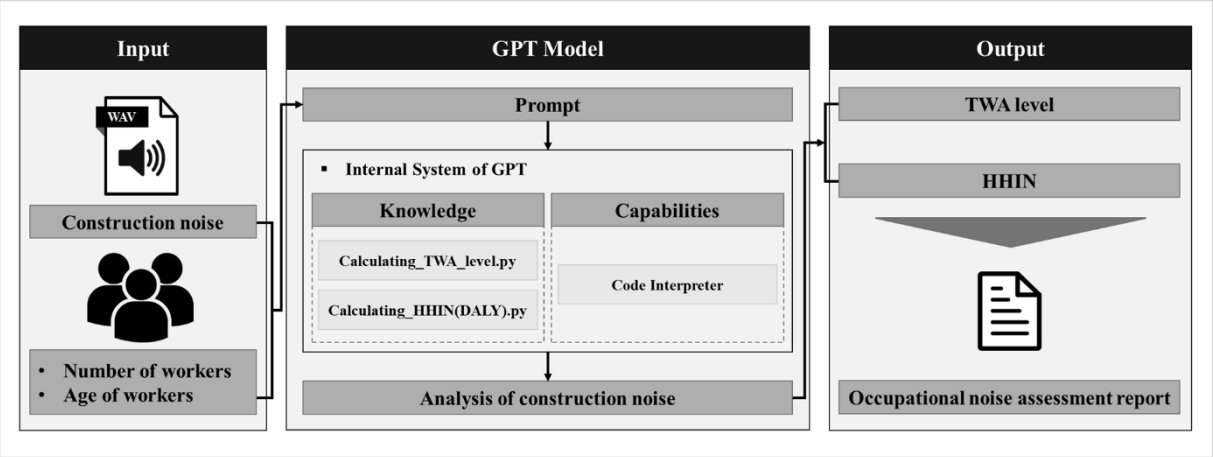

Figure 1. Framework for automated assessment of construction noise using GPT model

2.1. TWA level assessment method

Occupational noise exposure can be assessed using the TWA metric. TWA represents the value obtained by multiplying the noise measurement value by the occurrence time and then dividing that by 8 hours for a 8-hour workday. In this study, a standard for assessing workers' TWA levels was selected based on the *Exposure Standards for Chemical Substances and Physical Agents* of the Ministry of Employment and Labor. The standard requires that the TWA level not exceed 90 dBA for 8 hours, and applies a 5 dBA exchange rate. The TWA level can be calculated using Eq. (1). Here, *Dose* is the cumulative noise exposure level calculated by comparing the noise exposure level of workers with the acceptable noise exposure level.

$$TWA = 16.61 \log_{10}\left(\frac{Dose}{100}\right) + 90 \quad (1)$$

When the TWA level exceeds 90 dBA, the allowable noise exposure time (T_{allow}) for continuous exposure to noise above the standard is calculated using Eq. (2). Here, *L* is the noise level in the noise exposure section, and *ER* can be applied with 5 dBA in accordance with the standards of South Korea.

$$T_{allow} = \frac{8}{2^{(\frac{L-90}{ER})}} \quad (2)$$

2.2. HHIN assessment method

The workers' HHIN is calculated using the Disability-Adjusted Life Year (DALY) index. DALY is a value that considers both health loss due to disability and life loss due to premature mortality and can be calculated using Eq. (3) (Hofstetter et al., 2005). Here, *DALY* is HHIN, N_i is the number of workers in age group *i*, ER_i is the estimated excess risk of age group *i*, and *DW* is the disability weight. The *DW* value is applied with 0.192, which is the disability weight of NIHL based on the Korean standard (Mathers et al., 2003).

$$DALY = \sum_i (N_i \times ER_i \times DW) \quad (3)$$

ER represents the percentage value of additional risk caused by noise exposure in a specific age group. *ER* can be estimated based on the A-weighted noise exposure level normalized to an 8-hour working day ($L_{EX,8h}$). The estimated excess risk is defined differently depending on the noise exposure level and increases as the age group increases (Li et al., 2016). However, when $L_{EX,8h}$ is less than 85 dBA, the estimated excess risk of all age groups is calculated at 0. In other words, when $L_{EX,8h}$ is less than 85 dBA, HHIN does not occur.

3. CASE STUDY

A case study was carried out to verify the performance of the GPT model. To do this, construction noise was measured in three areas (i.e., zone A, B, and C) on the construction site, and information on the number of workers and age groups was obtained from daily construction logs.

The case study results are as follows. First, the TWA level was the lowest at 82.13 dBA in zone A and did not exceed the TWA standard (i.e., 90 dBA). On the other hand, the TWA levels of zones B and C were 97.23 dBA and 95.74 dBA, respectively, which exceeded the TWA standard. Second, the HHIN of workers were 0.1247 DALY and 0.1559 DALY, respectively, in zones B and C. However, it was 0 in zone A, where the TWA level of workers was below the standard (i.e., 90 dBA) (refer to Table 1). Therefore, HHIN did not occur in areas where the TWA level did not exceed the standard, but HHIN occurred in areas where the TWA level exceeded the standard. Third, an occupational noise assessment report was generated based on the construction noise assessment results. The report includes measures for regulatory compliance in areas where the TWA level is exceeded. For example, when continuous exposure to noise above the legal regulatory standard (i.e., 90 dBA) occurs in zones B and C, T_{allow} shall not exceed 2.9 hours (i.e., zone B) and 3.6 hours (i.e., zone C), respectively. This allows field managers to identify areas where the TWA standard is exceeded based on the occupational noise assessment report and take measures for regulatory compliance.

Table 1. GPT model-based construction noise assessment results

Zone	TWA level (dBA)	HHIN (DALY)	T_{allow} (hr)
A	82.13	-	-
B	97.23	0.1247	2.9
C	95.74	0.1559	3.6

Note. HHIN is the human health impact of noise-induced hearing loss; and T_{allow} is the allowable noise exposure time.

The GPT-based model helped assess occupational noise to calculate workers' TWA level and HHIN and generate an occupational noise assessment report that includes measures to reduce impacts on workers' health. This confirms the potential of the GPT model as an initial model for automated assessment of workers' health impacts from construction noise.

3. CONCLUSION

To reduce workers' health impacts from construction noise, this study proposed a framework for assessing and managing occupational noise based on a GPT model. To verify the performance of the model, a case study was carried out using actual construction noise. The results confirmed that the GPT model is capable of calculating the TWA level and HHIN of occupational noise, based on which an occupational noise assessment report can be generated. It is expected that the results of this study can be used as basic data for monitoring construction noise regulations and automating noise management.

SUMMARY
Evaporative humidifiers are widely used to humidify the mechanically ventilated air. To minimize the probable contamination, an evaporative humidifier shall have the emitted liquid aerosols as few as possible. However, the liquid aerosol emissions from an evaporative humidifier are unclear so far. This investigation measured the liquid aerosol concentrations, inferred the particle/droplet emission rates, and examined the particle size spectrum. The particle emission rates in the humidifier above the packing, inside the packing, and below the packing, respectively, were quantified. Impacts of some operating parameters on the particle emissions were evaluated. The results revealed that most of the emitted liquid aerosols were from below the packing, and only a few from above the packing and few from the packing inside. A higher water circulation rate or a higher water dripping height results in increase of the particle emission rate and a higher percentage of the particles larger than 0.5 μm.

Keywords: evaporative humidifier, droplet emission, liquid aerosols, particle size spectrum, measurement

1. INTRODUCTION

Low-humidity indoor air may induce eye irritation, nasal allergy, dry throat and other non-specific syndrome symptoms (Wolkoff, 2018; Byber et al., 2021). Evaporative humidifiers are widely used to humidify the mechanically ventilated air for their simplicity, low cost, and ease for use. An evaporative humidifier comprises components of water distributor, packing, reservoir, and pump for water circulation. The air for humidification passes through the packing of the humidifier, which evaporates water into vapor. The dripped water from water distributors colliding with the packing, the air blowing the wet packing, and the water dripping into the reservoir, may generate droplets and their nuclei. In case the water for humidification is contaminated, the emitted droplets and their nuclei may contain pathogens (Strindehag et al., 1991; Lee et al., 2012; Hamilton and Iii, 2018). Consequently, an evaporative humidifier shall have the emitted droplets as few as possible, while maintaining humidification of the air majorly from evaporation of the water film inside the packing. However, the emitted liquid aerosol numbers and the particle size spectrum of an evaporative humidifier remain unclear so far. The exact emission of the droplets in different components/regions of the humidifier and impacts of the operating parameters to the emitted droplets are unknown either.

2. METHODS

2.1 Experimental test mockup and measurement instruments

This investigation conducted tests to measure the droplet or droplet nuclei emission rates and size spectrum and visualize the droplet emissions. Fig. 1 presents an evaporative humidifier for study. The multiple water distribution heads spray water to the packing below. The water inside the packing streams down and forms the water film, which is swept by the horizontal airflow from the ventilating duct. The unevaporated water drips down to the reservoir and subsequently is pumped to the water distribution heads for next evaporation cycle.

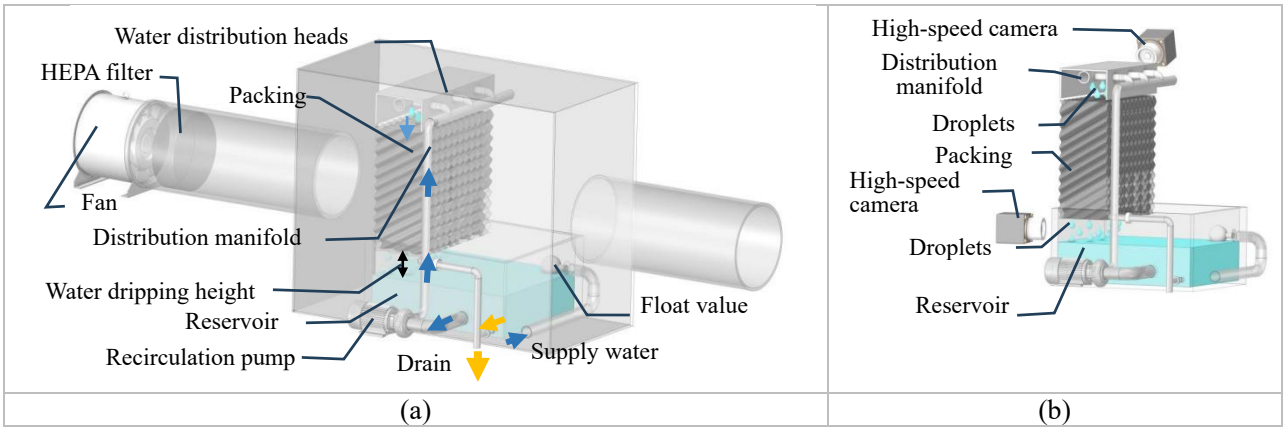

Figure 1. Schematic diagram of an evaporative humidifier for study: (a) overview of the test mockup and each individual component, (b) positioning of a high-speed camera for photographing the droplet emissions.

The tested humidifier has dimensions of 55 × 25 × 45 cm. The humidifier adopts the CELdek cellulose as the evaporation medium of the packing. The sizes of the packing are 25 × 10 × 25 cm, with 3 cm between the water distribution heads and the packing's upper rim. The humidifier is connected to circular ducts with a diameter of 11 cm. An axial fan with adjustable frequency mobilizes the ventilated air passing through the humidifier. To mitigate inference of the ambient aerosols to the tests, a high-efficiency particulate air (HEPA) filter is incorporated in upstream of the fan, thereby ensuring that the drawn air into the test humidifier are nearly ambient-particle free.

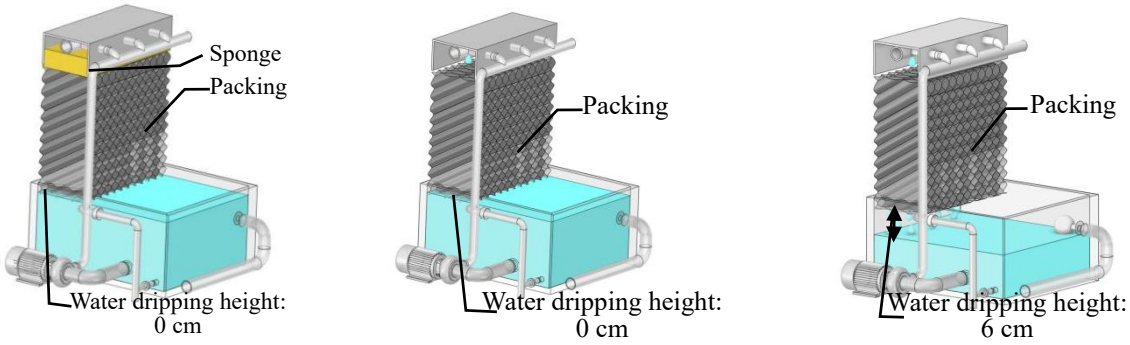
The number concentrations of the liquid aerosols were measured in downstream of the humidifier inside the duct. An optical particle sizer (type: 3330; TSI, USA) was adopted for measuring the particle concentrations and examining the size spectrum. The particle sizer counted particles in 16 bins with the particle size ranging from 0.3 to 10 μm. A high-speed camera (type: acA2000–340 km; Basler, Germany) was adopted to observe the splashed water and the generated droplets above the packing, the sprayed water streaming into the packing, and dripping of the water from the bottom packing to the reservoir, as shown in Fig. 1(b). Hence, the camera was positioned either slightly above the water distribution manifold or below the packing but higher than the water surface. During tests, the ventilation volumetric rate was measured by an anemometer (type: 425; TESTO, Germany). The ventilated air temperature and humidity were monitored by a temperature and humidity datalogger (type: 174H; TESTO, Germany).

2.2 Inference of the droplet nuclei emission rates and overview of the measurement cases

With the measured particle concentrations, the particle emission rates can be inferred. The governing equation of the particle concentrations in downstream of the humidifier can be cast as:

$$\frac{dC}{dt} = \frac{E}{V} + P \cdot \alpha \cdot C_{out} - (\alpha + k)C \quad (1)$$

where C is the temporal particle concentration in downstream of the humidifier, #/cm^3; t is time, s; E is the particle emission rate, #/s; V is the void volume of the humidifier, m^3; P is the particle penetration rate from the outside to the humidifier; α is the air exchange rate of the humidifier, s^{-1}; k is the particle deposition loss rate, s^{-1}. The particle emission rate, E, can be obtained by integrating Eq. (1) over time.



(a) Case 1 (b) Case 2 (c) Case 3

Figure 2. Schematic diagram of measurement scenarios for inferring the particle emission rates in different regions of the humidifier: (a) from only the packing inside in Case 1, (b) from both above and inside the packing in Case 2, (c) from above, inside, and below the packing in Case 3.

Table 1 Operating parameters of the evaporative humidifier for inferring the particle emission rates from different regions of the humidifier

Case with particle emission in different regions	Water circulation rate (L/h)	Water dripping height (cm)	Ventilated air velocity (m/s)
Case 1: inside the packing (with sponge filled above the packing), as shown in Fig. 2(a)	60	0	1.0
Case 2: above and inside the packing, as shown in Fig. 2(b)	60	0	1.0
Case 3: above, inside and below the packing, as shown in Fig. 2 (c)	60	6	1.0

In principle, droplets can be emitted from different regions of the humidifier, i.e., above the packing, inside the packing, and below the packing. Fig. 2 presents the schematics to illustrate the particle emissions from different regions of the humidifier in three cases. Table 1 presents detailed operating parameters of the three cases. All of the three operating cases were maintained with the same ventilating velocity of 1 m/s inside the ventilating duct and the same water circulation rate of 60 L/h. In Cases 1 and 2, the packing bottom was immersed into the reservoir, so that the water dripping height was zero. Note that there was nearly no water splashing above the packing in Case 1 due to the buffering by the filled sponge layer. Case 3 corresponded to the ordinary operation of an evaporative humidifier with the water dripping height of 6 cm. Assume that the particle emissions in different regions of the humidifier are repeatable and do not vary with the adjusted conditions in other regions. Then the particle emission rates inside the packing can be obtained from Case 1, the emission rates above the packing can be obtained by subtracting Case 1 from Case 2, and below the packing by subtracting Case 2 from Case 3.

It is intuitive that different water circulation rates, water dripping heights, and ventilated air velocities may affect the droplet emission rates. To evaluate impact of each individual parameter on the droplet emissions, only one parameter was varied while maintaining the other two operating parameters unchanged, as shown in Table 2. The water circulation rate was varied from 10 to 60 L/h with an increasing interval of 10 L/h, the water dripping height from 0 to 6 cm with an increasing interval of 1 cm, and the ventilated air velocity from 0.4 to 2 m/s with an interval of 0.4 m/s. In these test cases, both the particle emission rates and the particle size spectrum were examined.

Table 2 Variations of some operating parameters of the evaporative humidifier for evaluating their impacts on the droplet emission rates

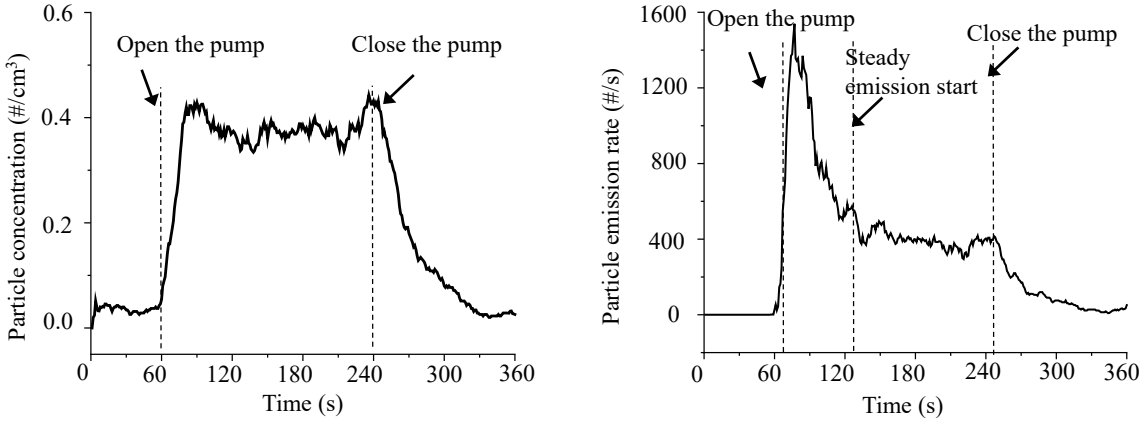
Variable	Water circulation rate (L/h)	Water dripping height (cm)	Ventilating air velocity (m/s)
Water circulation rate	10-60	6	0.4
Water dripping height	60	0-6	0.4
Ventilating air velocity	60	6	0.4-2.0

3. RESULTS AND DISCUSSION

This section presents the measured temporal particle concentrations and the inferred droplet emission rates in a typical case. Then the inferred droplet emission rates in different regions of the humidifier are presented. Finally, impacts of some operating parameters of the humidifier to the droplet emissions are addressed.

3.1 Temporal particle concentrations and droplet emission rates in a typical case

A representative operating case with the water circulation rate of 60 L/h, the water dripping height of 5 cm above the reservoir, and the ventilating velocity of 1 m/s, was selected to analyze the measured particle concentrations and the inferred droplet emission rates. This case was quite similar to Case 3 in Table 1 but with a slightly lower water dripping height.



(a) Particle concentration (b) Particle emission rate

Figure 3. Measured particle concentrations and inferred particle emission rates in a typical case with the water circulation rate of 60 L/h, the water dripping height of 5 cm above the reservoir, and the ventilating velocity of 1 m/s.

Fig. 3(a) presents the measured temporal particle concentrations in downstream of the humidifier. The pump for water circulation was switched on at t = 60 s and switched off at t = 240 s. Before the pump was switched on, the average particle concentration was approximately 0.037 #/cm^3, which implies there were some of the leaked particles from the HEPA filter or some of the respuspended particles from the duct's inner surfaces or the humidifier. Once the pump was switched on at t = 60 s, the water was started for circulation. It took approximately 5 s for the water in the reservoir to be pumped to the water distributor. Then the water was sprayed from the multiple distribution heads to the packing and some of the water was splashed but finally streamed into the packing. The water started to drip down to the reservoir at t = 75s and then the full water circulation cycle was established. The recorded particle concentration was rapidly increased from 0.037 #/cm^3 at t = 60 s to 0.43 #/cm^3 at t = 80 s. After t = 120 s the concentrations fluctuated slightly in surrounding to the average value of 0.35 #/cm^3. At t = 240 s, the pump was shut off and the concentration started to decrease gradually to the slightly over the background particle concentration.

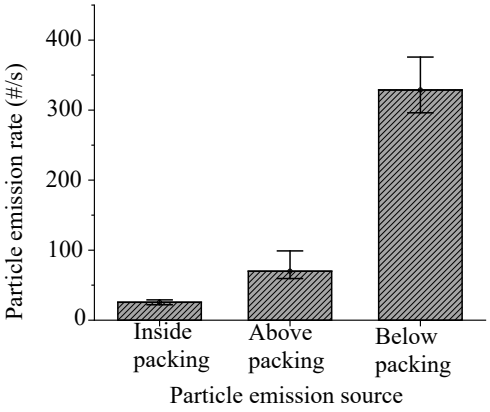
Fig 3(b) presents the inferred temporal droplet emission rates from Eq. (1). The emission rate was zero until t = 65 s. The particle emission rate was sharply increased to the peak emission rate of 1530 #/s at t = 65 s. Then the emission rate dropped gradually to approximately 560 #/s at t = 120 s. The sudden increase of the droplet emission rate might be due to the splashing of the water in the initially dry packing, which contained nearly no particle inside and thus promoted the particle emission. Once the water circulation was established, the dropping droplets and the formed water film inside the packing might capture some of the airborne particles to the circulated water, which refrained the particle emission somehow. The particle emission rates tended to be stabilized since t=120 s. The averaged particle emission rate was approximately 410 #/s, which can be deemed as the relatively steady particle emission rate in this case.

3.2 Emitted droplets in different regions of the humidifier

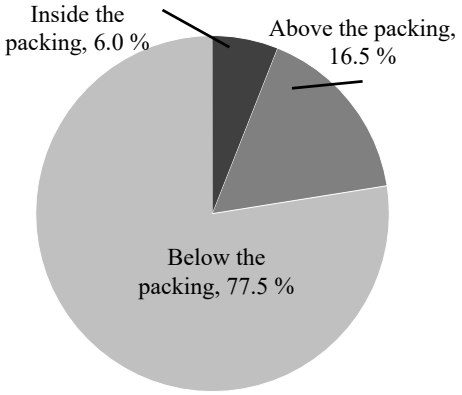
Similar to the measurements and data operations as in Section 3.1 above, the average particle emission rates were obtained for all three cases shown in Fig. 2 and Table 1. Fig. 4(a) presents the droplet emission rates in different regions of the humidifier. The droplet emission rate inside the packing was close to 25 #/s, which was nearly negligible. This was because the ventilated air swept the water film inside the packing gently. The quite few generated droplets were mainly from the occasionally formed water drips in some intersections of water flow channels inside the packing. The droplet emission rate above the packing was inferred to 70 #/s, due to the sprayed water from the water distribution heads which was splashed once colliding with the upper rims of the packing. In contrast, the droplet emission below the packing was closed to 330 #/s. The huge number of emitted droplets below the packing was due to interaction of the dripping water from the packing with the water surface inside the reservoir.

Fig. 5 presents interaction of dripped water from the packing with the water inside the reservoir. The falling water from the packing formed water drips in different sizes due to the surface tension at t=1 ms. The large water drip hit the water surface and formed a hemispherical cavity in the water and some of the water was splashed at t = 4 ms. The cavity was contracted and broken, resulting in upward ejection of a sharp water jet at t = 12 ms. The upper section of the up-moving water jet

was broken and several secondary droplets were ejected at t = 16 ms. The jet lost momentum and was broken into more secondary droplets at t = 20 ms. The falling water drips also collided with the secondary droplets. The hitting, splashing, bubble breaking, jet breaking, collision, impacting, etc., were responsible for emission of water droplets, some of which were later evaporated into the droplet nuclei for airborne transmission.



(a) Particle emission rates in different regions



(b) Proportion of particle emission in different regions

Figure 4. Particle emission rates in different regions of the humidifier under the operating conditions with the water circulation rate of 60 L/h, the water dripping height of 6 cm above the reservoir, and the ventilating velocity of 1 m/s.

Fig 4(b) shows the emitted droplet nuclei below the packing possessed 77.5% of the total emission, which was the most contributor of the particle (droplet nuclei) source. Above the packing, the emitted particles possessed 16.5%. The emitted particles from the packing inside were quite few, possessing only 6.0 %.

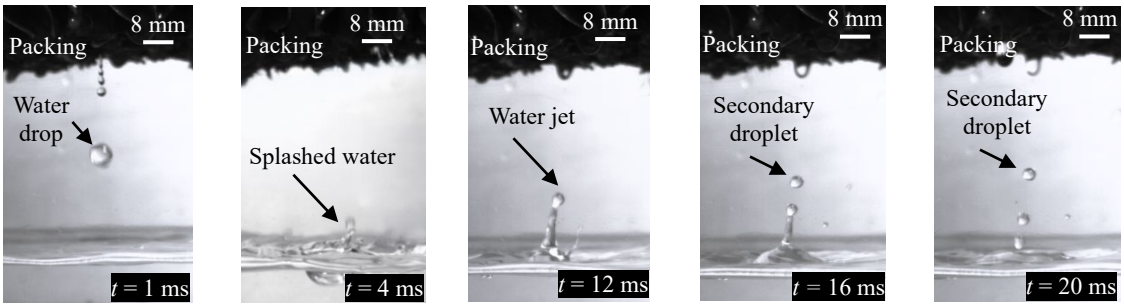


Figure 5. Images of interaction of the dripped water from the packing with the water in the reservoir at different time.

3.3 Impacts of operating parameters to the droplet emission rates

Fig. 6 presents variation of the particle emissions with the water circulation rate. With increase of the water circulation rate, the particle emission rate steadily increased, as shown in Fig. 6(a). The humidifier produced 130 #/s at the water circulation rate of 10 L/h, whereas the humidifier at 60 L/h produced 600 #/s, which was 4.62 times that of 10 L/h. Fig. 6(b) shows with increase of the water circulation rate, the percentages of both supermicron particles and the particles between 0.5 to 1 μm steadily increased, while the percentage of the particles between 0.3 to 0.5 μm steadily

decreased. With an increasing water circulation rate, impact/collision of the dripping water with the water inside the reservoir also steadily increased, as shown in Fig. 6(c). The dripping water's impact/collision with the water surface resulted in a thick jet and emission of single secondary droplets regardless of the water circulation rate. The increased water circulation rate also led an increase of the proportion of particles in sizes between 0.5-2.0 μm.

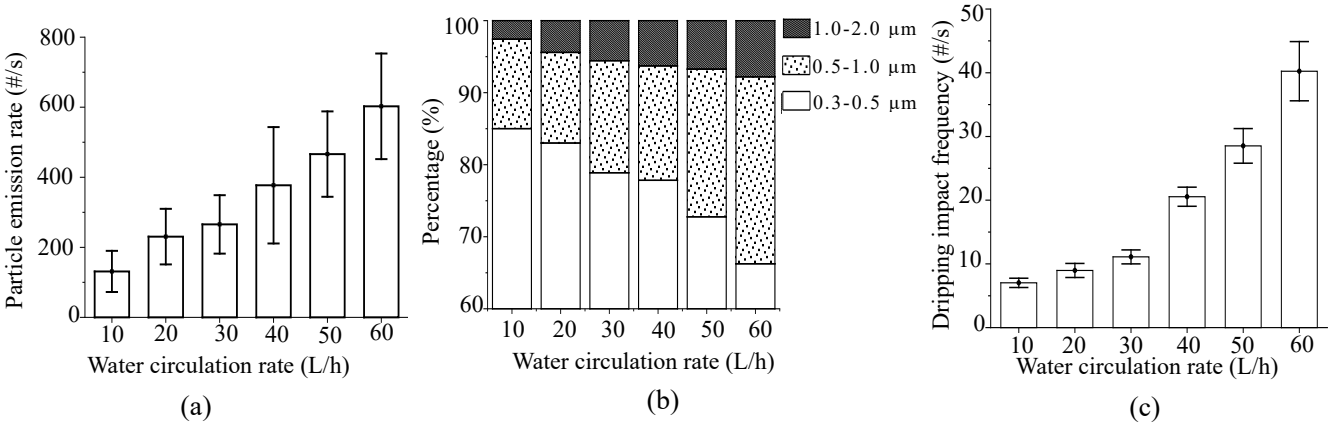

Figure 6. Variation of the particle emissions with the water circulation rates from 10 to 60 L/h under the fixed water dripping height of 6 cm and the fixed ventilating air velocity of 0.4 m/s: (a) particle emission rates, (b) particle spectrum, (c) impact/collision frequency of the dripping water from the packing with the water inside the reservoir.

Fig. 7 presents variation of the particle emission rate with increase of the water dripping height. Impacts of the water dripping height to both the particle emission rates and the particle spectrum resemble those of the water circulation rate. The particle emission rates and the particle percentages for both the supermicron particles and the particles between 0.5 to 1 μm steadily increased with the water dripping height. This was because with increase of the water dripping height, the water drips had higher energy and inertia to impact with the water inside the reservoir, which created stronger water jets and more secondary droplets in larger sizes. Notably, at the water dripping height of zero, only the submicron particles were emitted.

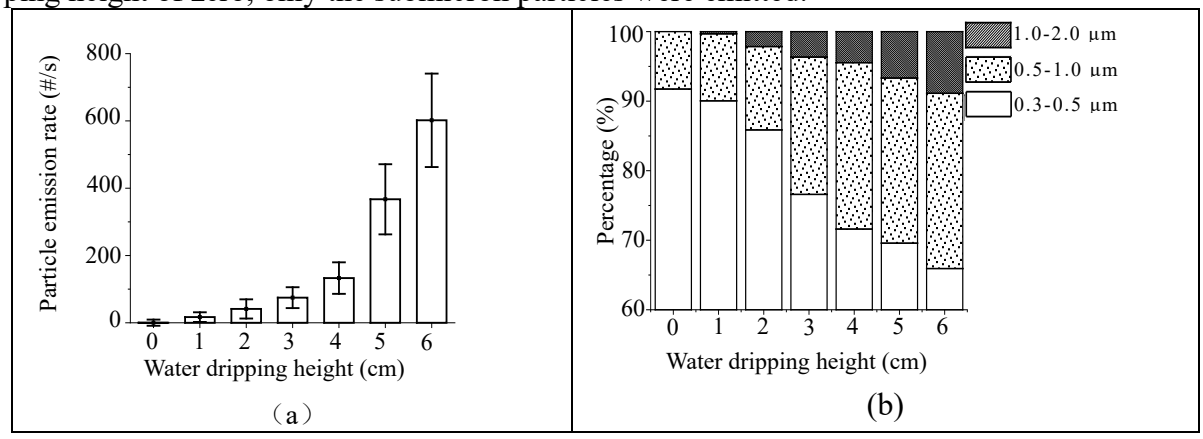

Figure 7. Variation of the particle emissions with the water dripping height of 0-6 cm under the fixed water circulation rate of 60 L/h and the fixed ventilating air velocity of 0.4 m/s: (a) particle emission rates, (b) particle spectrum

Fig. 8 presents variation of the particle emissions with the ventilated air velocity. Both the particle emission rates and the size spectrum were nearly independent on the tested ventilated air velocity.

This was because the tested velocity was no higher than 2 m/s, which was quite gentle to shear the water film inside the packing to form droplets for particle emissions. Note that the air velocity inside the packing was much lower than inside the ventilating duct.

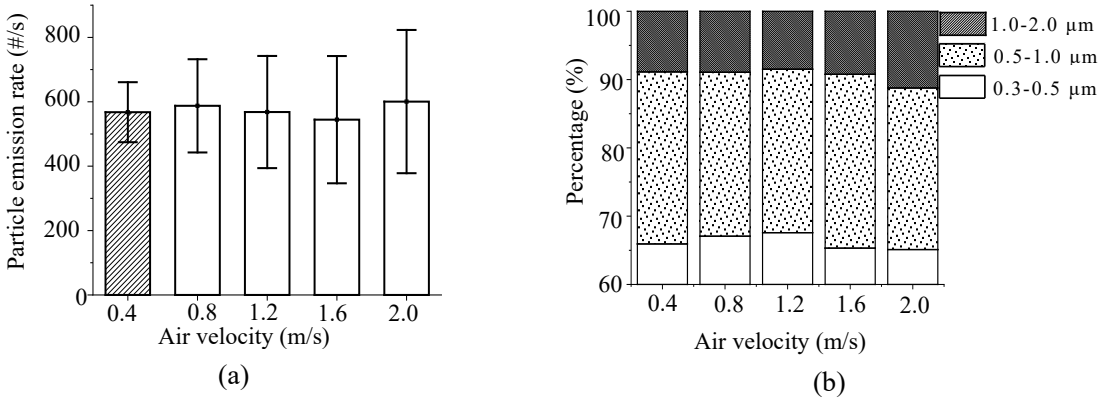

Figure 8. Variation of the particle emissions with the ventilated air velocity from 0.4 to 2 m/s under the fixed water circulation rate of 60 L/h and the fixed water dripping height of 6 cm: (a) particle emission rates, (b) particle spectrum.

4. CONCLUSIONS

This investigation measured the liquid aerosol concentrations, inferred the particle/droplet emission rates, and examined the particle size spectrum. The particle emission rates in the humidifier above the packing, inside the packing, and below the packing, respectively, were quantified. Impacts of some operating parameters of the humidifier on the particle emissions were evaluated. Based on the obtained results, the following conclusions can be drawn:

1. Most of the emitted liquid aerosols were from below the packing, and only a few from above the packing and few from inside the packing. The dripped water from the packing impacted with the water inside the reservoir, which generated secondary droplets in smaller sizes that may be transmitted in air after evaporation.
2. Both the water circulation rate and the water dripping height affected the particle emission rate and particle size spectrum in similar trends. A higher water circulation rate or a higher water dripping height resulted in increase of both the particle emission rate and the percentage of the particles larger than 0.5 μm.

SUMMARY
Kitchen smoke is often directly exhausted into internal corridor for many typical old residential buildings in Shanghai China, which severely pollutes air quality and directly affects residents' daily lives. While prior studies and field measurements have identified the problem, existing approaches fail to address dynamic factors like seasonal thermal effects and vertical pollutant diffusion patterns. This study utilizes CFD simulations to analyse smoke behaviours, revealing that discharged smoke accumulates in upper corridor sections and stairwells, with lower-floor emissions disproportionately impacting higher floors. Winter's thermal stack effect accelerates upward diffusion, whereas summer conditions result in slower dispersion but higher average corridor pollutant concentrations. To deal with these issues, the retrofit by adding intake draft fans in the internal corridor is proposed and verified by simulation. This study will provide references for future kitchen smoke exhaust renovations in other old residential buildings in China.

Keywords: old residential buildings, cooking smoke pollution, kitchen smoke exhaust retrofit.

1. INTRODUCTION

The 19th National Congress of the Communist Party of China emphasized the importance of improving people's livelihoods and enhancing the living conditions and quality of life for residents in old residential areas. This is a crucial measure to ensure that people live and work in peace and share the fruits of reform and development (Luo, 2019). The renovation of old urban residential areas has evolved from local initiatives to a major national-level livelihood project. According to the Shanghai Statistical Yearbook, the total area of residential buildings in Shanghai was 699.91 million square meters by the end of 2019, with buildings over 30 years old accounting for about 29.8% of the total residential building area. Nearly 30% of residential buildings require renovation or updating (Shanghai Municipal Statistics Bureau, 2021). The kitchen smoke exhaust methods in old residential areas in Shanghai mainly have two categories: 1) direct exhaust through external wall openings, and 2) exhaust into internal corridor through external wall openings. Field measurements have shown that the second method, which discharges smoke directly into internal corridor, significantly increases the PM2.5 concentration in the corridors during cooking periods. In some cases, the peak concentration exceeds the national standard (GB3095-2012) by more than eight times, reaching severe pollution levels (Gu, 2021). So there is an urgent requirement to deal with this issue by taking retrofit measures. Due to the limited height of corridor in old residential buildings, installing exhaust ducts would further reduce the net height of corridor and also increase

flow resistance, making it difficult for smoke to be effectively exhausted. Therefore, this study proposes in-stalling intake/exhaust draft fans at the external windows of the internal corridor used for diluting or exhausting kitchen smoke. How to effectively carry out the retrofit design of the draft fan, it is necessary to investigate to better understand the airflow characteristics of smoke in corridor of residential buildings, and its impact on indoor air quality, which help to find the optimal retrofit proposal to minimize exposure risk.

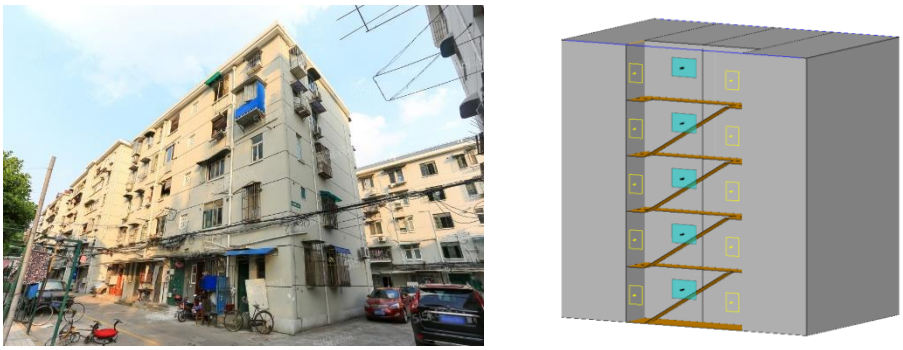
Existing research mainly adopts the method combining numerical simulation and experimental verification, focusing on aspects such as the smoke diffusion mechanism, pollutant distribution characteristics, and ventilation optimization strategies. He et al. (2021) proposed a kitchen air quality evaluation method based on air age and ventilation efficiency, providing a theoretical framework for quantitatively evaluating ventilation performance. Regarding the smoke diffusion law, Guo et al. (2025) systematically revealed the dynamic diffusion patterns of particles under different cooking scenarios through the collaborative analysis of orthogonal experiments and CFD simulations, and optimized the ventilation system de-sign based on the window opening and closing conditions. Xu et al.(2024), through experimental research and orthogonal experimental design, explored the coupled action mechanism of ventilation modes and cooking methods on the PM2.5 con-centration distribution in the kitchen and adjacent rooms, and further quantified the human exposure risk. In addition, Chen et al. (2025) deeply explored the pollutant removal efficiency of kitchen hoods and natural ventilation openings under different seasonal conditions through CFD simulations, revealing the differential impacts of winter and summer ventilation strategies on the air flow organization and pollutant distribution. Although scholars have conducted a large amount of research on the problem of kitchen smoke diffusion, existing studies have rarely investigated the conditions when the smoke is exhausted into corridor in old residential buildings. Moreover, how to reasonably select the fan type, choose the fan installation location, and determine the fan control strategy are the issues that need to be determined.

Therefore, this paper utilizes computational fluid dynamics tool to simulate airflow distribution to further analyze the diffusion patterns and characteristics of cooking smoke in internal corridor under different cases, providing references and suggestions for retrofit proposal.

2. METHODOLOGY

2.1 Model Setup

Computational Fluid Dynamics (CFD) is a widely used tool for simulating various airflow-related scenarios such as optimization of kitchen ventilation. Its ad-vantages include the ability to simulate results for different settings by adjusting conditions. Researchers have used CFD to assess airflow in kitchens to support the exhaust system effectively during cooking while minimizing undesirable air-flow patterns and smoke dispersion (Zhou, 2016). Therefore, the simulation analysis in this study was conducted using Airpak 3.0 software, with the primary goal of investigating the impact of residential kitchen smoke on the air quality in corridor. A typical five-story residential building in an old residential area in Shanghai was selected for modeling. The building has a floor height of 3 meters, with the corridor located on the north side. The corridor was set as the computational domain, with all apartment doors assumed to be closed and windows facing the outdoor area open. Figure 1 shows the 3D model of the residential building.



(a) (b)

Figure 1. 3D model of the residential building.

2.2 Model settings and case design

2.2.1. Current Scenario

There are two exhaust vents for two families on each floor. Based on market survey, the airflow rate of kitchen hoods currently sold on the market ranges from 16 m³/min to 21 m³/min. For this study, the airflow rate was set at 18 m³/min, with an exhaust vent area of 0.04 m², resulting in an exhaust velocity of 7.5 m/s. The temperature of the exhaust smoke was set at 30°C and the CO_2 was used as a representative pollutant due to its high relationship with smoke concentration(as shown in Figure 2) to analyze the airflow diffusion of pollutants based on field test (Gu, 2021). The outdoor CO_2 concentration was set at 400 ppm. The CO_2 concentration at the exhaust vent was set at 2000 ppm by field test, and the outlet was set as the windows on the outer side of each floor's corridor, with free outflow conditions. The effect of outdoor wind is not considered in this study. To study the impact of kitchen smoke exhaust on the corridor and the interaction between different floors, six simulation cases were set up, as shown in Table 1. The simulations were conducted for both winter and summer cases. The average outdoor temperature for winter was set at 4.2°C, and for summer, it was set at 31.2°C, based on Shanghai's typical outdoor temperatures.

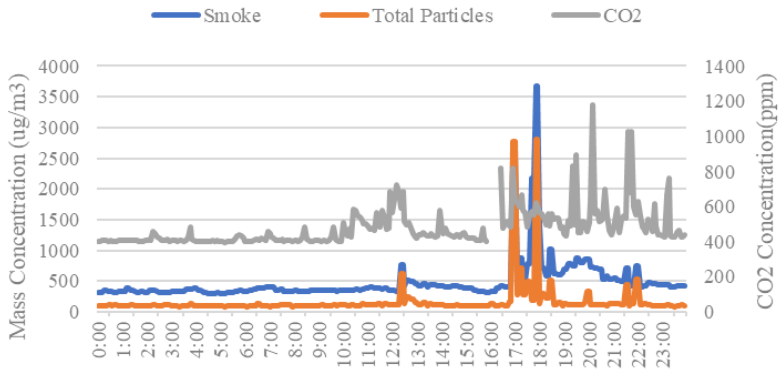


Figure 2. Pollutant concentrations relationships among somke, particles and CO_2 (Gu, 2021)

Table 1. Simulation cases for airflow distribution of current scenario.

Case No.	Definitions
C1	First-floor exhaust vents work
C2	Second-floor exhaust vents work
C3	Third-floor exhaust vents work
C4	Fourth-floor exhaust vents work

C5	Fifth-floor exhaust vents work
C6	All exhaust vents work on all five floors

2.2.2. Retrofit scenario

In order to effectively carry out the retrofit design of the draft fan, it is necessary to investigate factors such as the layout position, quantity, fan type and airflow capacity of the draft fan. Based on the above simulation results, smoke tends to accumulate in the area near the entrance stairwell and is difficult to diffuse out-ward due to the floor slab obstruction in winter. In summer, smoke diffusion is more uniform on both sides of the corridor. The draft fans can be installed at the external windows on east or west side or both sides of the corridor. It's better to use less fans. The airflow capacity of the fans can be referenced from the kitchen ventilation design standards, with air change rates between 40-60 times per hour, and the base airflow capacity is set at 0.5 m³/s. The worst smoke exhaust condition is selected for study, i.e. all the smoke exhaust vents work on all five floors. Therefore, the following cases are designed for simulation (as shown in Table 2), and the final solution can be determined by comparing the effectiveness of draft fans in different cases.

Table 2. Simulation cases for airflow distribution of retrofit scenario.

Case No.	Definitions
RP1	One intake fan at east side, fan airflow capacity 0.5000 m^3/s
RP2	One exhaust fan at east side, fan airflow capacity 0.5000 m^3/s
RP3	One intake fan at west side, fan airflow capacity 0.5000 m^3/s

RP5	One intake fan at east side, one intake fan at west side, fan airflow capacity 0.5 m^3/s
RP6	One intake fan at east side, one exhaust fan at west side, fan airflow capacity 0.5 m^3/s
RP7	One exhaust fan at east side, one intake fan at west side, fan airflow capacity 0.5 m^3/s
RP8	One exhaust fan at east side, one exhaust fan at west side, fan airflow capacity 0.5 m^3/s
RC1	The best RP case with fan airflow capacity 0.125 m^3/s
RC2	The best RP case with fan airflow capacity 0.250 m^3/s
RC3	The best RP case with fan airflow capacity 0.500 m^3/s
RC4	The best RP case with fan airflow capacity 1.000 m^3/s

3. RESULTS AND DISCUSSIONS

3.1 Current scenario

3.1.1. Winter results

Figure 3 shows the pollutant concentrations on each floor at a height of 1.5 meters above the pedestrian area under different cases in winter. It is evident that the emission of pollutants on the current floor has a direct impact on the pollutant concentration of the floor above. When all five floors are operational, the fifth floor exhibits the highest concentration of pollutants, followed by the third, second, fourth, and first floors, in descending order. The analysis reveals that while pollutants increase progressively with each floor, the diffusion to the fourth floor is unique. The absence of a staircase on the fifth floor allows the smoke from the left side of the fourth floor to ascend rapidly to the fifth floor without lingering or accumulating on the fourth floor, resulting in a significantly higher concentration of pollutants on the fifth floor compared to the others. Both the second and third floors are subject to the obstruction of staircases, which causes pollutants to linger, leading to slightly higher concentrations than on the unobstructed fourth floor.

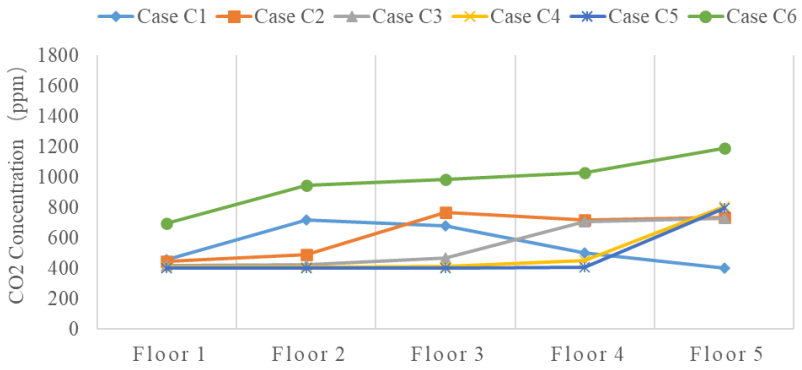

Figure 3. Pollutant concentrations at 1.5m above pedestrian area in winter

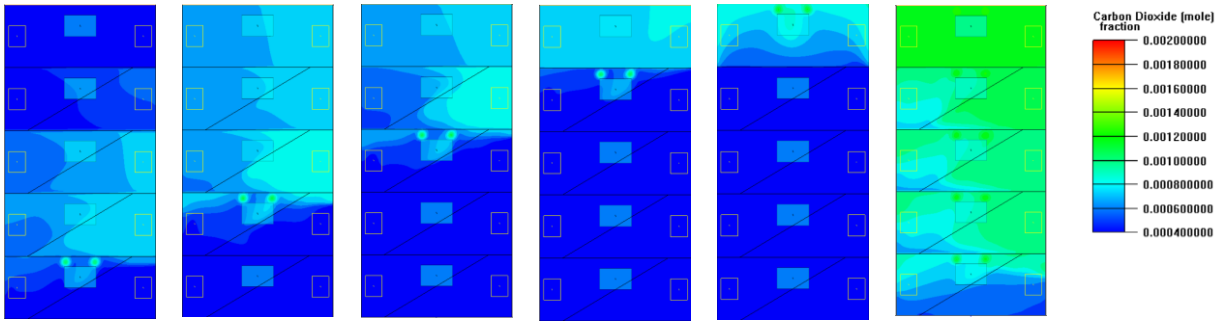
Figure 4 shows the pollutant concentration distribution in the corridor under these cases. The results indicate that kitchen smoke exhaust on the current floor affects the upper floors, with the most significant impact on the adjacent upper floor. The effect gradually weakens as the floor level increases. Due to the thermal stack effect, pollutants rise along the stairwell, with higher concentrations on the right side due to the stairwell's structure. The more exhaust vents are open on lower floors, the higher the pollutant concentration on upper floors. When all five floors' exhaust vents are open, the pollutant concentration on the fifth floor is 3.6 times higher than when only the current floor's vents are open.



(a) Case C1 (b) Case C2 (c) Case C3 (d) Case C4 (e) Case C5 (f) Case C6

Figure 4. Pollutant concentration distribution in the corridor section in winter

3.1.2. Summer results

Figure 5 shows the pollutant concentrations on each floor at a height of 1.5 meters above the pedestrian area under different cases in summer. It can be seen that the emission of pollutants on the current floor exerts a direct influence on the pollutant concentration of the floor immediately above. The concentration of pollutants on the same floor exhibits a significant increase compared to that in the winter conditions. The main reason is attributed to the big temperature difference between the corridor and the outdoor environment during winter, which facilitates the diffusion and dilution of smoke due to the stack effect. Conversely, the temperature difference between the corridor and the outdoor environment is relatively small during summer, which reduce the dispersion of pollutants, leading to their accumulation and higher concentration levels within the building's interior spaces. From Figure 6, it can be observed that kitchen smoke exhaust on a given floor primarily affects the current floor and the floor above, with less noticeable thermal stack effects. The pollutant distribution across floors is more uniform in summer. The average pollutant

concentration across all floors is significantly higher in summer than in winter.

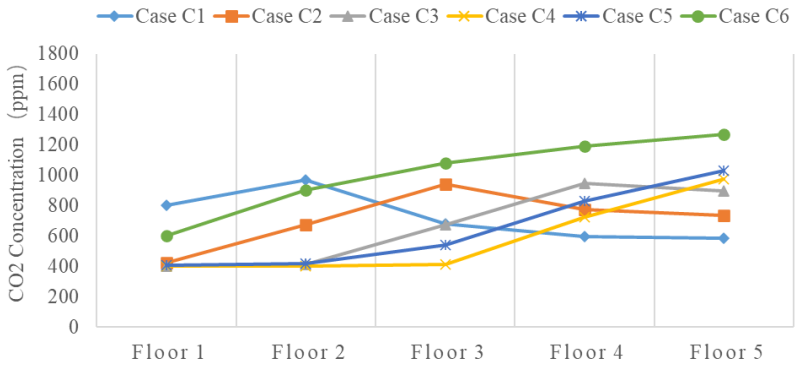


Figure 5. Pollutant concentrations at 1.5m above pedestrian area in summer

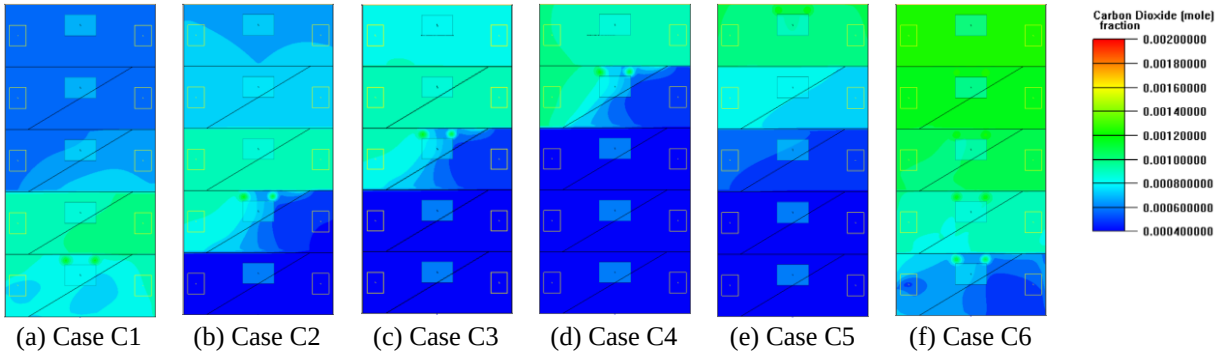

(a) Case C1 (b) Case C2 (c) Case C3 (d) Case C4 (e) Case C5 (f) Case C6

Figure 6. Pollutant concentration distribution in the corridor section in summer

3.2 Retrofit scenario

3.2.1. Effect of fan retrofit design

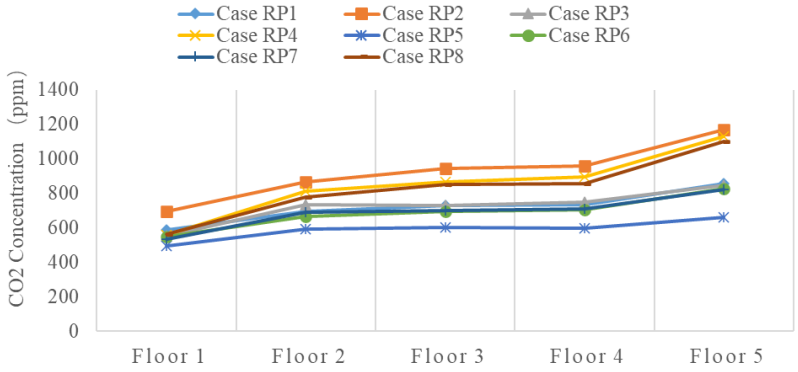

Figure 7. Pollutant concentration comparisons under different retrofit cases

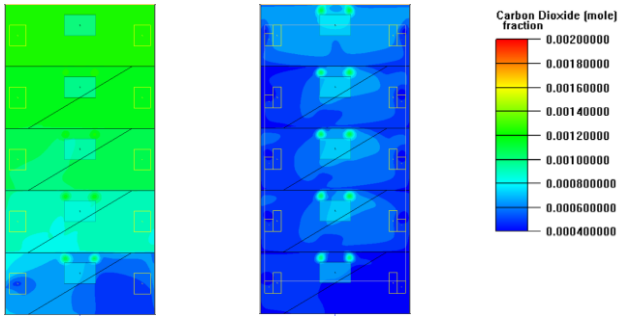
Figure 7 compares the simulation results of pollutant concentrations under various cases, considering different fan positions, types, and quantities. From this figure, it can be observed that when only one fan is installed (cases RP1-RP4), the position of the fan has a small impact on the dilution of pollutants. Supply fans exhibit better pollutant dilution performance compared to exhaust fans, primarily because the fans are positioned in the middle of open windows, which

limits their ability to create effective suction. Comparing cases RP5-RP8, where two fans are installed, the best pollutant dilution effect is achieved when both fans are supply fans (Case RP5), showing a significant improvement over a single supply fan. However, when one of the fans is an exhaust fan, increasing the number of fans provides very little improvement in pollutant dilution. Therefore, the optimal retrofit solution (Case RP5) is to install supply fans on both sides of the corridor, as illustrated in Figure 8. This configuration introduces fresh outdoor air into the corridor, effectively diluting kitchen fumes, which are expelled through the central opening of the corridor.



(a) Before retrofit (b) After retrofit

Figure 8. Pollutant concentration distribution in the corridor section for Case RP5

3.2.2. Effect of fan airflow capacity

The airflow rate of the fans affects pollutant dilution efficiency, fan energy con-sumption, and operational noise. Therefore, the pollutant removal efficiency under different airflow rates was compared. Figure 9 shows the simulation results of pollutant concentrations under various airflow rates. As the airflow rate increases, the steady-state pollutant concentration in the corridor significantly decreases, indicating that higher airflow rates improve dilution. However, this also leads to higher energy consumption and noise levels. Given that pollutant emissions in the corridor occur intermittently during cooking, the recommended airflow rate for the fans should not exceed 0.5 m³/s based on the calculation results.

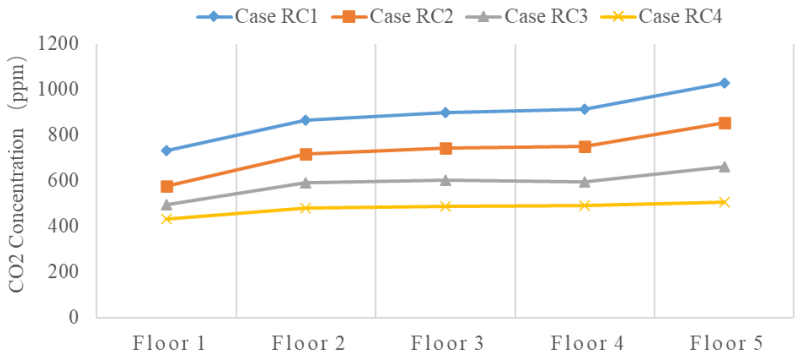


Figure 9. Pollutant concentrations on each floor after renovation under summer cases

Additionally, to further reduce energy consumption, considering the vertical distribution of pollutant concentrations, which increase with height, it is practical to install low-capacity fans on lower floors and high-capacity fans on upper floors. Furthermore, fan operation can be synchronized with the user-side kitchen hood or controlled using sensors for more efficient operation. PM2.5 or smoke sensors can be installed in the internal corridor. When the smoke

concentration exceeds a set threshold, the induced draft fans on the corresponding floor are activated. When the concentration falls below the threshold, the fans will be shut down.

5. CONCLUSIONS

This study investigates the real issue of direct kitchen exhaust emissions into the corridors of old residential buildings in Shanghai, which significantly impacts residents' quality of life and health. Therefore, this study uses simulations to analyze the dispersion patterns of pollutants within the corridors during both winter and summer seasons. Based on these findings, the retrofit proposal is given and verified. The main conclusions are as follows:The simulation results show that after being discharged into the internal corridor, kitchen smoke tends to linger in the upper part of the local floor and diffuse up-ward along the stairwell, with the most severe pollution occurring in the adjacent upper corridor. The more smoke exhaust on the lower floors, the greater the im-pact on the higher floors. In winter, due to the thermal stack effect, pollutants diffuse rapidly to the upper floors, while in summer, the diffusion is slower. However, the average pollutant concentration in the corridor is higher in summer than that in winter. To deal with these issues, the optimal retrofit solution by installing intake fans on both sides of the corridor is prosed and verified by simulation. This configuration introduces fresh outdoor air into the corridor, effectively diluting kitchen fumes, which are then expelled through the central opening of the corridor. The intake draft fans can be independently controlled based on the smoke concentration on each floor or linked to the kitchen hoods to ensure that the smoke con-centration remains low and does not adversely affect residents' lives. It is hoped that this study will provide references for future kitchen smoke exhaust renovations in old residential areas in Shanghai. The limitation of this study is that the simulation and analysis without considering the influence of the change of wind speed in the vertical direction of high-rise buildings on the effect of air flow distribution, which will be included in the future.

ACKNOWLEDGEMENTS

Evaluating indoor environment and electricity consumption of UK homes retrofitted with air source heat pumps

Rajat Gupta [1], Sahar Zahiri[1]

[1]*Low Carbon Building Research Group, School of Architecture, Oxford Brookes University, Oxford OX3 0BP, rgupta@brookes.ac.uk*

SUMMARY
Heat pumps are integral to the UK's Net Zero strategy. This study investigates the impact of air source heat pumps (ASHPs) on indoor environmental conditions and electricity use in nine retrofitted homes in Oxford during winter 2023–2024. Adopting a mixed-methods approach, indoor and outdoor temperatures, relative humidity, and CO_2 levels were monitored, alongside Energy Performance Certificate data and household surveys. Most homes maintained indoor temperatures above the WHO-recommended 18°C, though some fell below 20°C, which may be inadequate for vulnerable occupants. Smart meter data from four homes showed daily electricity use ranging from 9.4 to 23.2 kWh, with peak demand typically outside the 4–7 p.m. window. Variability of electricity use was strongly influenced by occupant behaviour. Findings highlight the potential for time-of-use tariffs to encourage off-peak heating and the need for tailored retrofit approaches that consider user practices. Optimising heat pump use requires balancing comfort, cost, and system efficiency through user engagement and adaptive control.

Keywords: Heat pump, electricity use, environmental monitoring, occupant behaviour

1. INTRODUCTION AND BACKGROUND

To meet its legally binding Net Zero emissions target by 2050, the UK Government aims to install 600,000 low-carbon heat pumps annually by 2028 (HM Government, 2020), accelerating the phase-out of gas boilers, which currently account for approximately 30% of national energy demand (BEIS, 2022; DESNZ, 2023). Within this ambition, an estimated 5 million heat pumps are expected to be deployed by 2030, rising to 19 million by 2050. The widespread adoption of heat pumps could place considerable strain on the electricity network, potentially exceeding the UK power system's current peak load capacity of 60 GW (Watson et al., 2021). This presents an urgent need for demand-side management strategies to ensure system stability and cost-effectiveness.

Smart control technologies have emerged as key enablers for managing peak loads and enhancing grid flexibility. Evidence suggests that smart systems can reduce energy use by up to 39% and shift demand away from peak periods, alleviating network stress (Pallonetto et al., 2021; Carbon Trust, 2020). Time-of-Use (TOU) tariffs, when combined with automated controls, allow households to shift electricity use to off-peak hours, reducing operational costs and peak demand (Rosenow & Lowes, 2020). For example, a Carbon Trust (2020) study found that integrating TOU tariffs in 15 London homes led to a 25% reduction in energy costs. Yet, such interventions are often undermined by behavioural and cultural dynamics, including fixed daily routines, concerns over comfort, and mistrust in automated systems (Dimitrokali et al., 2015; Powells et al., 2014).

Empirical studies have demonstrated that user operation mode is a critical determinant of heat pump performance. In a study of 50 social housing dwellings in Oxford, Gupta and Zahiri (2023) found that residents' preference for manual operation significantly increased electricity use compared to timer-based operation, which adapts to weather conditions. Similarly, thermal

performance of the building fabric plays a key role in determining heat pump efficiency. Research by Stafford and Bell (2009) and Sarbu and Sebarchievici (2015) emphasises that low-temperature heating systems perform best when combined with adequate insulation and airtightness.

Despite the growing deployment of air source heat pumps (ASHPs) across the UK, there remains limited evidence on their impact on indoor environmental quality, electricity use, and occupant behaviour - particularly across diverse household types and in real-world settings. Existing research often overlooks the dynamic interactions between residents, building performance, and heating technologies, as well as the broader implications for equity and system flexibility.

In this context, the present study investigates the effects of ASHP retrofits on indoor environmental conditions and electricity consumption in nine nearly identical dwellings in Oxford (UK) during the winter of 2023–2024. Using a mixed-methods approach, the study monitors indoor temperature, relative humidity, CO_2 concentrations, and electricity use via smart meters, supplemented by pre-heat pump household surveys and Energy Performance Certificate (EPC) data. This research aims to fill a critical gap in understanding how heat pump operation affects household energy demand, thermal comfort, and the potential for alignment with TOU tariffs during peak periods (4–7 p.m.). The findings provide empirical insights for policymakers, energy providers, and retrofit practitioners aiming to optimise heat pump performance while maintaining occupant comfort and reducing peak electricity loads.

2. METHODOLOGY

This study adopted a mixed-methods approach to investigate the impact of air source heat pump (ASHP) installations on indoor environmental quality and electricity consumption across nine residential dwellings (D01–D09) located in Oxford, UK. The approach combined quantitative monitoring of environmental parameters and electricity use with qualitative survey data to contextualise occupant experience. Environmental monitoring was conducted in bedrooms and living rooms, alongside outdoor measurements, from 21 December 2023 to 28 February 2024, a period characterised by peak seasonal heating demand. Indoor temperature, relative humidity, and CO_2 concentration were recorded at 15-minute intervals using Bluetooth-enabled HOBO data loggers. Outdoor temperature and humidity were also monitored. Smart meter data were extracted from four dwellings (D01–D03 and D07) using Ivie-Bud meters, allowing analysis of hourly electricity consumption, including time-of-use patterns and cost variability across tariff bands. To assess the change in energy consumption due to heat pump installation, post-installation electricity use (February 2024) was compared to pre-installation use during the same period in 2023. The specifications of the monitoring devices and smart meters are detailed in Table 1.

Table 1. Specification of the environmental monitoring devices, and smart meter

Monitoring devices		Location	Parameter	Range	Accuracy	Resolution
	HOBO MX2301	Garden	Outdoor temperature (°C)	-40-70	±0.2	0.036
			Outdoor relative humidity (%)	0-100	±2.5-3.5 (10% to 90%); ±5 (below 10% and above 90%)	0.01
	HOBO MX1101	Principal bedroom	Indoor temperature (°C)	-20-70	±0.2	0.024
			Indoor relative humidity (%)	1-90	±2 (20% to 80%) ±6 (below 20% and above 80%)	0.01
	HOBO MX 1102	Living room	Indoor temperature (°C)	0-50	±0.2	0.024
			Indoor relative humidity (%)	1-90	±2 (20% to 80%); ±6 (below 20% and above 80%)	0.01
			CO_2 (ppm)	0-5000	±50 ppm ±5% of reading at 25°C, less than 90% RH non-condensing and 1,013 mbar	N/A
	Ivie-Bud smart meter	Living room	Readings and Powers (Watt) Time period and segments Electricity cost (per hour) Ambient (amber, green, red)	N/A	N/A	N/A

In addition to monitoring, pre-installation Energy Performance Certificate (EPC) data were used to extract information on dwelling characteristics, including floor area, thermal fabric, energy efficiency rating, and annual space heating demand. This was complemented by in-person, questionnaire-based household surveys, which gathered information on thermostat settings, energy tariffs, satisfaction with heating systems, and attitudes towards energy use. The surveys incorporated scalar, nominal, and ordinal variables, including Likert-scale responses (1 = strongly disagree to 5 = strongly agree) and were carried out before installation of heat pumps. Socio-demographic and lifestyle segmentation was further informed by Acorn and Mosaic classifications to explore the influence of household characteristics on heating behaviours.

3. OVERVIEW OF THE CASE STUDY DWELLINGS AND HOUSEHOLDS

The nine case study dwellings, all retrofitted with ASHPs between April and November 2023, are located in the Iffley and Rose Hill areas of Oxford (UK). The sample included five end-terrace, three semi-detached, and one mid-terrace house, reflecting a range of typical UK housing typologies. Despite their similar construction age and external conditions, the dwellings varied significantly in floor area (62–128 m²), energy performance, and heating demand. Energy Performance Certificates (EPCs) revealed a broad range of pre-installation energy efficiency ratings, from B (very efficient) in dwelling D01 to E (least efficient) in D09. Annual space heating demands ranged from 6,804 kWh to 12,870 kWh, depending on insulation, building form, and glazing type. All homes were naturally ventilated and predominantly double-glazed, with varying levels of wall and loft insulation. Detailed dwelling characteristics are presented in Table 2.

Table 2. Dwelling characteristics extracted from energy performance certificates (EPCs)

Dwelling ID	Dwelling type	Floor area m²	No of bedroom	Energy efficiency rating	Heating demand kWh/year		Wall type	Roof type	Glazing type
					Space	Hot water			
D01	End-terrace house	92	3	91 B	6,804	1,934	Filled cavity wall with external insulation	Pitched, 270 mm and 350 mm loft insulation	Mostly double glazed
D02	End-terrace house	62	2	63 D	8,759	1,888	Cavity wall with and without insulation	Pitched, 270 mm loft insulation	Double glazed
D03	Semi-detached house	75	2	77 C	8,592	2,619	Filled cavity wall, with filled insulation	Pitched and dwelling with 100 mm loft insulation	Double glazed
D04	End-terraced house	117	3	57 D	12,870	2,958	Cavity wall, and solid brick with insulation	Pitched roof with 270 mm loft insulation	Double glazed
D05	Mid-terrace house	74	2	61 D	7,063	2,760	Filled cavity wall and solid brick	Pitched, 200 mm loft insulation	Double glazed
D06	Semi-detached house	128	3	68 D	12,078	2,303	Filled cavity wall insulation	Dwelling roof insulation	Mostly double glazed
D07	End-terrace house	77	3	64 D	8,475	2,076	Filled cavity wall, and solid brick	Pitched and dwelling roof, 150 mm loft insulation	Mostly double glazed
D08	End-terrace house	93	2	72 C	8,920	1,953	Filled cavity wall insulation	Pitched and dwelling roof, 100 mm lost insulation	Double glazed
D09	Semi-detached house	76	3	41 E	8,669	3,386	Filled cavity wall insulation	Pitched, 270 mm loft insulation	Double glazed

The socio-economic composition of the households was diverse in terms of tenure, income, age, and household structure. Six dwellings were owner-occupied, with residents having lived in the homes for between four and eleven years. The majority of respondents fell within the 36–55 age band, and household incomes ranged from £15,000–£19,999 (e.g. D02) to £50,000–£64,999 (e.g. D07), indicating a range of economic conditions. Lifestyle classifications indicated a mix of household types, including “mature families,” “elderly households,” and “mature singles.” One household (D06) included young children, while another (D05) comprised a family of five. Pre-installation survey results showed that one-third of respondents were on a standard tariff, and most set their main thermostat to 20°C. Heating usage was typically seasonal, operating between

October and March, with reported differences in thermal comfort preferences between occupants. Although two-thirds of participants indicated a reluctance to compromise on comfort to reduce energy bills, most expressed a willingness to adjust their energy use to reduce costs - highlighting the potential for behavioural flexibility. These contextual insights are essential to interpreting the monitored performance data in light of real-world user behaviour and preferences.

4. FINDINGS

4.1. Indoor temperature and relative humidity

Descriptive statistics and distributions of indoor temperature and relative humidity (RH) levels, presented in Figure 1, demonstrate spatial and temporal variability across bedrooms and living rooms in the nine case study dwellings between 21 December 2023 and 29 February 2024. Excluding the largely unoccupied dwelling D04, bedroom temperatures ranged from 15.5°C in end-terrace dwelling D02 to 21.5°C in semi-detached dwelling D03. Living room temperatures varied more widely, from 16.1°C (D02) to 21.5°C (D06). While bedroom temperatures largely conformed to the CIBSE Guide A comfort range of 17–19°C (CIBSE, 2021), most living rooms failed to achieve the recommended comfort range of 22–23°C, possibly due to the lower output temperatures of ASHPs and resident control preferences. Variations in indoor temperature closely correlated with RH levels, which ranged from 45% (D03, D05) to 75% (D08) in bedrooms, and from 49% (D06) to 71% (D08) in living rooms.

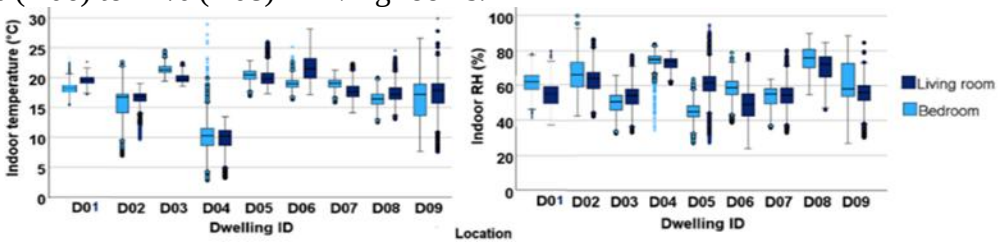

Figure 1. Distribution of indoor temperature and relative humidity between 21st December 2023 and 29th February 2024 in the bedrooms and the living rooms of the nine dwellings

As shown in Figure 2, daily temperature profiles remained relatively stable throughout the monitoring period, with most peaks occurring outside the national electricity peak demand window (4–7 p.m.). This suggests that ASHP operation in these homes may have been strategically or habitually aligned with off-peak periods.

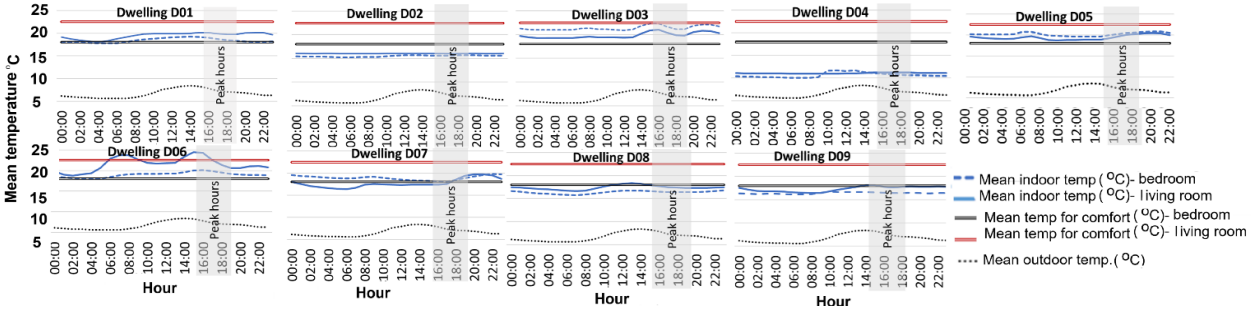

Figure 2. Mean daily indoor temperature profiles between 21st December 2023 and 29th February 2024 across the bedrooms and living rooms of nine dwellings

Indoor temperatures consistently exceeded the WHO-recommended minimum of 18°C in dwellings D01, D03, and D05–D07, with the highest recorded temperatures - up to 24.8°C - occurring at 8:00 a.m. and 3:00 p.m. in D06, a family home with young children. However, most

living room temperatures remained below the recommended 22–23°C comfort range, as well as the 20°C threshold for vulnerable groups set by WHO guidelines.

4.2 Indoor CO_2 concentration

The distribution and daily profiles of CO_2 concentrations, summarised in Figure 3, showed notable variation across living rooms in the nine dwellings. The highest recorded value- over 3000 ppm - occurred in D05, a mid-terrace home occupied by a family of five, where the mean daily CO_2 concentration reached 890 ppm. In contrast, the lowest mean concentration (427 ppm) was recorded in D04, which had limited occupancy. Despite some exceedances, the majority of daily mean concentrations remained within the 800–900 ppm threshold recommended for good indoor air quality. Temporal alignment between CO_2 and temperature peaks suggests that increased occupancy levels may have led to more frequent heat pump operation to maintain comfort, indicating behavioural coupling between environmental control and indoor air quality.

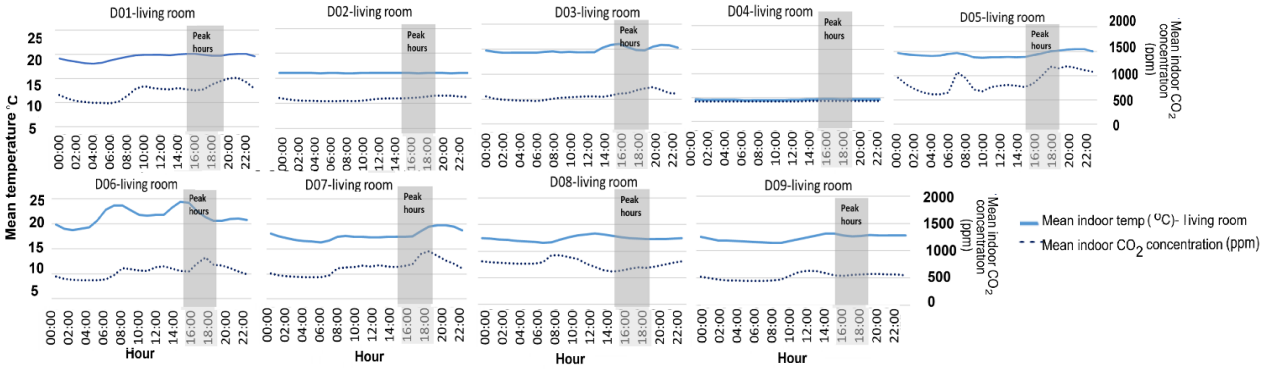

Figure 3. Distribution and mean daily indoor CO_2 concentration profiles between 21st December 2023 and 29th February 2024 across the living rooms of nine dwellings

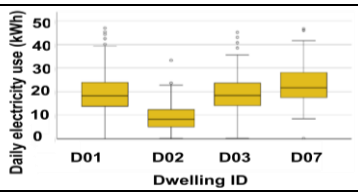
4.3 Electricity use in a subset of four dwellings

Smart meter data from four dwellings (D01–D03 and D07) were analysed to examine patterns in electricity use following heat pump installation. Descriptive statistics for daily electricity use are presented in Table 3. Mean daily usage ranged from 9.4 kWh in D02 to 23.2 kWh in D07 - both dwellings with similar energy efficiency ratings (D) but differing significantly in household income and occupancy, suggesting socio-behavioural factors strongly influenced energy demand.

Table 3. Descriptive statistics and distribution of daily electricity use between 21st December 2023 and 29th February 2024 in four dwellings

Descriptive Statistics- Daily electricity use (kWh)				
Dwelling ID	Min	Max	Mean	Std. Deviation
D01	.1	46.9	20.3	9.7
D02	.1	33.3	9.4	6.7
D03	.2	45.1	19.9	8.6
D07	.9	46.6	23.2	9.2



As illustrated in Figure 4, daily electricity use patterns mirrored fluctuations in outdoor temperatures, indicating that heating demand was the principal driver of energy consumption. While peak consumption generally occurred outside the 4–7 p.m. window - often around 6:00 a.m. - the highest recorded peak (1.25 kWh at 6:00 p.m.) was observed in D07, likely reflecting evening occupancy patterns and concurrent appliance use.

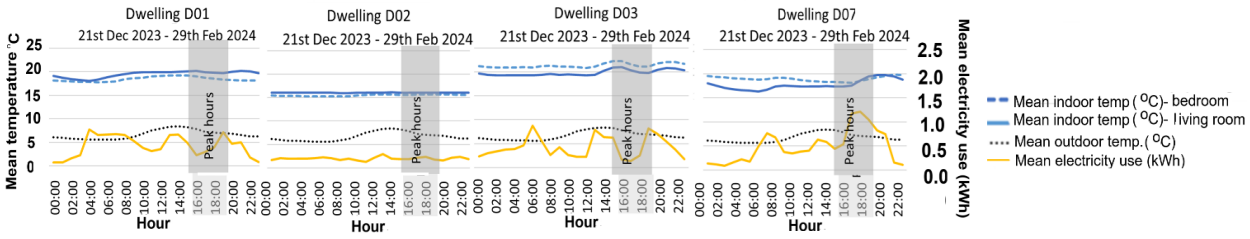


Figure 4. Daily electricity use and mean indoor and outdoor temperature profiles in four dwellings between 21st December 2023 and 29th February 2024

4.3.1 Electricity use before and after heat pump installation

Electricity consumption was compared across two matched timeframes: pre-installation (18–28 Feb 2023) and post-installation (18–28 Feb 2024). As shown in Figure 5, mean daily use increased significantly in all four dwellings post-installation, with D02 rising from 2.8 kWh to 9.7 kWh and D07 from 12.5 kWh to 21.8 kWh. These increases align with the added heating load of the ASHPs in winter. While total electricity use increased, peak demand remained largely outside the 4-7 p.m. period in most cases. Exceptions included D07, where a peak of 2.4 kWh was recorded at 6:00 p.m., again suggesting behavioural patterns may override economic incentives for off-peak usage. Interestingly, electricity use patterns remained consistent in terms of timing, suggesting limited behavioural adaptation following heat pump installation. This indicates that while ASHPs can operate efficiently during off-peak hours, achieving demand-side response (DSR) benefits may require more proactive control strategies or greater user engagement.

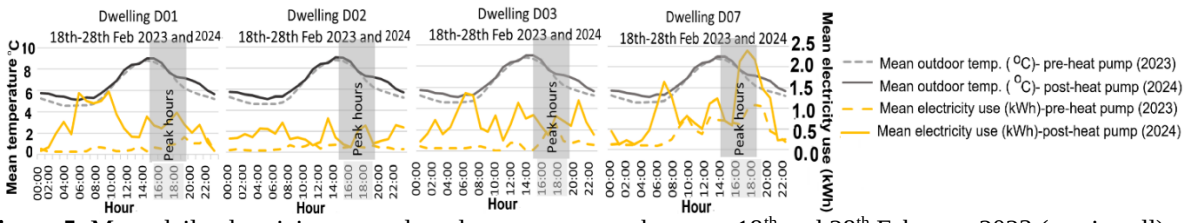

Figure 5. Mean daily electricity use and outdoor temperature between 18th and 28th February 2023 (pre-install) and 2024 (post-install) across four dwellings

5. DISCUSSION

The pre-heat pump installation household surveys revealed that most occupants maintained their heating systems from October through March, with thermostat settings typically around 20°C. This indicates a strong preference for thermal comfort, suggesting that resident training on the operation of low-flow continuously operating heat pumps could enhance performance. Encouraging adaptive thermal behaviours, supported by smart heating controls, may optimise energy use by enabling more efficient setpoint schedules while maintaining comfort. Although two-thirds of respondents were reluctant to compromise comfort to reduce energy bills, a majority expressed willingness to modify electricity use patterns to save on energy costs. This reinforces the potential of time-of-use (TOU) tariffs to encourage off-peak heating behaviours, particularly given the financial pressures on lower-income households in the current energy pricing landscape (Gupta & Zahiri, 2024).

Temperature data collected during the monitoring period demonstrated that while mean daily bedroom temperatures largely aligned with the CIBSE Guide A comfort range (17–19°C), mean living room temperatures averaged only 17.6°C-below both the CIBSE-recommended range (22–23°C) and the WHO's minimum of 20°C for vulnerable residents. These findings highlight the importance of personalised temperature control and the need to better align heat pump operation

with occupant comfort requirements. Although indoor temperature variations were primarily influenced by occupant behaviour, the role of building fabric performance was also evident, supporting existing literature on the importance of fabric upgrades prior to low-temperature heating system retrofits (Sarbu & Sebarchievici, 2015; Stafford & Bell, 2009).

Smart meter data from four dwellings indicated that electricity consumption increased significantly following heat pump installation, with mean daily use ranging from 9.4 kWh (D02) to 23.2 kWh (D07), despite similar dwelling types and energy ratings. These discrepancies are likely attributable to socio-economic differences and household size. For instance, D02-a low-income, single-occupant household-recorded the lowest energy consumption and indoor temperatures, likely due to cost constraints. In contrast, D07-occupied by a higher-income family-demonstrated greater electricity use and warmer indoor conditions, particularly during colder periods. These patterns confirm that occupant behaviour, influenced by income and household structure, is a key determinant of heat pump energy use. Interestingly, peak electricity consumption occurred predominantly outside the 4–7 p.m. peak demand window, supporting the potential role of ASHPs in reducing network stress when supported by appropriate behavioural or automated control strategies. However, in some cases (e.g., D07), peaks aligned with evening activity, suggesting that behavioural factors may limit flexibility unless incentivised through pricing or automation.

Indoor air quality was generally within acceptable limits, with most dwellings maintaining mean daily CO_2 concentrations below the 800–900 ppm threshold. While dwelling D05 exceeded 3000 ppm during periods of high occupancy, this was an exception. These findings suggest that natural ventilation was largely sufficient, though occupancy-related variation reinforces the importance of tailored ventilation strategies to support both energy efficiency and indoor environmental quality.

Although this study was limited to a single winter season, early findings suggest strong interdependencies between occupant behaviour, socio-economic context, building performance, and heat pump operation. Future longitudinal studies across multiple seasons can capture changes in household practices over time, understand behavioural adaptation, and optimise post-retrofit performance in diverse household types.

6. CONCLUSION

This study evaluated the impact of air source heat pumps (ASHPs) on indoor environmental quality and electricity consumption in nine retrofitted dwellings in Oxford (UK) during the winter of 2023–2024. Using a mixed-methods approach, the research combined high-resolution monitoring of temperature, relative humidity, CO_2 levels, and electricity use, alongside household surveys and Energy Performance Certificate data.

Findings showed that most dwellings maintained indoor temperatures above the WHO minimum threshold of 18°C during the heating season. However, mean living room temperatures remained below recommended comfort levels, particularly for vulnerable populations, emphasising the need for tailored thermal comfort strategies and greater occupant awareness of heat pump operation. While electricity consumption increased following ASHP installation, smart meter data revealed off-peak usage patterns in most households, suggesting compatibility with TOU tariffs and demand-side response schemes. Socio-economic variation and household composition significantly influenced heating behaviours and energy consumption. Lower-income households

appeared to restrict energy use due to affordability, while higher-income households tended to maintain greater thermal comfort. These findings underscore the importance of personalised retrofit strategies that address both building performance and behavioural factors.

To encourage broader adoption of heat pumps and ensure optimal performance, policymakers should support residents with tailored energy tariffs, user-centred controls, and targeted communication strategies. Financial and technical support for low-income households is especially important to ensure equitable outcomes. Furthermore, future policies should promote longitudinal evaluation of heat pump use to better understand behavioural adaptation and system performance over time. Aligning these strategies with broader decarbonisation goals will be critical to supporting a just and efficient transition to low-carbon residential heating in the UK.

ACKNOWLEDGEMENT

This study has been undertaken as part of the Clean Heat Streets research project (Ref: PRJ 884) funded under the Heat Pump Ready innovation programme sponsored by the UK Department for Energy Security and Net Zero (DESNZ). We are grateful to the residents of the case study dwellings.

SUMMARY
The transport of the odorants from the indoor environment to the human respiratory tract is still poorly understood. This study used the computational fluid dynamics and physiologically based pharmacokinetic models (CFD-PBPK) to investigate the spatiotemporal transport patterns of acetaldehyde (released from a yogurt vessel as the source of the odorants) within different measuring spots, namely the indoor domain, breathing zone, the source of the released odorant, the nostrils, the fluid region of the airway, and the mucus-to-tissue layers of the airway microstructure. The results indicate that the nostrils and olfactory regions can capture a reasonable odorous concentration of the chemicals that correctly reflects the perceived intensity in the logarithmic correlations. However, the quantified volume-average concentration in the breathing zone or the room scale reflected unreasonable or odourless concentrations. Emphasizes the importance of the airway microstructure scale for assessment of indoor air quality by using the *in-silico* models, particularly for the harmful contaminants.

Keywords: Indoor Environment, Odorants, Air Quality, Airway Microstructure.

1. INTRODUCTION

Olfaction is a central function in assessing the acceptability and quality of the indoor environment, influencing communication, behavior, and food preferences (Dan et al., 2021; Hsieh et al., 2017). The transport dynamics of the odorants from the indoor environment to the respiratory tract remain poorly understood, with challenges induced by ethical considerations, *in-vivo* quantification complexities, and individual variability. Literature has highlighted the relationship between indoor air quality and acetone concentration (Bluyssen and Fanger, 1991), prompting studies aimed at enhancing odor perception and supporting healthy building principles. However, traditional odor intensity assessments relying on trained panelists are often inconsistent. While recent findings suggest a logarithmic correlation between odor intensity and concentration (David et al., 2024), these studies frequently overlook the complex interactions within the human airway domain, neglecting the microstructural complexities of the olfactory region. The literature lack empirical data of the relationship between odor intensity and concentration in each environmental scale, particularly the perceived intensity by human in the olfactory region. By integrating computational modeling and previous experimental data, this study aims to bridge these gaps, offering insights into odorants transport and interaction mechanisms at the receptor level, enhancing predictions of olfactory perception, and advancing indoor air quality research.

2. METHODOLOGY

This study used a coupled computational fluid dynamic (CFD) and physiologically based pharmacokinetic (PBPK) models to simulate odorant dynamics. The validated respiratory tract model incorporated a multi-layer air-mucus-tissue-blood (AMTB) model for odorant absorption analysis, as proposed by Tian and Longest (2010). The surface concentration was calculated at the air-mucus boundary using the absorption equilibrium and diffusion flux conservation equations for the low-viscosity layer. Odorant concentrations in the yogurt vessel were replicated from the experimental data to ensure consistent initial conditions and comparability to the parameters concluded from the odor sensory tests (OSTs). The acetaldehyde was used as a key odorant of the yogurt, as it includes guideline substances for assessing indoor air quality. The computational domain consisted of a CT-scanned seated computer-simulated person (CSP) combined with an airway model and placed in the center of a mixed-ventilated room (Fig. 1). The respiratory tract consists of seven main sections, while the olfactory surface region was divided into four segments to detect the spatial olfaction dynamics (Kuga et al., 2024; Kuga et al., 2023). Three breathing profiles were tested: normal breathing with two different airflow rates of 38 L/min and 24 L/min, and a sniffing cycle. The validation and verification of the computational domain were applied according to the prior studies (Yoo and Ito, 2022; Ito, 2016). The CFD boundary conditions and solving methods are summarized in Table 1.

Table. 1. Boundary conditions and solving methods for the CFD-PBPK numerical model.

Domain/	**Boundary Conditions**
Indoor Inlet Boundary	Velocity inlet = U_{in} = 0.51 m/s - Relative Humidity: RH_{in} =50 % RH
	Ambient air temperature: T_{in} = 25 °C (fixed value)
Indoor Outlet Boundary	Gradient zero conditions
Wall Treatment (room)	Temperature: adiabatic condition - Humidity: gradient zero
Airway Inlet Boundary	Velocity inlet, transient profile, 20 seconds durations
Wall treatment (airway)	Local PBPK integrated model - Wall Temperature = $T_{surface}$ = 36 °C
Wall Treatment (CSP)	No-slip wall, Fanger's model for heat generation.
Wall Treatment (Yogurt Vessel)	Temperature: adiabatic condition - Exterior walls: No Slip walls
Grid Design	Polyhedral Meshing. Total number of cells = 9.5 million.
Turbulence Model	SST k-ω model
Scheme/Algorithm	SIMPLE for Pressure-velocity coupling
Radiation Model	Surface-to-surface (S2S) model using "view factors"

3. RESULTS & DISCUSSION

In terms of concentration profiles across different measurement spots, fluctuation of odor concentration in the nostrils and the source of the odorants (the yogurt headspace) was associated with the breathing airflow jet during the inhalation and exhalation stages and the continued release of the chemicals from the yogurt vessel. The indoor domain showed negligible and highly mixed time-average concentration, reflecting the vast gap between the source of odorants and the surroundings. Fig 1A illustrates the correlations between the perceived odor intensity as a function of time-averaged equilibrium concentration measured in the indoor domain (Spot A), the headspace of the yogurt (Spot B), breathing zone (Spot C), nostrils (Spot D), and mucus layer in the olfactory wall (Spot E). The correlation coefficient R^2 indicates that nostrils and olfactory regions are good indicators as measuring spots, reflecting acceptable logarithmic approximation of the perceived odor intensity. The assessments of odorant concentration in the indoor domain or

the breathing zone can significantly overestimate or underestimate the odor intensity.

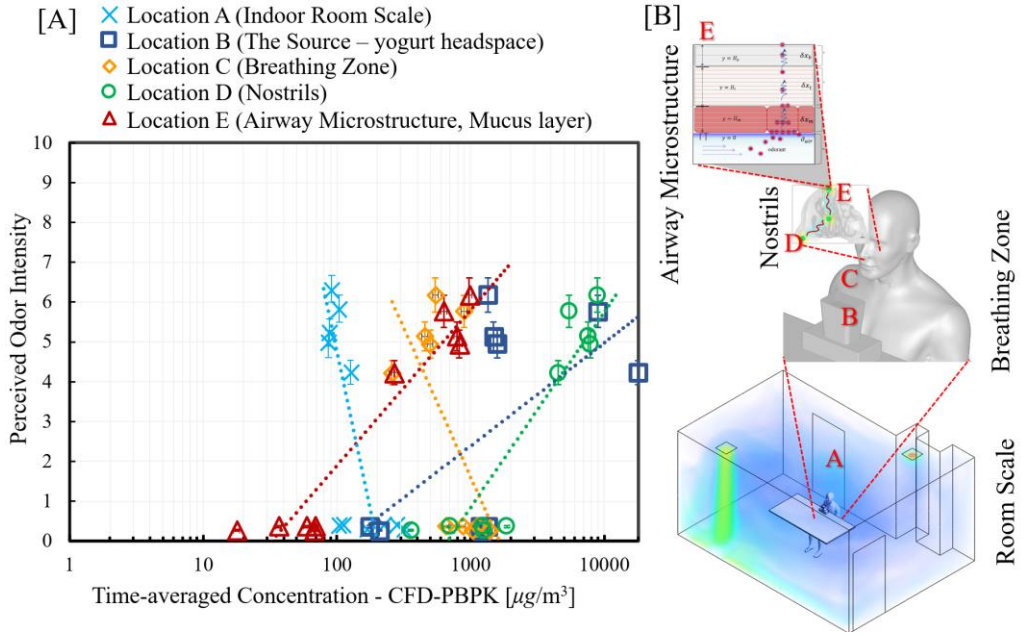

Figure 1. Panel [A] shows the correlation between perceived odor intensity and time-average concentration of the acetaldehyde in different physical scale. Panel [B] identifies these scales, which represented in the room scale, breathing zone, the source, nostrils, and the airway wall microstructure.

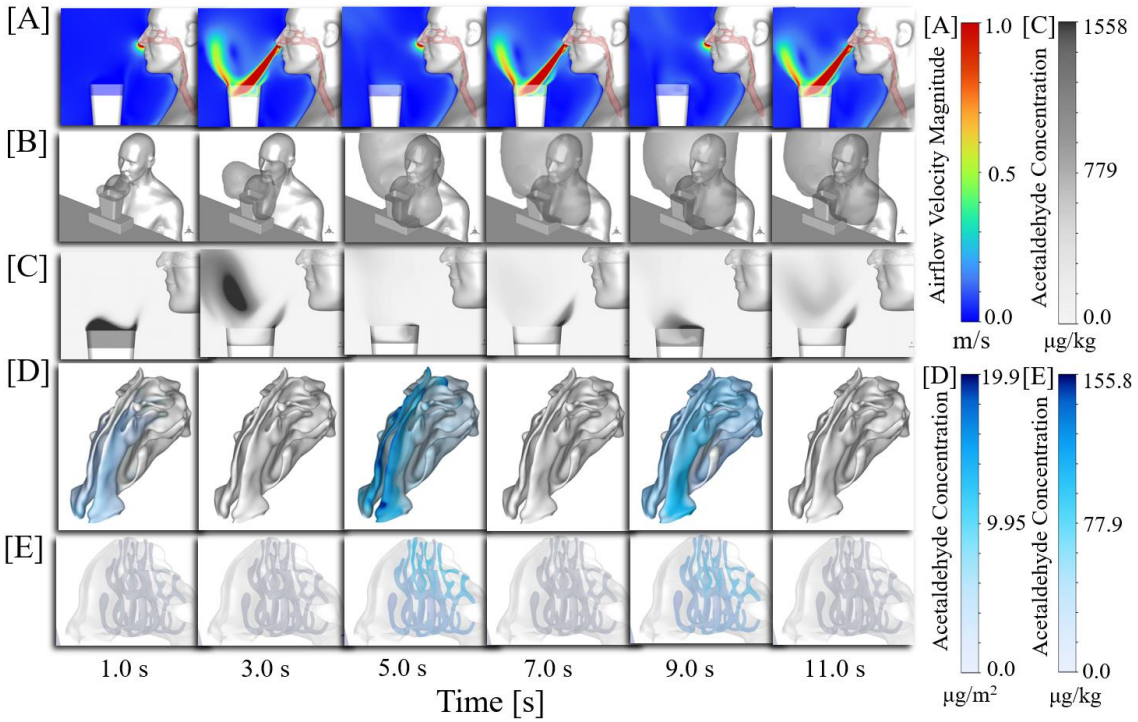

Figure 2. Visualizations of the spatial distribution of acetaldehyde concentration in the different regions. Figures in panel [A], [B], [C], [D], and [E] illustrates the velocity magnitude, scalar iso-surface, scalar concentration in the breathing zone, odor concentration in the nasal cavity wall, and inside the nasal passages, respectively.

The visualizations through the CFD-PBPK track can enrich our understanding of the transport of odorants in the room domain and the small passages of the olfactory recess. That reflects the

olfaction dynamics and transport between the indoor environment and microstructure of the airway wall (Fig. 2). Once the simulation was initialized with the first inhalation phase in parallel with the opening of the yogurt vessel, the acetaldehyde was released from the headspace with a dispersion route directed toward the nose. However, due to the distance between the vessel and the olfactory region with a short duration of inhalation, a low concentration of acetaldehyde reached the tissue layers. At 3.0 seconds, the peak of the exhalation phase, the puff from the nostrils caused extensive scattering of acetaldehyde into the outer regions. Correspondingly, low concentration was observed in the airway domain induced by the clearance. Furthermore, the yogurt lost its condensed odorant concentration in the headspace, which was reflected in the low concentration trend of the first cycle. During the second breathing cycle (around 5.0 seconds), the CSP inhaled the diffused odorants near the breathing zone, which occurred in the prior exhalation phase. Therefore, the second cycle showed higher concentration distribution in the airway domain compared to the first cycle. After the third cycle and subsequent cycles, the concentration started to be almost constant or with a slight increase.

4. CONCLUSION

This study has concluded that the perceived odor intensity from OSTs can be predicted logarithmically in correlation with the odorant concentration in the olfactory mucus layer. This offers a reliable *in-silico* prediction model for odor sensation based on numerically quantifiable parameters. Neglecting the human respiratory domain or the airway microstructure leads to underestimation of the olfaction phenomena and indoor air quality assessments, as the study proved that such domains could properly reflect the intensity of the odorants, unlike the wide room domain. This model offers potential implications for electric noses, food assessments, fragrance development, and indoor air sensor applications, particularly for long-term exposure in industries that emit odorous and harmful compounds.

SUMMARY
This study examines the feasibility of incorporating Phase Change Materials (PCMs) into residential building walls across three Omani climates (i.e., hot, moderate, and high-altitude) to reduce energy consumption, particularly for cooling energy. Using DesignBuilder software, a typical villa was simulated where various PCMs thermal properties such as melting temperature, latent heat, and thickness were explored. PCM layers performed best when placed on the inner wall side in hot climates and the outer side in high-altitude climates, with 25 mm thickness offering the greatest energy reduction. The optimal melting temperature was found close to the indoor setpoint (~24-25°C) for the hot climates but lower (19°C) for the high-altitude climate. The results indicated that energy consumption can be reduced by as much as 3.93% in a high-altitude climate, 3.65% in a hot climate, and 2% in a moderate climate for 25 mm PCM thickness. Several heat transfer enhancement techniques, such as adding Ferrochrome slag and thermal insulation were explored but did not yield better results than pure PCM. In conclusion, the study found that the PCMs behaved as a thermal insulation and therefore any thermal conductivity enhancement technique may reduce its thermal performance.

Keywords: Annual Energy Consumption, Hot climates, Phase change Materials (PCMs)

1. INTRODUCTION

The building sector contributes significantly to global energy consumption and greenhouse gas (GHG) emissions, accounting for approximately 41% of energy use and 30% of annual GHG emissions (Ahmed and Asif, 2021). This trend is driven by increasing comfort demands and the absence of energy-efficient standards, particularly in developing countries. In Oman for example, residential and commercial buildings consumed about 83% of electrical energy in 2020, according to the Authority for Public Services Regulation (APSR) report (APSR, 2020). More than 70% of this energy is attributed to the use of air conditioning systems (JICA and TEPCO, 2013). To

address these challenges, Phase Change Materials (PCMs) have emerged as a promising solution for reducing energy consumption in buildings by enhancing thermal energy storage.

PCMs store and release heat during phase transitions, providing higher energy storage capacity than conventional materials (Frigione et al., 2019). Most applications in building structures consist of PCM panels or the incorporation of a PCM into a concrete, mortar mix, or plaster. There is a good potential for reducing energy using PCMs in the envelope for residential buildings in hot climates. For example, fixing a PCM layer with a thickness of 20 mm reduced the heat gain by 15.4% and 13.8% through the roof and walls, respectively, in a Kuwait City residential building (Al-Rashed et al., 2021). In a study conducted in six Australian climates, the results indicated a reduction in annual energy of 17-23% (Alam et al., 2014). A study by Panayiotou et al. (2016) under the Cyprus climate (Mediterranean climate) concluded that combining PCM with thermal insulation may achieve a 67.6% reduction in energy consumption. Integrating conventional PCM wall panels (paraffin wax and ethylene-based polymer) in the envelope of a house in a Saharan climate (i.e., Ghardaia, Algeria) could reduce energy consumption by 36.4% when using PCMs (Hamdani et al., 2021). The literature indicated the potential of using the PCM in hot climates and its effect in reducing energy consumption or indoor peak temperature. Numerical results by Jin et al. (2016) concluded that many factors could affect the selection of the optimal PCM in a wall. These factors are layer thickness, latent heat capacity, interior wall surface temperature, and melting temperature. In order to optimize the PCM selection, these parameters should be studied for the climate under consideration. Therefore, the objective of this study is to explore the potential of PCMs in reducing energy consumption in extreme climates and select the optimal thermal properties for the proper deployment of this technology.

2. METHODOLOGY

2.1 Climate context

Based on Al-Saadi et al. (2023), the Omani climate is classified into a hot-dry climate, a hot-humid climate, a warm-humid climate, and a high-altitude climate, as illustrated in **Figure 1**. The high-altitude climate is mainly in Al Jabal Al Akhdar, where both heating and cooling are required. The warm-humid climate exists in southern Oman due to the monsoon season (i.e., represented by Salalah City), while the hot-humid climate is found in the seaside areas of the Sea of Oman (i.e., represented by Muscat City). According to this study, the rest regions of Oman are mainly desert with a hot and dry climate (i.e., represented by Nizwa).

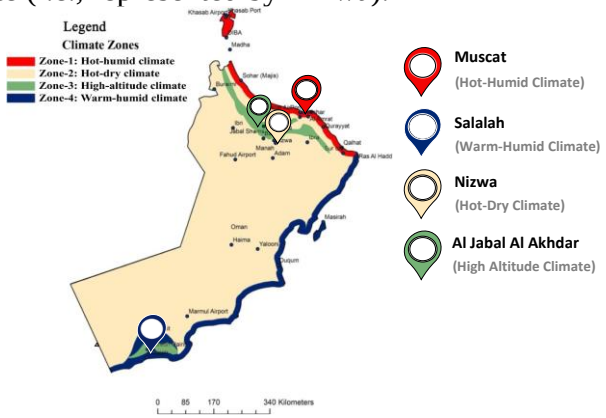

Figure 1. Climate Classifications in Oman (S. Al-Saadi et al., 2023).

2.2 Case study, model, and calibration

The base case for this study is a conventional Omani villa suggested by (S. N. Al-Saadi & Al-Jabri, 2020; Al Shamsi, 2017), as illustrated in **Figure 2**. The simulation tool used is the DesignBuilder software, a graphical user interface (GUI) of EnergyPlus. The model results were then compared to the actual utility bills using the Normalized Mean bias error (NMBE) and Coefficient of Variance (Root-mean-square error) (CV(RMSE)). The NMBE and CV (RMSE) were -1.03% and 7%, respectively, which were found to be within ± 5% and + 15% as per the acceptable range specified in ASHRAE guideline 14 (ASHRAE, 2014).

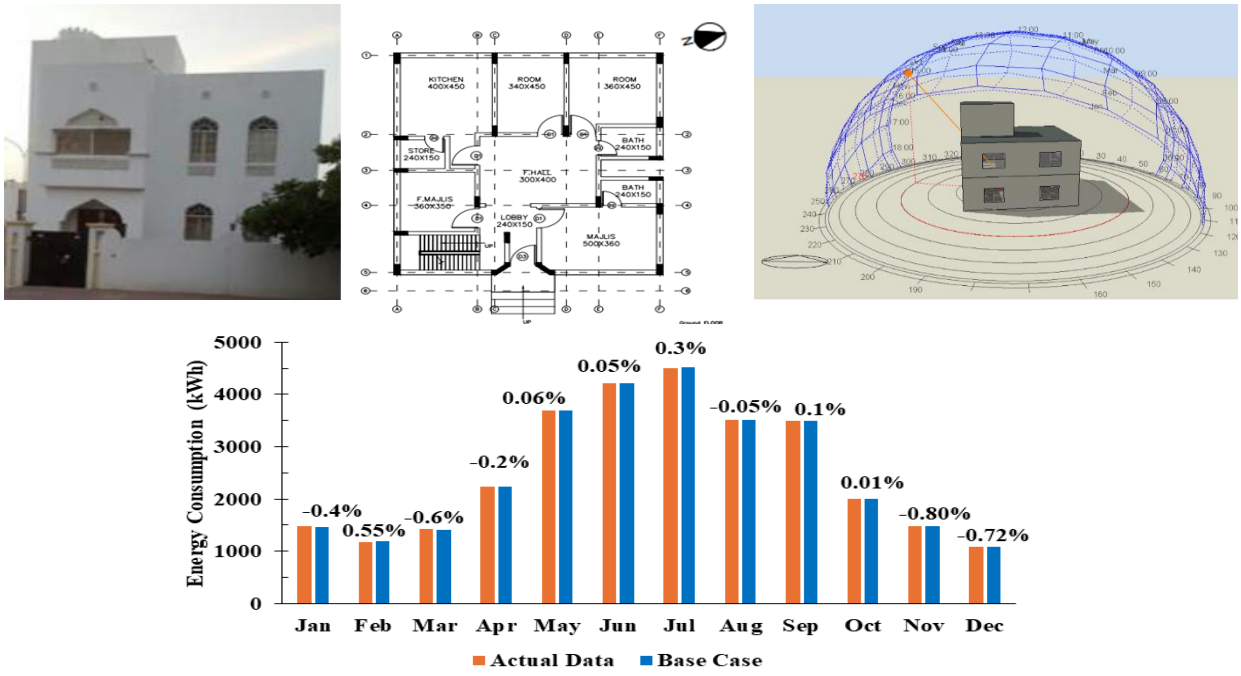

Figure 2. Building image, typical floor plan, 3D model in DesignBuilder, and model calibration.

2.3 Numerical modeling of PCMs in EnergyPlus

DesignBuilder uses EnergyPlus engine to calculate the building energy. This engine uses a Conduction Finite Difference (CondFD) algorithm to model PCMs. The (CondFD) algorithm approximates the wall layers into nodes and mathematically solves the heat transfer equations using a finite difference method (FDM) (EnergyPlus Engineering Reference, 2021). This study chooses the fully implicit scheme combined with the enthalpy-temperature function for PCM. Several studies found a good agreement between the simulation of the PCM in EnergyPlus and the experimental studies (Sarri et al., 2021).

2.4 PCM-embedded wall designs

The work investigates the impact of using PCM when embedded in wall systems in four different climates of Oman. The PCM used for each climate could differ according to the thermal properties (i.e., melting temperature, melting range, latent heat of fusion), thickness, and location. In addition, other parameters may also have an impact on the thermal performance such as the availability of

thermal insulation or other materials that may influence the thermal conductivity. The parameters that have been considered in this study are listed in **Table 1**.

Table 1. PCM thermal and physical characteristics for different wall designs.

Melting Temperature (°C**),** (Inside and outside)	18	19	20	21	22
	23	24	25	26	
Latent Heat (kJ/kG), (Inside and outside)	50	100	150	200	250
	300	350	400		
Melting Range (°C)	0.05	0.1	0.5	1	2
	3	4	5		
PCM Thickness (mm)	10	25	50	100	150
Insulation Thickness (mm), (Inside and outside)	10	25	50	100	150
Cement-PCM-Ferrochrome Slag-Mixture Plaster	Several cement-PCM-Ferrochrome mixes where the thermal conductivity varies between 0.38 to 0.86 W/m.K (Both sides, inside and outside)				

3. RESULTS

3.1 Impact of Thermal Properties

The impact of thermal properties of a 10 mm PCM layer was investigated for the four climates. Selected results for one climate are discussed and a summary of results for other climates is afterwards presented. **Figure 3** illustrates the percentage reduction in the annual energy consumption (and annual cost) for the different cases under Muscat climate. In this figure, the T23H200 case represents PCM with a melting temperature of 23 ºC and latent heat of 200 kJ/kg, and as such all cases are designated in this manner. As clear from the figure, when the PCM layer is located indoors, the reduction in energy consumption is higher than when it is located outdoors. The optimal melting temperature is when it is close to the setpoint temperature (i.e., 24°C). It is also interesting to note that as the latent heat of fusion increases beyond 250 kJ/kg, the benefits are reduced. The maximum savings in annual energy consumption is 1.45% and the corresponding reduction in annual energy cost is 1.56%, as represented by the red bar in **Figure 3**. **Table 2** summarizes the results for the four climates. It is observed that the PCM performs better (~2%) in high-altitude climates (i.e., Jabal Al Akhdar) with a higher latent heat of fusion when PCM is located on the exterior side compared to other climates. The optimal melting temperature is 19°C.

3.2 Impact of PCM thickness

In addition to the PCM base case thickness (i.e., 10 mm), four different thicknesses were evaluated: 25 mm, 50 mm, 100 mm, and 150 mm. The optimal thermal properties of the PCM layer from the previous section were assumed. For comparison purposes, the PCM layer was replaced with an Expanded Polystyrene (EPS) thermal insulation layer that has identical thermophysical properties to the PCM layer but no latent heat. As clear from **Figure 4**, the PCM layer acts as an insulation layer. This means that the PCM layer is in a liquid form most of the time of the year or the diurnal temperature is limited in this climate which hinders the charging and discharging process of the PCM layer. Likewise, the performance of the PCM is similar in other climates with a slightly improved performance in the high-altitude climate (3.93%) and lower performance in the warm-humid climate (2%) for the case when the PCM thickness was 25 mm.

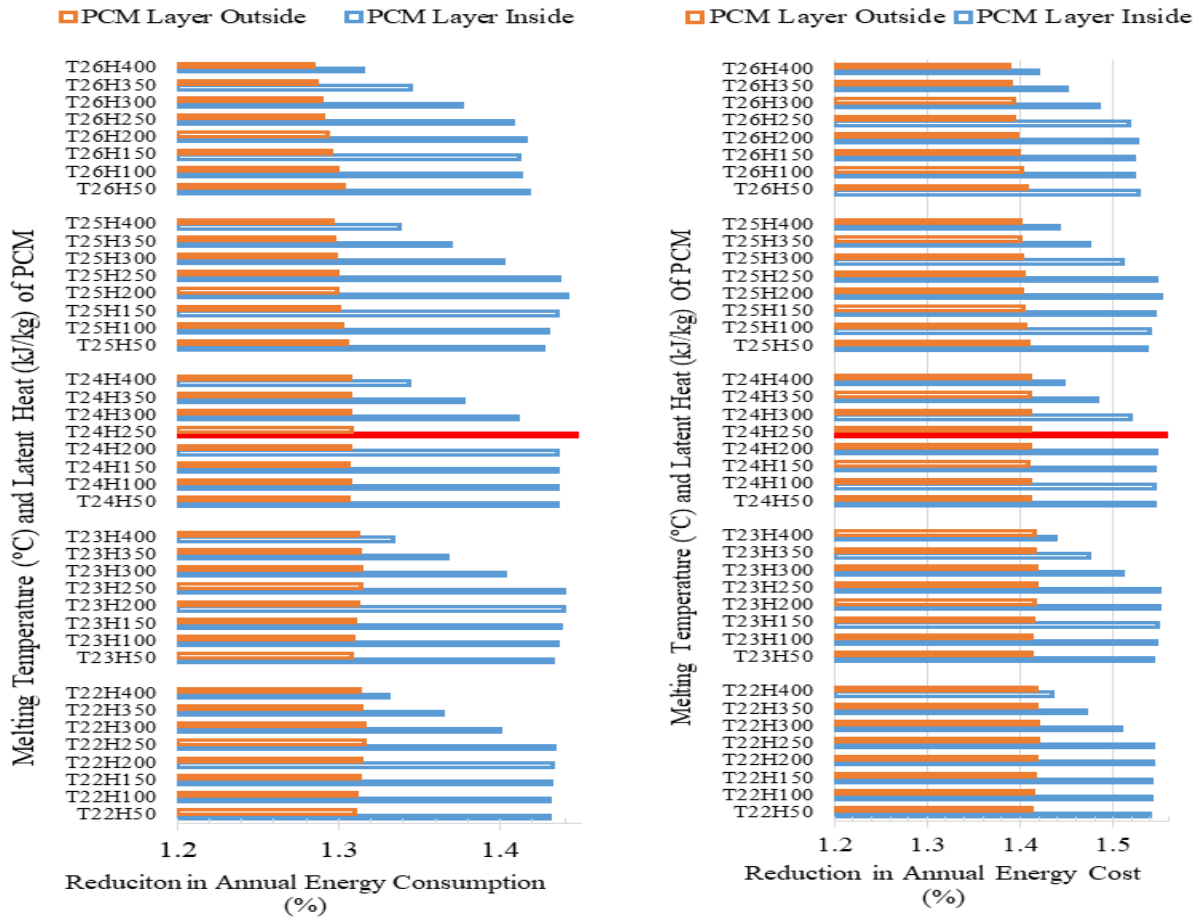

Figure 3. Impact of different PCM's melting temperature and latent heat under Muscat climate on annual energy consumption and cost.

Table 2. Optimal Cases of Melting Temperature, Latent Heat, and PCM Location.

Climate	Melting Temp. (°C)	Latent Heat (kJ/kg)	PCM Layer Location	Reduction in Energy Usage	Reduction in Energy Cost
Muscat (Hot-Humid)	24	250	Inside	1.45%	1.56%
Salalah (Warm-Humid)	24	250	Inside	0.79%	0.79%
Nizwa (Hot-Dry)	25	200	Inside	1.56%	1.63%
Al Jabal Al Akhdar (High-altitude)	19	400	Outside	1.99%	1.99%

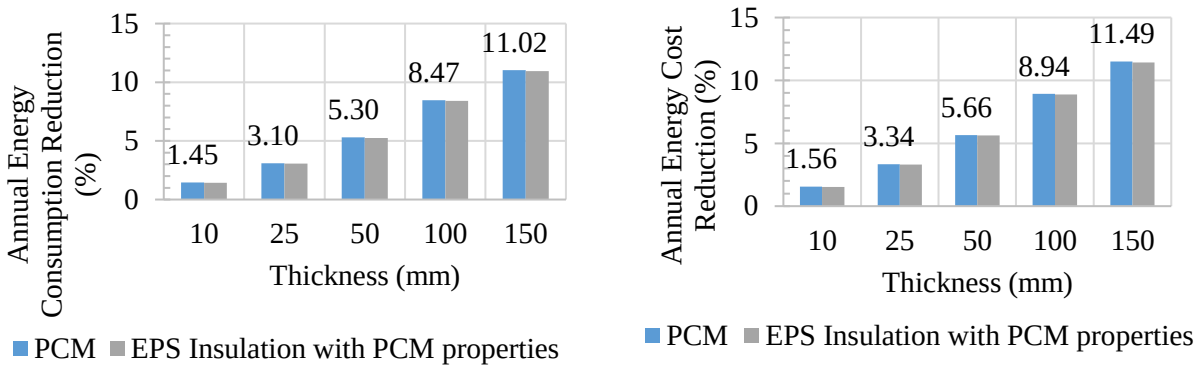

Figure 4. Impact of different PCM's thicknesses under Muscat climate on annual energy consumption and energy cost.

3.3 Impact of thermal insulation when integrated with PCM layer

In order to enhance the PCM's energy performance, a thermal insulation layer was added to the interior and exterior sides. The thickness of the thermal insulation was varied at 1 cm, 2.5 cm, 5 cm, 10 cm, and 15 cm, as shown in **Figure 5**. For all the cases, PCM thickness was fixed at 1 cm for the analysis in this section. The first observation from the figure is that the thermal insulation performs better when located on the interior side. However, its performance is slightly lowered when the PCM is combined. When the PCM is combined with exterior insulation, the performance of the system is better when compared to the insulation case only. **Table 3** summarizes the results for other climates when PCM is combined with 1 cm thermal insulation. In all cases, the thermal insulation provides better savings due to its higher thermal properties. The thermal insulation thickness of 1 cm was selected due to the effect of diminishing returns when increasing the thermal insulation thickness, making it appropriate to combine 1 cm of PCM with a similar thickness of insulation.

Table 3. Reduction of the annual energy consumption for the PCM when integrated with insulation layer for other climates.

Climate	1 cm PCM only	1 cm Insulation only	Combined
Muscat (Hot-Humid)	1.45% (inside)	4.98% (inside)	5.4%
Salalah (Warm-Humid)	0.79% (inside)	2.78% (inside)	3%
Nizwa (Hot-Dry)	1.56% (inside)	5.7% (inside)	6.2%
Al Jabal Al Akhdar (High-altitude)	1.99% (outside)	4.9% (inside)	6.1%

3.4 Enhancing the thermal conductivity of the PCM with ferrochrome slag (FeCR)

In this section, a mixture of PCM, ferrochrome slag (FeCr), and cement was used as a partial replacement for regular indoor/outdoor cement plasters. With the addition of ferrochrome slag (FeCR) slag, the thermal conductivity was increased. Despite the fact that increasing the thermal conductivity for the PCM is advantageous to enhance the charging the discharging process. In this case, it became a disadvantage because the PCM lost its thermal resistance capability.

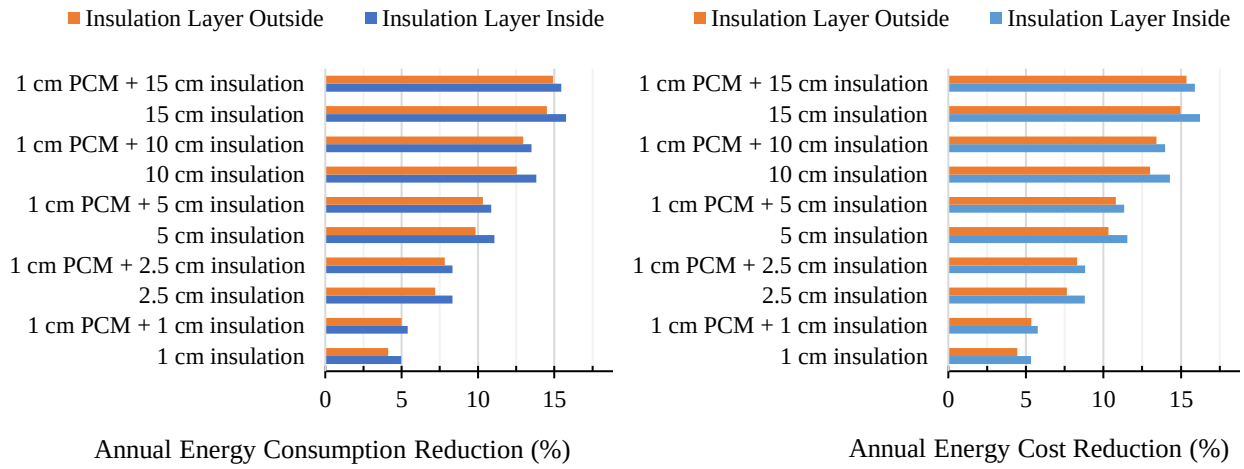

Figure 5. Impact of thermal insulation when combined with PCM layer under Muscat climate on annual energy consumption and energy cost.

4. CONCLUSIONS

In this work, PCMs were evaluated when integrated into wall systems in residential buildings in extreme climates. The following can be concluded:

1) The results indicate that the PCMs provided an equivalent energy performance as thermal insulation across climates in Oman.
2) For hot climates, the best location for the PCM is indoors whereas for the high-altitude climate is outdoors.
3) For hot climates, the optimal melting temperature was found close to the indoor setpoint between 24°C to 25°C, but for high-altitude climates, it was found 19°C.
4) A maximum of 250 kJ/kg is found appropriate for hot climates but as high as 400 kJ/kg is appropriate for high altitude climates.
5) An optimal thickness of 25 mm of PCM layer can be considered which provided between 2 and 3.93% of annual energy and cost savings.
6) Enhancement with thermal insulation materials was not significant.
7) When PCM was mixed with cement plaster, the thermal resistance was improved providing extra heat resistance. However, when Ferrochrome slag was added, the energy performance was reduced.

SUMMARY
This study investigates the thermal performance of a single-pipe horizontal Earth-Air Heat Exchanger (EAHE). The laboratory experiment utilized a 0.0254 m (1 inch) copper pipe embedded in a cylindrical soil volume. Air is passed through the pipe at controlled inlet temperature and volume flow rate. Temperature variations were captured using 20 thermocouples positioned at the air inlet, air outlet, and throughout the soil. Soil properties were directly measured, including density (905 kg/m3), moisture content (50.62%), thermal conductivity (0.339 W/m·K), and specific heat capacity (2109 J/kg·K). A transient numerical model of the laboratory experiment was developed in COMSOL and validated with the experimental data. Simulations showed strong agreement with experimental data, confirming the model's accuracy. Minor discrepancies arose due to soil heterogeneity affecting thermal properties and slight inlet air temperature fluctuations. This validated energy model provides a foundation for simulation studies to optimize EAHE design and operation.

Keywords: Earth-Air Heat Exchanger, Greenhouse Energy System, Energy Modelling and Optimization.

1. INTRODUCTION

Building energy systems encompass various power generation and energy storage technologies designed to meet heating and cooling demands. One of these technologies is the Earth-to-Air Heat Exchanger (EAHE). EAHE systems consist of pipes buried in soil, often under or adjacent to a building, through which air is moved by a fan or blower. The air source can be either inside or outside the building, depending on the EAHE implementation, while the air exiting the EAHE is typically supplied to the building interior. EAHE systems utilize sensible heat transfer between the air and soil to store thermal energy in the soil surrounding the pipes to regulate indoor temperatures across diverse building applications with varying energy demands (Guezgouz et al., 2019). The primary function of EAHEs, like other heat exchangers, is to reduce the heating and cooling loads of conventional energy systems, thereby lowering operational costs and improving overall system efficiency (Pintaldi et al., 2015). Researchers have also explored the integration of EAHEs with auxiliary energy systems such as combined heat and power (CHP) units and heat pumps to enhance performance efficiency (Tian and Zhao, 2013)).

The performance of an EAHE will depend on the interior climate needs of the building, and the weather and climate of the building surroundings. There remains a significant research gap in the energy modeling and optimization of EAHEs (Aresti et al., 2018; Bordoloi et al., 2018). Accurate energy models of EAHEs would support design and optimization to maximize the benefit of an

EAHE in a building system. Some researchers have developed custom heat transfer and energy models tailored to EAHEs and their surrounding systems, while others have utilized specialized simulation tools such as ANSYS Fluent and COMSOL for fluid flow and heat transfer analysis (Al-abidi et al., 2013). Existing studies on EAHEs and building energy simulations can be broadly classified into time-dependent (transient) and steady-state models. While steady-state models are the most prevalent in the literature due to their lower computational demands and simpler calculations (Fazlikhani et al., 2017), transient models provide deeper insights into EAHE operation, and are needed to optimize an EAHE installation. Transient energy models vary in dimensional complexity, ranging from one-dimensional to three-dimensional representations. Most studies have employed one-dimensional models (Belloufi et al., 2022). These models are typically implemented using MATLAB (Belatrache et al., 2017) or Python (Misra et al., 2018), consider heat transfer only in the radial direction, omitting axial heat transfer along the pipes and surrounding soil (Benzaama et al., 2019). Two-dimensional models, which account for both radial and axial heat transfer, offer improved accuracy but require more complex calculations (Bady and Ouzzane, 2024). Three-dimensional models are generally reserved for specialized EAHE designs, often when more than one pipe is used. While COMSOL and ANSYS Fluent are the most widely used tools for EAHE energy simulations (Agrawal et al., 2018), some studies have used TRNSYS for building energy modeling, incorporating EAHEs as heat storage systems (Qi et al., 2022).

Despite the breadth of existing EAHE energy models, several challenges persist. Most studies are specific case studies of a particular EAHE installation in a particular climate, and results are often not generalizable or transferable. One major limitation of existing experimental studies is the scarcity of comprehensive datasets that cover a wide range of operational parameters. Some studies present limited experimental results, which may not be sufficient for validating detailed numerical models. Another challenge lies in accessing experimental studies that report all essential data, including air temperature at different locations, moisture content, latent heat effects, soil temperature variations, and long-term experimental results under different environmental conditions. Most numerical studies validate their models using experimental data obtained from prior research (Heyat Jilani et al., 2023). While not all studies require such extensive datasets, some investigations necessitate more data than what is typically available (Sakhri et al., 2020). Moreover, most experimental EAHE studies are conducted in outdoor settings rather than controlled environments. As a result, fluctuating parameters such as air temperature, wind speed, and solar radiation can introduce variability in test results (Ahmed et al., 2015). While some useful studies exist for model validation (e.g. (Misra et al., 2018)), there is a need for more validation datasets with complete sets of reported and measured variables.

This study aims to develop an accurate transient energy model for a horizontal EAHE that can be utilized for system optimization. Additionally, an experimental setup of a horizontal EAHE has been constructed in a controlled laboratory environment, allowing characterization of operating parameters while minimizing environmental parameter fluctuations and maintaining a fixed inlet airflow. This experiment in controlled conditions will enable validation of simulation models.

2. EXPERIMENTAL STUDY

A laboratory-scale horizontal closed-loop EAHE was designed and built for this study. A 2.54 cm (1 inch) interior diameter straight copper pipe was centered in a cylindrical container filled with

soil and insulated at both ends. The soil volume is 112 cm long and has a radial thickness of 15 cm outward from the pipe wall. A blower at the inlet of the air pipe ran continually during the experiment and producing a consistent measured mean air velocity of 10.0 m/s. The air pipe upstream of the soil was wrapped in electric heater tape and connected to a PID controller that maintained a consistent inlet air temperature of 44.75 °C in the pipe measured at the location where it enters the soil volume. Twenty thermocouples installed in the system recording inlet, outlet, before the heater, and ambient air temperatures. Thermocouples are evenly distributed inside the soil volume (3 on the outer pipe wall and 12 in the soil), measuring temperature; therefore, we record the data for 3 longitudinal segments and 5 radial layers (Fig. 1). A Keysight data logger continuously recorded data from all thermocouples during experiments.

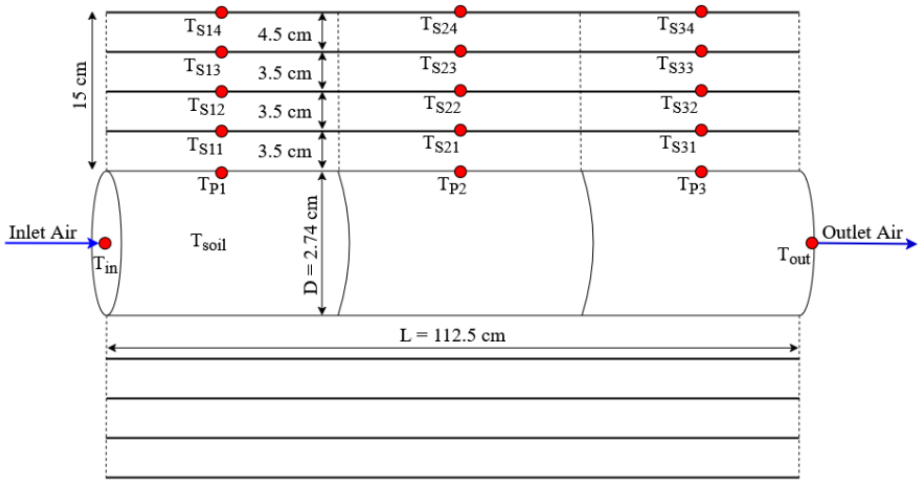

Fig. 1. Thermocouple placement in the EAHE lab experiment

Fig. 2 shows an example of experimental data collected over a 29 hour run. The experiment commenced with the activation of the fan; the heating system was started and inlet air temperature maintained at 44.75 °C beginning 40 minutes after experiment start. The several-degree increase in air temperatures during the first 40 minutes in Fig. 2 is due to waste heat from the blower motor unavoidably warming the inlet air before the heating system was engaged. Soil temperatures show an asymptotic exponential response that would be expected following a step change in inlet air temperature, with the soil closest to the pipe warming fastest and reduced rates of temperatures increase at greater radial distances from the pipe.

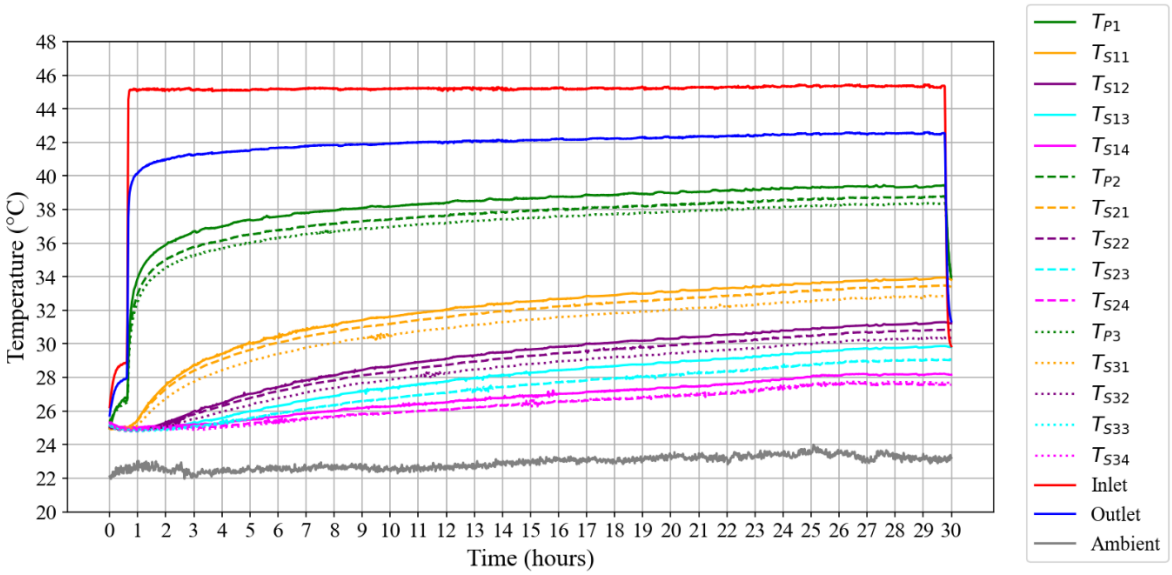

Fig. 2. Experimental results of EAHE

The soil used in the experiment was garden topsoil (Green Horizons Sod Farms, Breslau, ON, Canada). Soil density was calculated from the system mass difference before and after filling, divided by measured soil-occupied volume. Soil thermal conductivity and specific heat capacity were measured by transient line heat source method using a Decagon KD2 Pro Thermal Properties Analyser (SH1 – 04837 11323 – 04 03/31/17 with SH-1 probe) with tests conducted on multiple samples at different times and ambient. Soil moisture content was measured by oven drying. Table 1 shows the resulting measured soil parameters used in the simulations.

Table 1. Measured soil properties.

Property/Value	**Variable**	**Mean value**	**Number of tests**	**Standard deviation**
Soil thermal conductivity	k_{soil}	0.339 (W/m·K)	12	0.005 (W/m·K)
Soil heat capacity	cp_{soil}	2102 (J/kg·K)	12	29.17 (J/kg·K)
Soil density	ρ_{soil}	905 (kg/m^3)	1	-
Moisture percentage		50.62%	5	5.512%

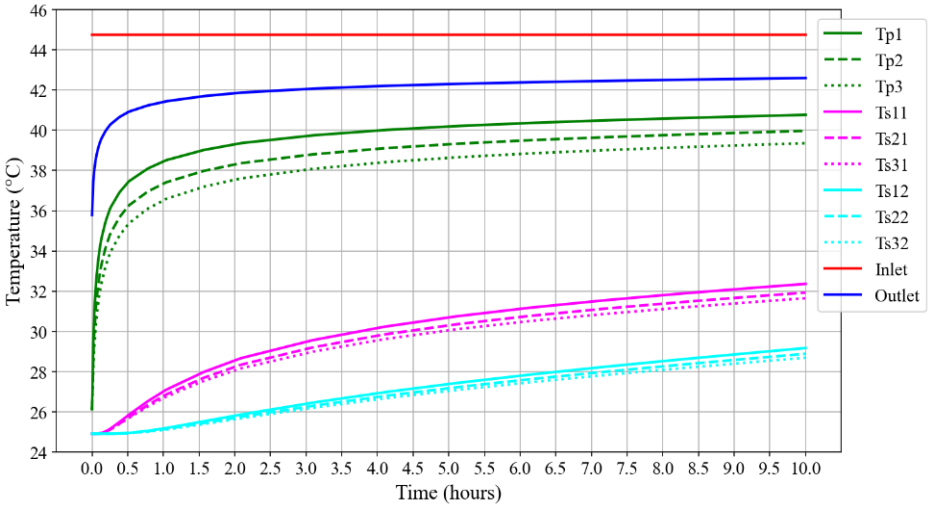
3. NUMERICAL MODEL

A transient numerical model of the laboratory EAHE was developed in COMSOL v.6.3 using the presented experimental results to represent the lab setup. Table 2 shows the details of the parameters used in the simulation. The energy model was developed in COMSOL using the conjugate heat transfer and heat transfer in solids and fluids modules. The inlet airflow was set to a constant 44.5 °C with a 10 m/s velocity resulting in a Reynolds number based on pipe diameter of 16,000. Table 2 shows simulation parameters. Inflow and outflow boundaries were used at the pipe inlet and outlet. Heat transfer mechanisms applied include convective heat transfer between the fluid flow and the pipe wall, and conductive heat transfer between the pipe wall and the surrounding soil layers. The outer surface of the cylindrical soil volume and the soil ends were adiabatic. Simulation time period was 10 hours. Normal meshing settings were used with additional mesh refinement at the boundaries.

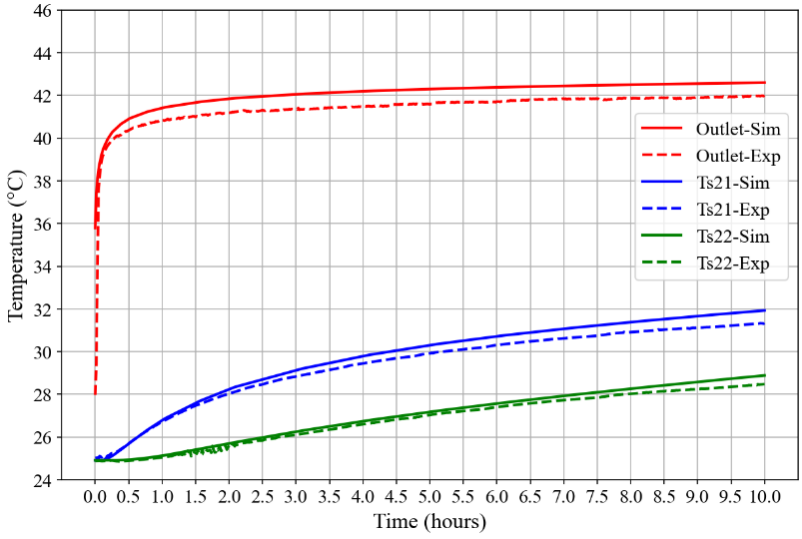
Table 2. COMSOL simulation parameters.

Parameter	Value	Description
T_{amb}	23 °C	Ambient air temperature
T_{in}	44.75 °C	Inlet air temperature
T_{i_pipe}	25.3 °C	Initial pipe temperature
T_{i_soil}	24.3 °C	Initial soil temperature
cp_{pipe}	385 J/kg·K	Pipe specific heat capacity
cp_{soil}	2102 ± 29.17 J/kg·K	Soil specific heat capacity
d	2.54 cm	Pipe inner diameter
D	2.74 cm	Pipe outer diameter

Parameter	Value	Description
d_{soil}	0.15 m	Soil thickness around the pipe
k_{pipe}	400 W/m·K	Pipe thermal conductivity
k_{soil}	0.339 ± 0.005 W/m·K	Soil thermal conductivity
L	1.125 m	Pipe length within soil
v_{air}	10.0 m/s	Inlet air velocity
ρ_{pipe}	8700 kg/m³	Pipe density
ρ_{soil}	905 kg/m³	Soil density
ρ_{air}	1.225 kg/m³	Air density



(a)



(b)

Fig. 3. (a) EAHE simulation results and (b) comparison with experimental data.

Fig. 3a shows resulting simulated and experimental data, particularly in terms of temperature variation trends over time. Fig. 3b compares simulated temperature at example soil locations to corresponding experimental data. Fig. 3 suggests good agreement between the simulations and experiment. Root mean square error (RMSE) and mean absolute error (MAE) for the TS21 node temperature comparison were 0.58 °C for RMSE and 0.35 °C for MAE. However, there are differences between the simulation and experiment. Potential sources of these differences include variation in soil properties. Even though soil density, thermal conductivity and specific heat capacity were measured, potential error remains due to probe accuracy and potential nonhomogeneity of the soil. Unavoidable variations in compaction, air, and moisture content within the soil volume could lead to variation in conductivity and heat capacity, as moisture and latent heat transfer significantly influence heat transfer. Additionally, although less impactful, the model assumes adiabatic condition at the outer soil radius, which may slightly affect results. Finally, the initial soil temperature was approximated by averaging values from different axial and radial measurement positions, introducing further potential deviation from the actual case.

The rate at which heat can be transferred into or out of storage in the soil is an important aspect of EAHE performance. Heat storage was calculated based on the temperature difference between inlet and outlet air, assuming all heat loss from the air was transferred to the soil. A sensitivity analysis was conducted to examine the impact of inlet air velocity on heat storage rates in the EAHE. Air velocities of 0.5, 1, 2, 4, 6, 8, and 10 m/s were simulated using the model. The resulting heat storage rates were then analyzed and compared with the experimental test results (Fig. 4).

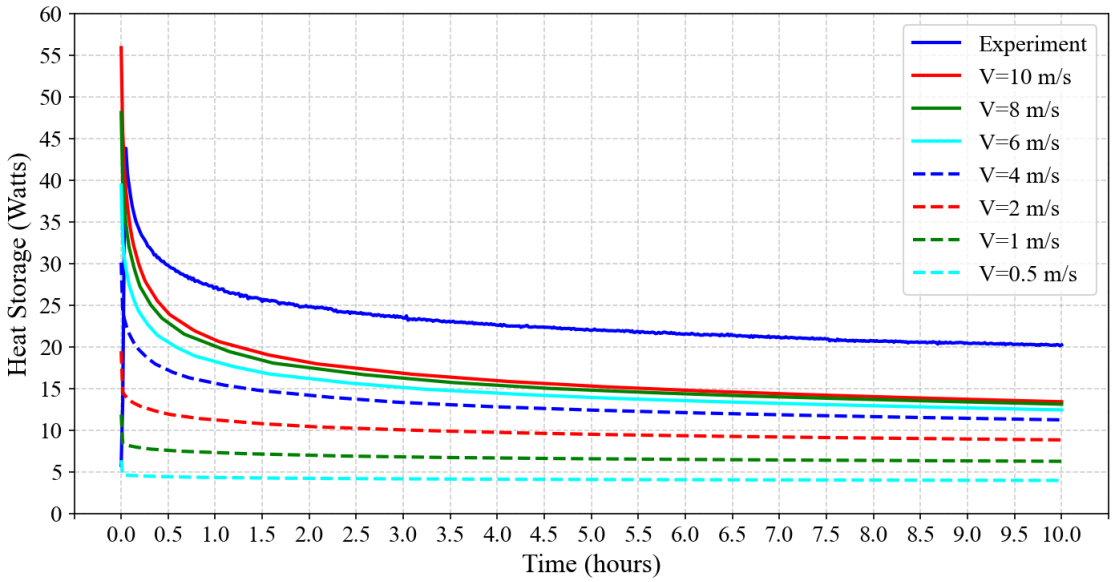


Fig. 4. Heat storage rate in EAHE for simulated and experiment models

The calculated results show an average heat storage rate of 17 W for the numerical model and 23 W for the experimental test over 10 hours of heater operation (Fig. 4). As expected, the storage rate decreases as the gradient diminishes over time. Lower air velocities result in lower outlet temperatures, as air remains in contact with the pipe and soil longer, enhancing heat absorption. A lower outlet temperature, relative to a fixed inlet, indicates greater heat transfer. Initially, heat

transfer is high near the pipe inlet due to the larger temperature difference. As air travels and its temperature nears that of the pipe and soil, especially at low velocities, heat transfer decreases. Higher velocities shorten residence time, preserve the temperature gradient and sustain a higher heat transfer rate. Higher velocities correspond to a higher mass flow rate, which increases total heat transfer into the soil, but decreases the efficiency of heat transfer from the air to the soil. (Since the air exits the EAHE at higher temperature, smaller fraction of the available thermal energy in the air is transferred to the soil.) Sensitivity analysis of inflow velocity on heat transfer rate confirms that higher velocities enhance heat transfer in the EAHE system. After prolonged operation, changes in heat transfer rate reduce as temperature gradients in the soil stabilize, reducing temperature variations at the outlet. When designing an EAHE system, factors such as achievable inlet air velocity, pressure drop and cost must be considered to find an optimal value of the inlet air velocity that satisfies different objectives.

4. CONCLUSION

This study examined a laboratory-scale earth-to-air heat exchanger (EAHE) in a controlled laboratory environment, which was then used to validate simulations of the EAHE in COMSOL software. Temperatures were measured throughout the soil volume, and soil properties including moisture content, thermal conductivity and specific heat capacity were experimentally measured to reduce uncertainties in heat transfer calculations. There was good agreement between the numerical model and experimental results, with RMSE and MAE values of 0.58 °C and 0.35 °C, respectively. A sensitivity analysis showed that higher air velocities enhance heat transfer due to increased mass flow and sustained temperature differences. This study has provided a foundation for future research on EAHE performance and optimization. The developed simulation tools will next be used to analyze various influencing parameters and explore optimal design and operational strategies for EAHEs in building thermal storage applications.

ABSTRACT
Double skin facades (DSFs) are widely used in modern buildings as a sustainable design element. However, its cavity overheating or overcooling problem often leads to high energy consumption, room temperature fluctuation, and poor thermal environment. Although integrating phase change materials (PCMs) into the shading devices can improve the thermal performance of the system, most of the current systems adopted opaque metal shell blinds, which affects the light transmittance of the facade. In this paper, a PCM blind with a transparent shell was proposed for integration into DSF system. Experimental study on the proposed system was carried out during both high and low-temperature seasons. A comparison of the photothermal performance was conducted on the PCM-DSF system and DSF with traditional aluminium blind. The results show that during the high temperature season, the maximum blind surface temperature was about 52°C, which was 5.2°C lower than the aluminium blind. The cavity air temperature was stable for the PCM-DSF system and the maximum cavity air temperature was about 47°C. In addition, the 45°blind tilt angle provided a stabilized state of scattered radiation with a maximum value of about 200 W/m² for two hours. During the low temperature season, the PCM blind surface temperature with tilt angle of 45° was 17.5~21.8°C, and the thermal stability effect can last 7 hours. The PCM blind with 45° tilt angle can provide smooth scatter radiation and remains stability after a peak of 271 W/m². Therefore, the PCM blind with 45° tilt angle was able to maintain a comfortable indoor thermal environment, and stable indoor scattered radiation which helps to create a preferable indoor light environment.

Keywords: double skin façade, phase change material, photothermal performance, blind system.

1 INTRODUCTION

As urbanization accelerates, global building energy consumption continues to grow at an average annual rate of 1.5 %(Araji M T et al., 2024). Building energy consumption is the main type of energy consumption, accounting for 33 % of total energy consumption in China, and up to 40 % in the United States (Liu X J et al., 2023). As a major component of the building envelope, curtain wall play an important role in maintaining comfortable thermal and optical indoor environment. However, traditional single-layer glass curtain walls often suffer from poor natural ventilation, poor thermal comfort, susceptibility to glare, and excessive energy consumption (Shameri M A et al.,2011)(Zhou J,2010)(Blanco J M et al.,2014). As a promising passive building technology, double skin facade (DSF) shows significant potential for improving energy efficiency and indoor thermal comfort (Zhao M et al.,2022).

DSF refers to one or more layers of curtain wall structures covering a building façade, often

separated by air cavities and equipped with controlled shading systems. It can act as thermal barriers against adverse climatic influences with natural or mechanically-assisted ventilation, reduce heat loss from the building in winter. The DSF can also reduce lighting energy consumption, not only by taking into account the position and orientation of the building and interior spaces, but also by introducing internal sunshade louvers to ensure that daylight does not adversely affect the occupants (Hien W N et al., 2005).However, in the summertime, the DSF often suffer from overheating effect which increases the building's cooling energy consumption (Gratia E, 2007). The DSF overheating problem is often mitigated by ventilation or the addition of solar shading louvers, but the effect is limited.

Phase Change Materials (PCM) have attracted much attention for their applications in thermal storage and temperature regulation systems (Ahmed M M S et al.,2021)(Koželj R et al.,2021)(Meng Q et al.,2022). Integrating PCM into DSF can effectively alleviate the problem of cavity overheating in summer and reduce the cooling load; in winter, it could also release the heat stored during the day through the phase change process and reduce the heating load (Huang Y et al.,2021) (Zhang Z et al.,2023) (Zhang S et al.,2022). However, most of previous PCM integrated DSF systems are encapsulated in opaque shell, which may hinder the transparent feature of the DSF system and reduce the natural light into the building (Berardi U, 2014). Compared with conventional aluminum shell, transparent shell has good light transmission, low cost, and moisture and fire resistance, suitable for large-scale applications.

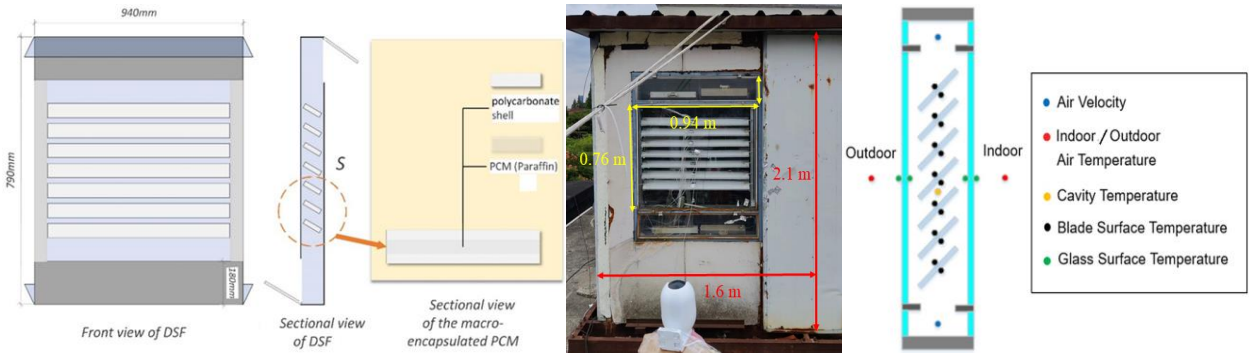
So far, there is still a relative lack of research on semi-transparent PCM blind system for DSFs, and the existing research seldom consider the impact of PCM blind systems integrated DSF on the coupling effect of indoor thermal and optical environments in buildings. Therefore, it is necessary to develop a semi-transparent PCM blind system and to evaluate the photothermal performance of the system in a DSF to comprehensively understand its influence on the indoor thermal and optical environment.

2 METHODS

2.1 Development of the PCM blind in DSF system

Figure 1(a) demonstrates the schematic diagram of the PCM blind in DSF system with transparent polycarbonate encapsulated paraffin PCM to optimize the DSF photothermal performance. As shown in Figure 1(b), the integrated system is with a size of 940 mm × 790 mm and an air cavity of 180 mm. The blind tilt angle can be adjusted to adapt to different seasons and sunlight; The PCM was encapsulated with a transparent polycarbonate shell to ensure light transmittance and to support the PCM to maintain light transmittance in the process of heat absorption and heat release.

The experimental test rig was located on the roof of an office building in University of Shanghai for Science and Technology, facing 30° southeast. The experiments were conducted from July 1st to August 31st, 2022 during the high-temperature season, and from January 1st to January 8th, 2022 during the low-temperature season. Data collection was conducted, including measurements of blind surface temperature, cavity temperature, indoor temperature, solar radiation, and wind speed. The distribution of the experimental measurement points is shown schematically in Figure 1(c).



(a) (b) (c)

2.2 Characterization of optical properties of PCM

The spectral properties are directly related to the absorption and reflection ability of the PCM , thus the transmission spectra properties of the PCM were measured and analysed. The transmission spectra tests were conducted by using a ultraviolet(UV)-3600 plus dual-beam UV-visible spectrophotometer manufactured by Shimadzu, and the principle of the UV-3600 plus dual-beam UV-visible spectrophotometer is shown in Figure 2. In order to determine the optical constants of PCM in the high temperature and low-temperature seasons, the transmission spectra of two PCMs before and after the phase transition were examined at different optical ranges. The temperature was kept constant during the experiment, and the transmission spectra of selected paraffin waxes with melting points of 40 ℃ and 20 ℃ were measured before and after the phase transition at optical ranges of 5 mm and 10 mm, respectively. In addition, the transmission spectra of 40 ℃ paraffin wax were measured at 65 ℃ and 20 ℃ paraffin wax at 35 ℃.

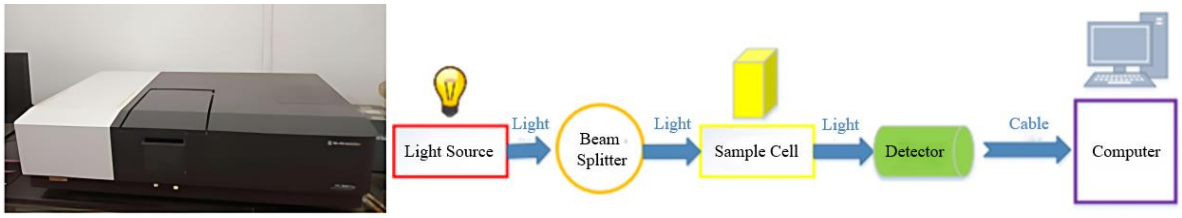

Figure 2 UV-3600plus Dual-beam UV-Vis Spectrophotometer and its main components diagram

2.3 Coordination index of the system photothermal performance

A coordination index was proposed for evaluating the photothermal performance of the PCM-DSF system, which encompasses two proportion: indoor heat gain and natural lighting. The indoor heat gain index mainly considers the radiant heat transferred through the DSF and the heat absorbed by the PCM blind. Meanwhile, natural lighting is represented by the average daylighting factor (ADF), where a higher ADF value corresponds to better lighting quality. A coupling coordination index was applied to achieve a balance between lighting and thermal performance, and an entropy weighting method was used to calculate the weights of the index. The coupling degree (C) measures the interaction between the subsystems; the comprehensive coordination index (T) indicates the overall coordination effect; and the coupling coordination degree (D) reflects the overall coordination quality, with a larger D value signifying better coordination. These indices enable an assessment of the photothermal performance and coordination of the PCM-DSF system under various operating conditions. The coupling coordination degree is calculated as follows:

$$C = \frac{(\prod_{i=1}^{n} U_i)^{\frac{1}{n}}}{\frac{1}{n}\sum_{i=1}^{n} U_i} \quad (1)$$

$$T = \sum_{i=1}^{n} \omega_i U_i \quad (2)$$

$$D = \sqrt{CT} \quad (3)$$

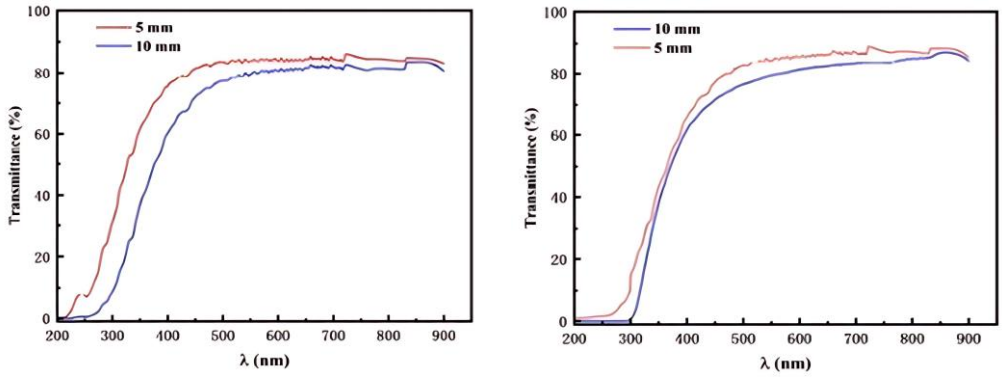
Table 1. Classification of coupling coordination relationships

Type of coupled coordination	Degree of coupling coordination	Coupling Harmonization Level
Dysfunctional Decline Type	[0.0,0.1)	Extreme Dissonance
	[0.1,0.2)	Severe Dissonance
	[0.2,0.3)	Moderate Dissonance
	[0.3,0.4)	Mildly dysfunctional
Coordinated Transitional	[0.4,0.5)	Nearly dysfunctional
	[0.5,0.6)	Barely coordinated
Coordinated Developmental	[0.6,0.7)	Elementary coordination
	[0.7,0.8)	Intermediate coordination
	[0.8,0.9)	Good coordination
	[0.9,1.0]	Quality coordination

3 RESULTS AND DISCUSSION

3.1 Analysis of PCM transmissivity

Figure 3(a) refers to the transmission spectrum of paraffin wax at 40 ℃ for different light ranges. Decreasing the optical range increased the transparency of paraffin waxes in the UV and visible wavelengths to about 58.06 % at a range of 10 mm. The lowest transmittance of paraffin waxes in the visible wavelengths was about 62.74 % at a range of 5 mm. In the near- ultraviolet(NUV) band from 200 to 400 nm, the optical range decreases, and the difference in the transmittance of paraffin wax rises rapidly with the wavelength, with a maximum of 11.28 percent in the UV band of 377 nm, while the growth rate of the transmittance of paraffin waxes in the visible band from 400 to 900 nm decreases gradually.



(a) (b)

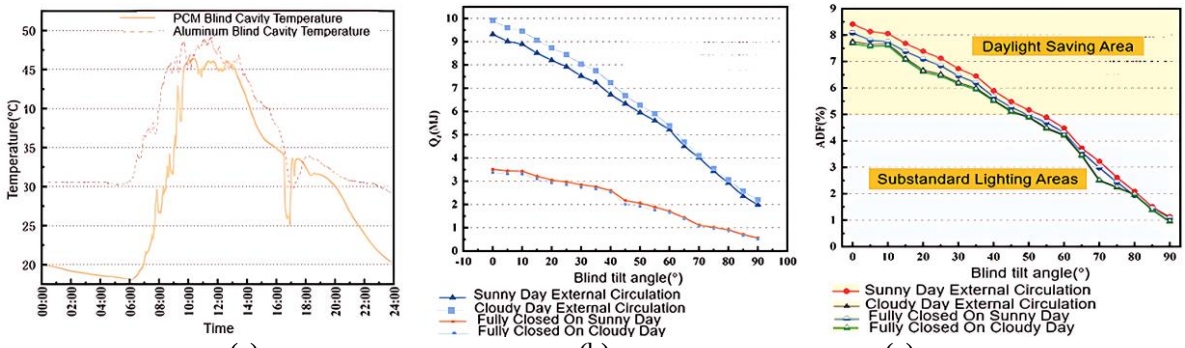
Figure 3 Transmission spectra of paraffin waxes at different temperatures with different optical intervals (a)at the 40 ℃ (b) at the 20 ℃

Figure 3(b) shows that the maximum difference in the transmittance of 20 °C paraffin at 35 °C for different optical ranges was about 27.41 % in the NUV band. In the visible band, the effect of optical range on transmittance gradually decreases and finally reaches a steady state, and the maximum difference in transmittance is about 15.25 %. The lowest transmittance of paraffin wax in the visible band was about 60.54 % for the 5 mm optical range, and the lowest visible transmittance of paraffin wax in the visible band was about 75.77 % for the 10 mm optical range. The transmittance difference of paraffin waxes increased rapidly with the wavelength as the light range decreased in the near-ultraviolet band, and the transmittance difference reached a peak value of 27.41 % at 330 nm.

3.2 System performance during high temperature season

As shown in Figure 4(a), the PCM blind maintains the cavity temperature at 44~46.2 ℃ during peak hours (10:00-13:30), lowering the peak temperature by 3.1 ℃ and the average temperature by 2.6 ℃ compared to the aluminum blind. At night, their heat release slows the cooling process, demonstrating optimal thermal storage. Overall, the PCM blind reduces the minimum temperature to 20 ℃, outperforming aluminum blind (29 ℃), effectively enhancing building thermal comfort and energy efficiency.

Figure 4(b) shows that as the blind tilt angle increases, indoor heat gain decreases due to increased shading. On sunny days, external circulation ventilation is more effective than the fully enclosed mode in reducing heat gain between 0° and 60°, enhancing heat dissipation. Beyond 60°, both modes converge, indicating that a large tilt angle reduces the effectiveness of external ventilation. On cloudy days, with weaker solar radiation, the difference between the two modes is smaller, but external circulation still slightly reduces heat gain in the 0°–60° range, with the difference diminishing as the tilt angle increases.



(a) (b) (c)

Figure 4. (a) Comparison of cavity temperatures between aluminum blind and PCM blind systems on a typical day. **(b)** Indoor heat gain under different conditions on a typical day. **(c)** Average indoor lighting coefficients under different working conditions on a typical day.

Figure 4(c) shows that the ADF is higher for external circulation than for the fully enclosed condition on both sunny and cloudy days. On sunny days, the ADF for external circulation is 0.2%–0.5% higher than for the fully enclosed condition at tilt angles between 0° and 60°, with the difference decreasing as the angle increases. On cloudy days, the ADF difference is minimal. Overall, ADF decreases with higher tilt angles, following similar trends for both conditions. On sunny days, external circulation achieves an ADF greater than 5% in the 0°–50° range, meeting lighting requirements and improving indoor lighting. Under cloudy conditions, the impact on

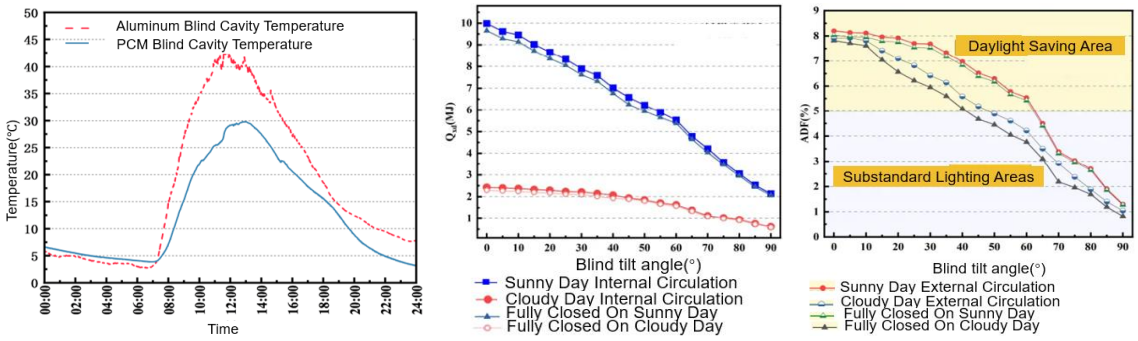
daylighting is minimal due to the small ADF difference.

3.3 System performance during low temperature season

As shown in Figure 5(a), the PCM blind excels in regulating cavity temperature. During the day (10:01-13:15), its PCM absorbs heat, reducing the peak temperature by 12.3 °C and delaying it by 36 minutes. In the evening (15:30-18:28), heat release slows cooling, extending the effect for about 3 hours. Overall, the PCM blind stabilizes temperature throughout the day, enhancing building thermal comfort and energy efficiency.

Figure 5(b) shows that as the blind tilt angle increases, radiative heat gain in the PCM-DSF system decreases under both sunny and cloudy conditions, primarily due to increased solar shading. On sunny days, internal circulation ventilation results in higher heat gain than the fully enclosed mode at tilt angles between 0° and 90° because it utilizes solar radiation more efficiently. However, as the tilt angle increases, the difference between the two modes decreases. On cloudy days, weaker solar radiation reduces heat gain for both modes, with minimal differences, indicating that ventilation mode has little impact on heat gain.

Figure 5(c) shows that indoor heat gain in the PCM-DSF system decreases with higher blind tilt angles on both sunny and cloudy days. On sunny days, heat gain decreases at 0°–55° due to shading, increases slightly at 55°–60° from direct radiation, and decreases again at 60°–90° as shading increases. On cloudy days, heat gain decreases at 0°–40° with shading, increases slightly at 40°–45° from radiation absorption, and declines at 45°–90°. Overall, heat gain decreases with higher tilt angles, showing similar trends for both conditions. On sunny days, internal circulation ventilation leads to higher heat gain than the fully enclosed mode at 0°–55°, with the difference reducing as the angle increases. On cloudy days, the difference is greater at 0°–40° but diminishes with higher angles, weakening the impact of ventilation mode.



(a) (b) (c)

Figure 5. **(a)** Comparison of cavity temperatures between aluminum blind and PCM blind systems on a typical day. **(b)** Indoor heat gain under different conditions on a typical day. **(c)** Average indoor lighting coefficients under different working conditions on a typical day.

3.4 Optimal operation modes of the system under different seasons

Based on the coupling coordination model, the coupling coordination degree D value of the PCM-DSF system is analyzed in different climates with different tilting angles of blinds, and the corresponding control strategies for the tilting angle of blinds and ventilation mode are proposed. On a sunny day in the high-temperature season, the maximum coordination D is 0.73 when the external circulation ventilation mode is adopted and the tilt angle of blinds is 60°, which indicates

that the heat absorption and storage effect is good and the indoor temperature can be reduced effectively. On cloudy days, the maximum coordination D is 0.747, indicating the best performance. During the low-temperature season, the internal circulation ventilation mode has the highest D value with parallel blinds, which helps heat release and increases the room temperature. On cloudy days, a 10° inclination angle achieves the best performance. Meanwhile, the inclination range can be adjusted according to the D-value, which makes the system optimally coordinated in terms of natural lighting and comfort. The differences between model predictions and experimental data were 8.2% and 5.3%, respectively, confirming the model's accuracy and supporting its optimal design.

(c) Typical sunny day, low-temperature season. (d) Typical cloudy day, low-temperature season.

Figure 6. (a) Harmonization of photo-thermal indexes for PCM-DSF under different climatic conditions

4 CONCLUSION

This research paper centers on the PCM-DSF system to analyze its photothermal regulation performance. The experimental results show that liquid paraffin improves the lighting effect due to the low extinction coefficient in the visible light band, while solid paraffin reduces the heat gain from solar radiation through the high extinction coefficient. The comprehensive indoor heat gain index was established by considering the effects of louver inclination angle on transmitted radiation, long-wave radiation, and convective heat transfer. Meanwhile, based on the influence of the blind inclination angle on the uniformity of indoor natural lighting, the average lighting coefficient index is established. Combined with the coupled coordination model, the PCM-DSF photothermal performance evaluation system is constructed. For sunny days in the high-temperature season, the external circulation ventilation mode is recommended, and the louver

inclination angle is 60°, while the 60° inclination angle is optimal for cloudy days. On sunny days in low-temperature seasons, it is recommended to use the internal circulation ventilation mode with an inclination angle of 0°. In the range of 0~25° inclination angle, the system can maintain an excellent coordination level. When the blind inclination angle is set to 10° inclination angle on cloudy days in the low-temperature season, the performance is optimal.

To conclude, the PCM blind can provide satisfactory thermal and optical performance as compared with conventional aluminum blinds. Future studies can optimize PCM-DSF control strategies with intelligent technology for energy management and environmental monitoring.

SUMMARY
To enhance the efficiency of energy storage systems, this study proposed a novel biomimetic bamboo-joint latent heat thermal energy storage system (BBJ-LHTES), inspired by the structural characteristics of natural bamboo joints. A numerical model of the BBJ-LHTES system was developed using computational fluid dynamics (CFD), and the PCM melting process was compared, validated, and analyzed across three cases to evaluate system performance. The results indicated that the biomimetic bamboo-joint structure expanded the heat transfer area and significantly enhanced the PCM melting rate. When the biomimetic structure was positioned in the lower section of the energy storage system, the melting process was accelerated, the complete melting time of the PCM was reduced by 40 %, and the heat storage rate of the system was increased by up to 29.5 %. Additionally, the biomimetic structure facilitated vortex formation and intensified fluid disturbances within the system, thereby promoting heat transfer.

1. INTRODUCTION

With the global emphasis on achieving the "dual-carbon" targets and the increasing energy demand, phase change energy storage technology has garnered significant attention from the academic community. However, the large-scale application of phase change energy storage technology has been hindered by challenges related to heat transfer enhancement (Zheng et al., 2018). In recent years, fins have been widely employed by researchers to improve the heat transfer performance of shell-and-tube latent heat thermal energy storage (LHTES) systems, owing to their simple structure, low cost, and high efficiency.

In studying the effects of different fin shapes on the thermal performance of LHTES systems, Low et al. (Low et al., 2024) reviewed the geometric configurations of fins in various systems and classified them into longitudinal, annular, stepped, pin-shaped, and plate-type fins, thereby providing theoretical and technical guidance for system design. Dekhil et al. (Dekhil et al., 2021) analyzed the effect of longitudinal fins on LHTES systems and found that the melting rate increased by 27 % compared to that of systems without fins. Yang et al. (Yang et al., 2020) proposed a design employing non-uniformly distributed annular fins to address the uneven distribution of liquid fraction during PCM melting. The results showed that the PCM melting time and the average temperature difference were reduced by 62.8 % and 34.4 %, respectively. Baby and Balaji (Baby and Balaji, 2013) experimentally investigated PCM melting using aluminum pin fins in quantities of 33, 72, and 120. They found that the configuration with 72 fins exhibited the highest liquid fraction. Although the aforementioned fin designs effectively

enhanced heat transfer, the low thermal conductivity of PCM continued to hinder the optimization of LHTES system performance. This highlights the urgent need for new strategies to improve the performance of LHTES systems. Among these, innovative fin shapes represent a promising approach for improving system performance (Tian et al., 2021).

Nature has provided inspiration for addressing many challenges in heat transfer enhancement. Biomimetic design methods have recently attracted significant attention due to their potential to enhance thermal performance in energy storage systems by leveraging the principles of thermodynamics and fluid dynamics, and have been applied in optimizing LHTES systems (Rashid et al., 2025). Diaz and Yaconi (Diaz and Yaconi, 2023) numerically investigated PCM charging and discharging behavior in an annular LHS system equipped with tree-like and straight fins. The results indicated that tree-like fins outperformed straight fins in terms of thermal performance. Moreover, reducing the length of fin branches relative to the maximum fin length increased thermal contact between fins and PCM, thereby enhancing thermal performance. Sheikholeslami et al. (Sheikholeslami et al., 2016) proposed a novel fin geometry inspired by the crystalline structure of snowflakes. The branching pattern of the snowflake-shaped fins led to a more uniform temperature distribution across the fin surface, which enhanced effective thermal conductivity and significantly improved heat storage performance. Ren et al. (Ren et al., 2022) designed a vertical LHTES system incorporating an optimized spider web-shaped fin structure using response surface methodology. The study revealed that optimizing parameters such as spider web fin spacing, main fin thickness, and branching fin thickness shortened PCM solidification time and enhanced heat dissipation in the LHTES system. Specifically, reduced fin spacing improved heat transfer, increased main fin thickness decreased thermal resistance, and thicker branching fins led to a reduction in PCM volume. Redoine et al. (Redoine et al., 2024) introduced a novel approach by incorporating hexagonal honeycomb-shaped annular fins into the LHTES system. The results demonstrated that the inclusion of honeycomb fins significantly enhanced heat transfer, reducing PCM melting time from 840 to 216 seconds due to the increased heat transfer surface area. These studies collectively demonstrated that biomimetic structural designs significantly improved the energy storage efficiency of LHTES systems. Additionally, Gao et al. (Gao et al., 2024) inspired by the internal air channel distribution of lotus roots, proposed a new heat transfer enhancement technique and evaluated its thermal storage performance through numerical simulations. The results indicated that, compared to conventional LHTES systems, the bionic lotus root-inspired design reduced total PCM melting time by 89.1 %. This study offers valuable insights into improving LHTES system performance through biomimetic optimization of internal flow channel structures.

The literature review reveals that current strategies for optimizing LHTES system performance primarily involve structural modifications such as adding fins to increase heat transfer area or employing biomimetic structures to optimize internal flow channels. Accordingly, this study proposes a biomimetic bamboo-joint latent heat thermal energy storage system (BBJ-LHTES), inspired by the structural morphology of bamboo joints. The bamboo-joint structure extends outward from the heat exchange tube, simultaneously influencing heat transfer processes both inside and outside the tube. This design not only enlarges the heat transfer surface area but also induces flow disturbances within internal channels, thereby enhancing heat transfer and improving the system's energy storage efficiency. Initially, a transient numerical model was developed to simulate the melting heat transfer process. Based on the validated model, the

optimized OBBJ-LHTES system was compared with both the conventional shell-and-tube LHTES system and the original BBJ-LHTES design. The thermal performance of different biomimetic configurations was evaluated in terms of liquid fraction, temperature distribution, and flow field characteristics. This study is an extension of biomimetic design research for LHTES systems.

2. PHYSICAL AND MATHEMATICAL MODELS

2.1. Physical model

Fig. 1 illustrates the schematic of the BBJ-LHTES system, which consists of two concentric cylinders. The outer pipe has an inner diameter of 62 mm, while the bamboo-joint-shaped steel inner pipe features an inner diameter of 22 mm and a total length of 200 mm. The inner pipe serves as the fluid domain, and the annular space between the inner and outer pipes is filled with PCM. A high-temperature heat transfer fluid (HTF) flows through the inner pipe, transfers heat to the PCM, and then exits the system. Due to the symmetrical distribution and rotational symmetry of the system, the heat transfer characteristics remain consistent in the radial direction. To improve computational efficiency, the domain was simplified to a two-dimensional (2D) model, as shown in Fig. 1(c), while Fig. 1(b) presents the three-dimensional (3D) schematic. The bamboo-joint structures surrounding the inner pipe are defined by the joint spacing (l), the side length of the protruding triangle (h), and the interior angle (θ).

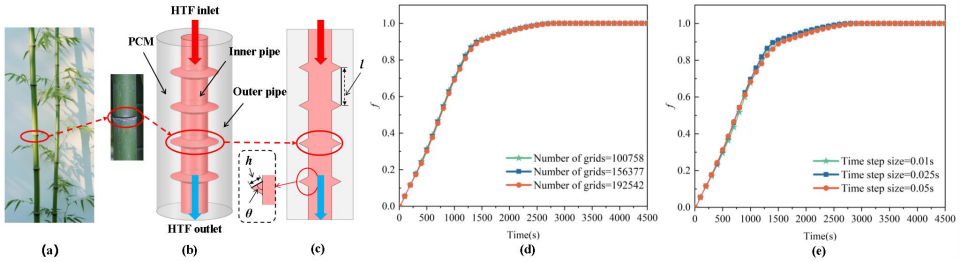

Figure 1. (a) Natural bamboo-joint structure; (b) 3D structure of the BBJ-LHTES system; (c) Simplified 2D model; (d) Grids independence; (e) Time steps independence

2.2. Mathematical model

Accurately tracking the phase change interface is a critical challenge in numerical simulations. The enthalpy-porosity method is considered the most appropriate approach, as it eliminates the need for explicitly defining the phase change interface. To ensure accurate simulation results, the following assumptions were adopted in the mathematical model (Shademan and Hossein Nezhad, 2021): (1) the liquid phase of the PCM is considered to be an incompressible laminar flow state; (2) the PCM density uses Boussinesq assumptions; (3) the contact thermal resistance between the PCM and the inner pipe, as well as the bionic structure surface, is neglected; and (4) the viscous dissipation effects are neglected. Based on these assumptions, the governing equations are simplified as follows.

Continuity equation :

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \tag{1}$$

Where u, v represent the velocity components of the fluid in the x and y directions, respectively.
Momentum equation:

$$\frac{\partial V}{\partial t} + \vec{V} \bullet \nabla \vec{V} = \frac{1}{\rho}\left(-\nabla P + \mu \nabla^2 \vec{V} + \rho \vec{g} \beta \left(T - T_{ref}\right)\right) + \vec{S} \quad (2)$$

Where v represents the fluid velocity; ρ is the density of the phase change material; P denotes pressure; μ is the dynamic viscosity of the fluid; g is the gravitational acceleration; T is the temperature, T_{ref} is the reference temperature; β is the thermal expansion coefficient, and S is the source term.
The porosity method treats the mushy zone as a porous medium, where porosity is the liquid fraction of the unit. When the unit is a solid, the porosity is zero, and the source term is zero. When considering the phase change induced by natural convection, Darcy's law damping term is added to the momentum equation as a source term, which is defined as follows:

$$S = - C \frac{(1-f)^2}{f^3 + \varepsilon} \quad (3)$$

Where C is a constant for the mushy zone with a range of 10^5 to 10^8 and was assumed to be 10^5 in this study. ε is a small number (0.001), used here to prevent mathematical singularities. f represents the liquid fraction in the computational domain, varying between zero (solid phase) and one (liquid phase), and is defined as follows:

$$f = \begin{cases} 0, & T < T_s \\ \frac{T - T_s}{T_l - T_s}, & T_s \le T \le T_l \\ 1, & T > T_l \end{cases} \quad (4)$$

Where T is the temperature of the phase change material.
Energy equation:

$$\frac{\partial(\rho H)}{\partial t} + \nabla \cdot \left(\rho \vec{V} H\right) = \nabla \cdot (k \nabla T) \quad (5)$$

Where k is the thermal conductivity of the phase change material, H is the enthalpy, defined as the sum of the sensible heat enthalpy H_{sens} and the latent heat enthalpy H_{lat}, defined as follows:

$$H = H_{sens} + H_{lat} = H_{ref} + \int_{T_{ref}}^{T} C_p \, dT + fL \quad (6)$$

Where C_p is the specific heat capacity of the phase change material and H_{ref} is the reference enthalpy at the reference temperature T_{ref}.

In practical applications, significant temperature differences between the LHTES system and its surroundings necessitate the consideration of heat loss. In this study, an empirical correlation for natural convection in infinite space was used to calculate the heat transfer coefficient h, which characterizes the heat exchange between the system and the environment (Al-Urabi and Salman, 1980):

$$Nu = \frac{hD}{\lambda} = 0.59(GrPr)_m^{1/4} \quad (7)$$

Where λ represents the thermal conductivity of air, D is the characteristic length of LHTES unit. To quantitatively compare and analyze the performance of thermal storage units with different bionic structures, the following parameters were used in this study.The heat storage rate at which the PCM melts when absorbing heat can be expressed as:

$$\eta_v = \frac{Q_{pcm}=mc_p(T_c-T_i)+mfL}{t} \quad (8)$$

Where the total thermal energy storage Q_{pcm} is divided into latent and sensible heat when they absorb heat and melt, Tc is the current temperature and Ti is the initial temperature. In addition, L is the latent heat value and C_p is the specific heat capacity.

3. NUMERICAL METHODS AND INITIAL CONDITIONS

3.1. Numerical calculation methods

In this study, specialized software was utilized for mesh generation and for solving the governing equations, ensuring both computational accuracy and efficiency. The mesh was generated using Mesh software, while Fluent 2021 R1 with the solidification/melting model was utilized to solve the governing equations. The SIMPLE algorithm was adopted for pressure-velocity coupling, while second-order upwind schemes were used for the discretization of the energy and momentum equations, and the PRESTO! scheme was applied for pressure discretization (Kalapala and Devanuri, 2021). A time step of 0.025 s and a mesh with 156,377 cells were selected based on a mesh independence analysis to balance computational efficiency and accuracy (Fig. 1). As shown in Fig. 2(a), the numerical model was validated against experimental data from Liu et al. (2023), exhibiting good agreement, with a maximum average absolute error of 4.61 ℃ and a relative error of 8.19%, thereby confirming the model's reliability for further analysis.

3.2. Initial conditions

The inlet temperature and velocity of the HTF were set to 350 K and 0.01 m/s, respectively, while the initial temperature of the system was 295 K. Coupled boundaries were defined at the interfaces between the biomimetic structure, the PCM, and the HTF. As shown in Table 1, the thermophysical properties of the PCM are provided in reference (Liu et al., 2023). Numerical simulations were conducted to compare three configurations: Case A (shell-and-tube LHTES), Case B (BBJ-LHTES), and Case C (optimized BBJ-LHTES with the biomimetic bamboo-joint structure positioned in the lower section). The raised triangular section in Cases B and C occupied 2.95 % of the PCM-filled volume, as illustrated in Fig. 2(b).

Table 1. Thermophysical values of paraffin wax

Thermophysical properties	Density (kg/m^3)	C_p ($J/(kg \cdot K)$)	Thermal conductivity ($W/(m \cdot K)$)	Dynamic viscosity ($kg/(m \cdot s)$)	Thermal expansion coefficient (K^{-1})	Latent heat of fusion (J/kg)	T_m (K)
Numerical value	880 (s)/ 760 (*l*)	2000	0.2	0.005302	0.001	160000	316-322

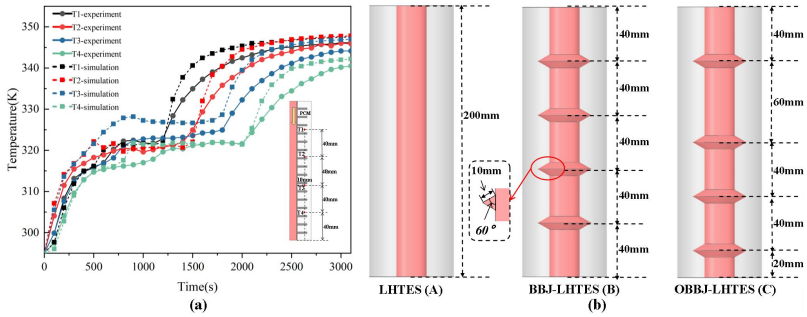

Figure 2. (a) Comparison between experimental data and simulation results; (b) Simulation cases A, B, C

4. RESULTS AND DISCUSSION

4.1. Analysis of PCM melting situation

Fig. 3(a) illustrates the variation of the liquid fraction of the PCM over time for different cases. The BBJ-LHTES (Case B) and OBBJ-LHTES (Case C) systems, both incorporating the biomimetic bamboo-joint structure, exhibited significantly higher PCM melting rates compared to the conventional shell-and-tube LHTES system (Case A). As shown in Fig. 3(b), the complete melting times for Cases A, B, and C were 4000 s, 2800 s, and 2400 s, respectively. This result indicates that Case C, which features the biomimetic structure in the lower section of the system, achieved the fastest melting rate, reducing the complete melting time by up to 40 %. Furthermore, at 800 s, the heat storage rate of the system increased by up to 29.5 %.

Fig. 4(a) illustrates the liquid fraction and temperature distributions during the PCM melting process for different cases, with the left side showing the liquid fraction distribution. As shown in Fig. 4(a), the solid–liquid interface initially formed near the heat exchanger tube, and the PCM near the system inlet melted first. This phenomenon occurred because heat was transferred sequentially from the heat transfer fluid to the heat exchanger tube, and subsequently to the PCM. The temperature near the heat exchanger tube was higher than in other regions of the system, resulting in its earlier melting. The PCM around the raised bamboo-joint structures in Cases B and C melted earlier than that in Case A. Subsequently, the molten PCM, which had a higher temperature, overcame gravity and moved upward due to the density difference, while the solid PCM, with a lower temperature, accumulated at the bottom.

As shown in Fig. 4(a), the PCM melting process after 800 s revealed that the system incorporating the bamboo-joint structure exhibited a progressively higher melting rate. This enhancement was primarily attributed to the bamboo-joint structure, which increased the heat transfer area and expanded the thermally affected region, thereby accelerating the PCM melting process. Notably, in conjunction with Fig. 3(b), it can be observed that at 800 s, the targeted placement of the bamboo-joint structure in the lower section of the system in Case C resulted in slower PCM melting in the upper region during the early stage. As a result, the early-stage heat storage rate of Case C (71.48 J/s) was slightly lower than that of Case B (72.03 J/s). However, the overall melting performance indicated that Case C achieved the fastest PCM melting rate. For instance, by 2500 s in the late melting stage, Case C had fully melted, whereas residual PCM was still present at the bottom of Case B. This finding suggests that placing the bamboo-joint structure in the lower section effectively enhanced the PCM melting rate in a vertically oriented

LHTES system. These results confirm that the incorporation and strategic placement of bamboo-joint structures significantly improve the melting performance of vertically oriented LHTES systems.

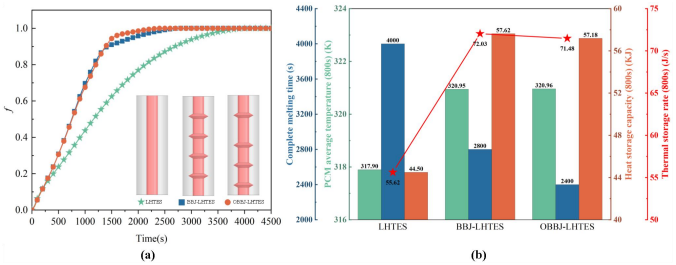

Figure 3. (a) Liquid fraction curves of PCM melting under different cases; (b) Thermodynamic performance analysis under different cases

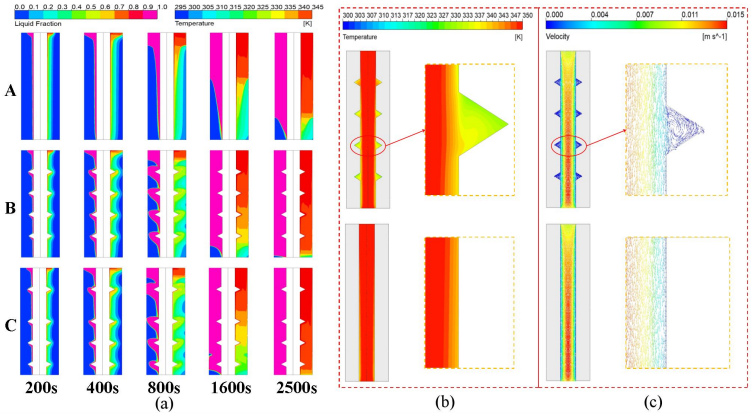

Figure 4. (a) Liquid fraction and temperature distribution of PCM melting under different cases; (b) Temperature distribution in the heat exchanger tube; (c) Velocity vector in the heat exchanger tube

4.2. Analysis of flow field in heat exchanger tube

To examine the influence of the biomimetic bamboo-joint structure on flow characteristics, Fig. 4(b) presents the temperature distribution within the heat exchanger tubes of both the LHTES and BBJ-LHTES systems, whereas Fig. 4(c) shows the corresponding velocity vectors. Fig. 4(b) clearly shows that the incorporation of the biomimetic structure resulted in a more pronounced variation in the temperature distribution within the heat exchanger tube. This phenomenon can be attributed to the vortex generation at the bamboo-joint structures, as shown in Fig. 4(c), where the induced vortices continuously sweep the tube walls, thereby disrupting the velocity and thermal boundary layers. Therefore, the incorporation of the biomimetic structure significantly influenced the internal flow characteristics, promoting vortex formation and development, and consequently enhancing the heat transfer performance within the heat exchanger tube.

5. CONCLUSIONS

In this study, a numerical model of the system was developed based on CFD, validated, and analyzed for performance. The conclusions of this study are as follows:

(1) The incorporation of the biomimetic bamboo-joint structure enhanced the heat transfer area

and significantly increased the PCM melting rate, reducing the total melting time by up to 40 %. Moreover, the early-stage heat storage rate of the system increased by up to 29.5 %.

(2) Placing the biomimetic structure in the lower section of the system accelerated the PCM melting process.

(3) The bamboo-joint structure facilitated vortex formation, disrupting the velocity and thermal boundary layers near the tube wall, thereby enhancing the system's heat exchange performance.

SUMMARY
Building rehabilitation represents a significant opportunity to improve energy efficiency and reduce the environmental impact of the building sector. Integrating phase change materials (PCM) within building components offers a promising approach for enhancing thermal regulation and efficiency in building retrofitting. This study focuses on evaluating the summer performance of an innovative latent thermal energy storage system (LTES) using a high PCM content embedded in a highly porous panel, combined with passive cooling strategies. Thermal analysis and computational simulations were used to evaluate the effectiveness of the composite PCM in moderating temperature fluctuations, highlighting the material and design efficiencies made possible by LTES systems. The results underline the potential of innovative LTES systems as a sustainable solution for retrofitting existing buildings, demonstrating improvements in thermal comfort.

Keywords: PCM-impregnated board, building simulation, night ventilation, occupant thermal comfort.

1. INTRODUCTION

In Europe buildings account for 40% of total energy consumption and 36% of greenhouse gas emissions, and 75% of EU buildings currently operating inefficiently (Recovery and Resilience Scoreboard, Thematic Analysis, Energy Efficiency in Buildings, 2023). In this context, the shift towards sustainable development is crucial, as is the retrofitting of buildings as an opportunity to improve energy efficiency and reduce the building sector's environmental footprint. The integration of Phase Change Materials (PCMs) into building components has gained significant attention as a promising solution to enhance thermal performance and reduce energy consumption in buildings (Cunha et al., 2016). By exploiting their latent thermal energy storage (LTES) capabilities, passive design strategies with PCMs can contribute to thermal comfort, reduced indoor temperature and lower HVAC energy consumption and sizes (Pielichowska & Pielichowski, 2014). However, to maximize their effectiveness, PCMs must undergo complete thermal charging and discharging cycles within a 24-hour period to efficiently absorb and release

heat energy (Ahmad & Memon, 2024). In this context, the integration of ventilation strategies has been identified as a key approach to optimizing PCM performance by enhancing the thermal charging and discharging process (Piselli et al., 2020). A review of the literature highlights a research gap in optimizing building envelope performance through the combined use of PCMs and ventilation (Salihi et al., 2024).

This study aims to investigate the potential of LTES coupled with different night ventilation configurations, analysing their impact on adaptive thermal comfort during the summer season. The analysis focuses on a recently developed innovative leak-proof porous calcium silicate panel impregnated with PCM (Cottone et al., 2025) assessing the potential application in building. Dynamic simulations, performed using Energy Plus software and a validated model on a sloping roof of a test room, assess the extent to which PCMs can optimise latent heat storage and release in conjunction with controlled night ventilation strategies. The primary objective is to improve thermal comfort by effectively utilizing the PCM's phase transition to moderate indoor temperatures. Roof structures play a critical role in heat transfer dynamics, as they are the area most exposed to solar radiation, making the attic particularly vulnerable to high summer heat loads and the risk of overheating (Liu et al., 2023). By incorporating PCMs into the roof structure, a significant portion of incoming solar radiation and ambient heat energy can be absorbed and later dissipated. This not only mitigates temperature peaks, but also helps stabilise internal temperatures, reducing fluctuations, and improving overall thermal comfort in the space below. Additionally, this study examines the effects of thermal hysteresis of the material on the PCM's charging and discharging behavior, which can influence its effectiveness in real-world applications. The findings provide key insights into the optimisation of PCM integration, offering valuable contributions to the field of energy-efficient building renovation and the development of resilient passive cooling solutions.

2. MATERIALS AND METHODS

The present study analyses a calcium silicate panel impregnated with 72 wt.% of paraffinic PCM Rubitherm RT27 (PCM-B-CRT27), characterised by a latent heat of fusion of 119 kJ/kg with melting temperature peak at 28°C, and a latent heat of solidification of 115 kJ/kg with a solidification peak at 26°C. An energy model of a Test Roofing Innovative System (TRIS), an experimental apparatus designed for the thermal analysis of advanced roofing components (Fantucci et al., 2022), was used to evaluate the summer performance of the developed system. The TRIS test cell, with a volume of approximately 2 m^3, is located in the attic of a residential building in the metropolitan area of Turin, Italy.

1.1 Energy model validation

For the validation of the energy model, the test cell without the PCM layer was modelled in EnergyPlus, and the model was calibrated using experimental data obtained during a monitoring campaign. Figure 1 shows a section of the TRIS cell with the roof stratigraphy and sensor layout, while Table 1 shows the input data for the roof materials. Different algorithms were considered for the determination of the convective transfer coefficients. The comparison between the simulated and experimental data showed a high correspondence using the TARP (Thermal Analysis Research Program) algorithm for the external surface, which considers both forced and natural convection, and the ASTM C1340 method for the internal surface, which takes into account the direction of heat flow. In addition, a variable flow rate as a function of wind speed was adopted for the air gap, which significantly reduced the uncertainty compared to the assumptions of

constant flow rate or still air. Figure 2 shows the comparison between the simulated and measured heat flow of a typical day, exchanged between the inner layer of the roof and the air in the cell, considering both conduction and convection. The simulated profile is comparabale to the experimental one, confirming the validity of the developed energy model.

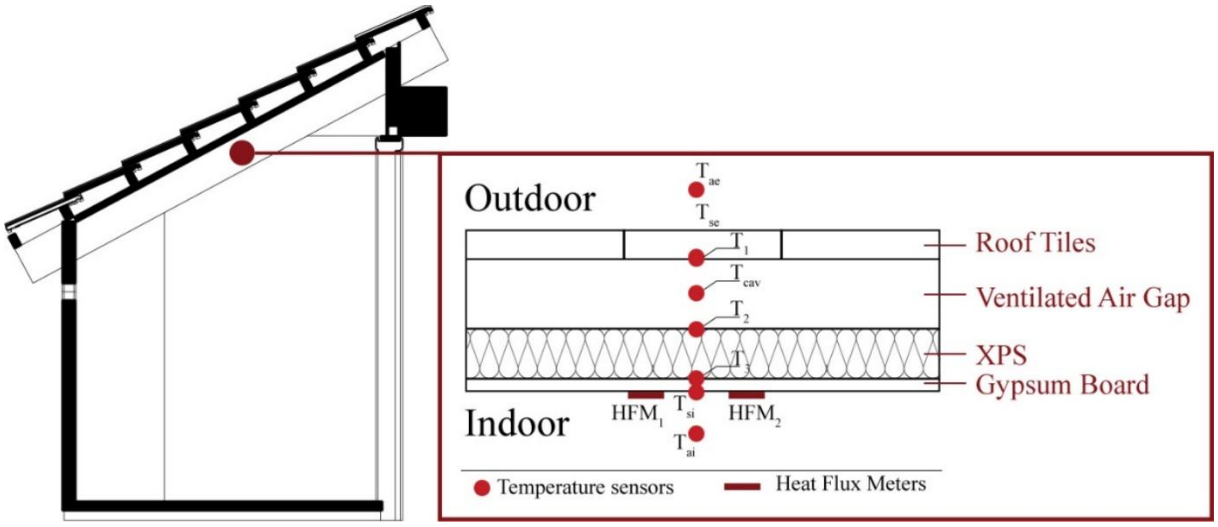

Figure 1. Section of TRIS cell and roof stratigraphy for model validation

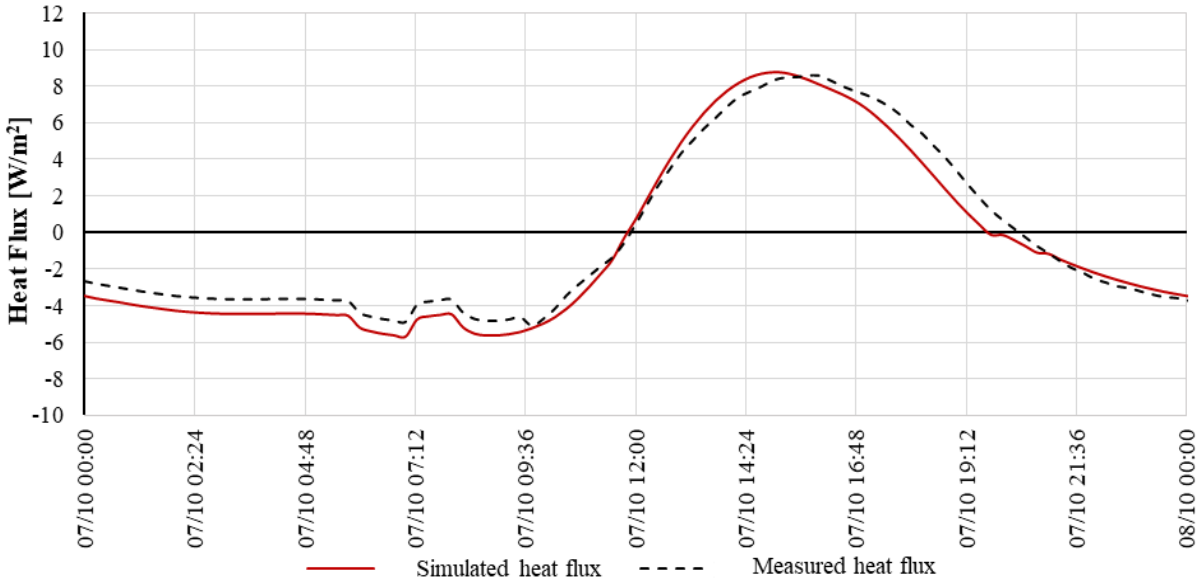

Figure 2. Comparison of measured and simulated heat flow

1.2 Evaluation of summer performance of the innovative system with PCM

The aim of this work is to employ the validated model to simulate the performance of the innovative panel system with embedded PCM (Figure 3). In particular, the conduction finite difference method (CondFD) was implemented for modelling the hysteresis of the PCM. Table 1 shows the stratigraphy of the roof together with the characteristics of the materials, highlighting in red the PCM-B-CRT27 layer with a thickness of 30 mm, placed close to the inner side of the room.

Table 1. Roofing stratigraphy.

Layers from outside	Thickness [mm]	Thermal conductivity [W/mK]	Specific heat [J/kgK]	Density [kg/m^3]	
Roof Tiles	30	0.700	840	1700	Ventilated Air Gap	70	-	-	-	
XPS	50	0.038	1500	33	
PCM-B-CRT27	30	0.190	2400	909	
Gypsum Board	12.5	0.250	1000	900	

As shown in the methodology workflow (Figure 3), a free cooling system based on night ventilation (NV), from 00:00 to 08:00, was implemented to allow the discharge of the PCM and maintain the internal temperature in the comfort zone during the day. The temperature in the middle node of the PCM layer was evaluated for the entire summer period, thus considering June, July and August. This approach allows the calculation of a performance indicator to identify the exploitation capability of the PCM in percentage terms through the following equation:

$$PCM\ exploitation\ (\%) = \frac{n°\ of\ hours\ in\ the\ latent\ phase}{n°\ of\ total\ hours\ in\ the\ considered\ period} \cdot 100 \quad (1)$$

In parallel, the adaptive thermal comfort was evaluated according to the ASHRAE 55 standard (ASHRAE, 2021), which defines threshold values of the indoor operating temperature as a function of the prevailing mean outdoor temperature. In particular, two scenarios were considered. The first assumed the absence of NV with only natural infiltration at 0.4 air changes per hour (ACH), while the second include NV at 5 ACH, in order to quanify how strategic implementation of NV maximises the utilisation of PCM-B-CRT27 without compromising thermal comfort.

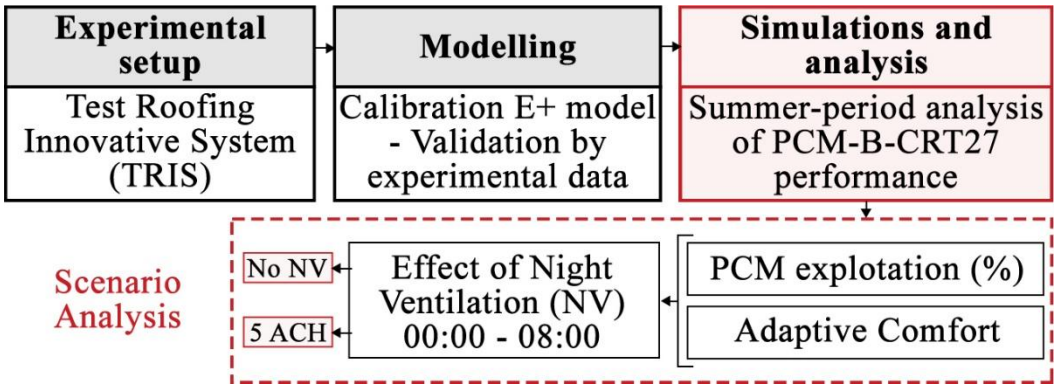

Figure 3. Methodology workflow

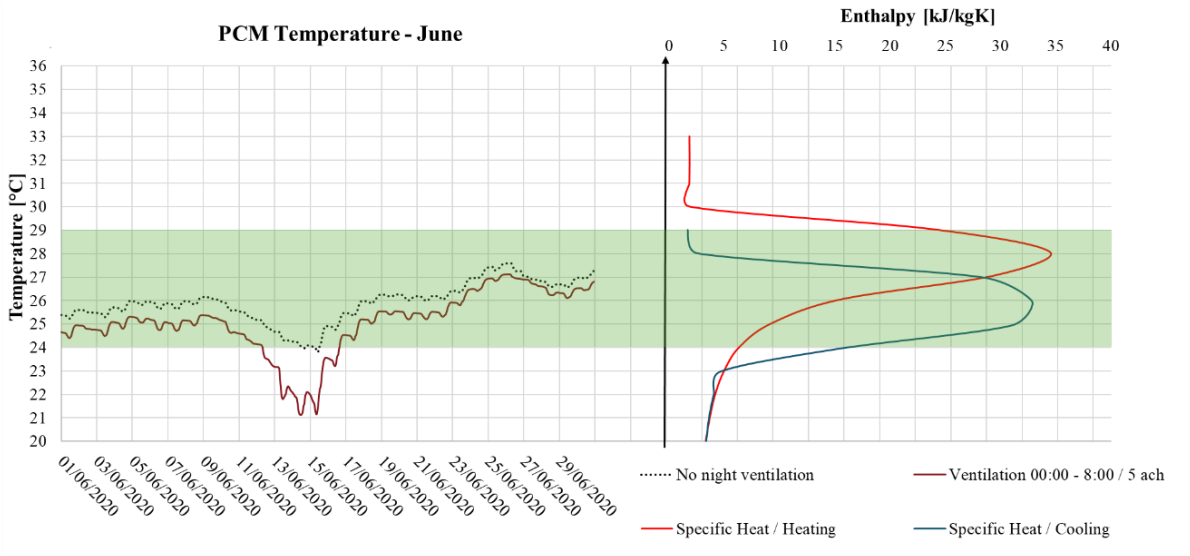
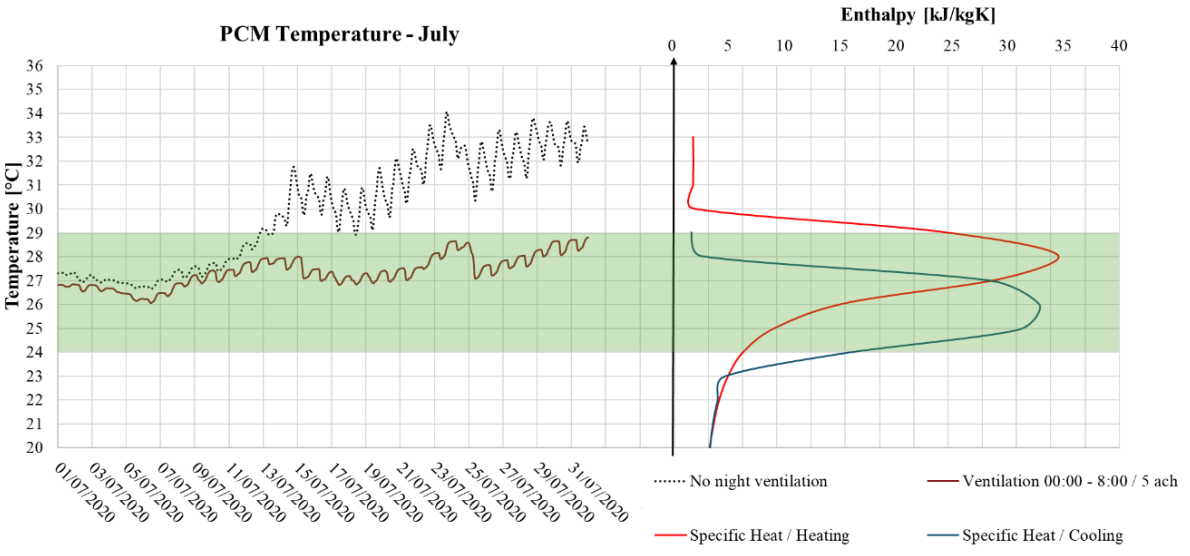
3. RESULTS

3.1 Phase Change Materials exploitation

Figure 4 shows the temperature trend in the inner node of the PCM-B-CRT27 layer as a function of the different simulated ACHs and the range of the latent phase, which is between 24 and 29 °C. It turns out that night ventilation is not necessary during the month of June, where the exploitation

of the PCM is already maximised up to 99% (see Figure 5). In addition, fixed ventilation rates of 5 ACH lead to temperatures out of the latent range of the PCM-B-CRT27 on the mildest days of June, which could generate indoor thermal discomfort. On the other hand, the analysis of July and August shows how the absence of NV is not sufficient to maximise the exploitation of the system and recharge the PCM-B-CRT27. Indeed, in July the exploitation is between 40% in the absence of NV, but with 5 ACH this increases to 100%, in fact the temperature profile of the PCM node falls completely within the latent phase marked by the green area. Similarly in August, an exploitation of 34% is reached in the absence of NV and 89% with 5 ACH, in fact, especially in the first ten days of the month a higher temperature occurs. It can therefore be concluded that to maximise the latent phase of the material studied, the implementation of NV is necessary.





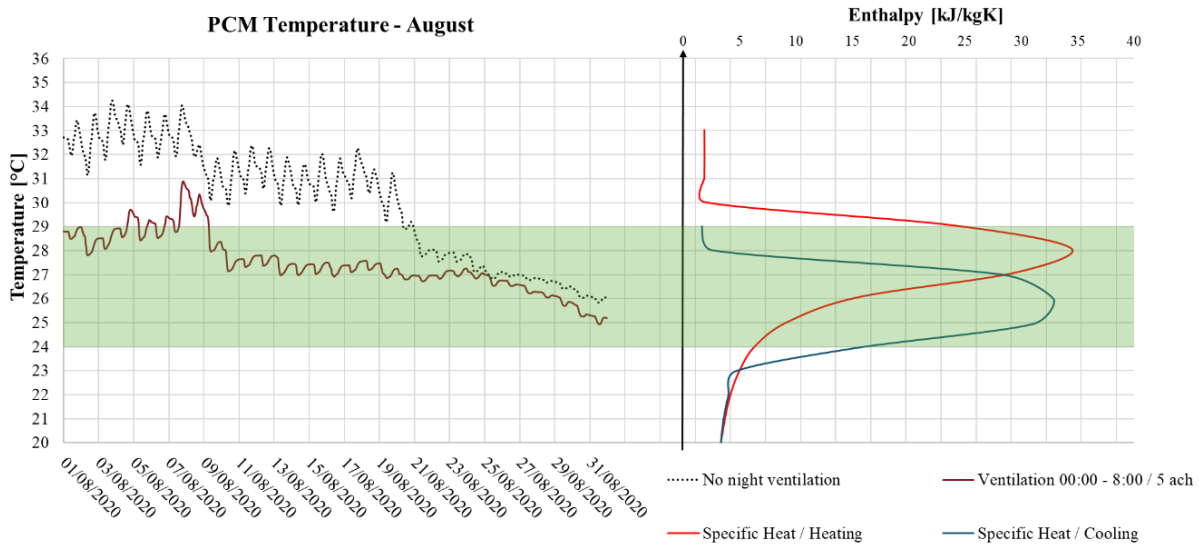


Figure 4. Temperature trend in the inner node of the PCM during the months considered: absence of night ventilation and different 5 air change per hour

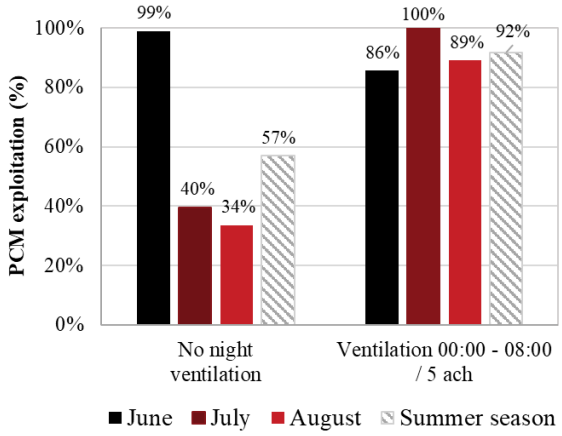

Figure 5. PCM exploitation with the absence of night ventilation and 5 ACH.

3.2 Indoor thermal comfort improvement

Figure 6 shows the number of hours above the upper limits of acceptability defined by the ASHRAE-55 standard for the assessment of adaptive thermal comfort, considering scenarios with and without the application of a PCM layer to evaluate the effectiveness of the material in the thermal regulation of indoor spaces. The results show that the application of night ventilation leads to a significant reduction in the number of hours when indoor conditions exceed acceptable limits. This trend can be observed in both scenarios with and without PCM. However, the combined effect of PCM and adequate night ventilation proves to be particularly effective in optimising thermal comfort. The application of a PCM layer amplifies the reduction of out-of-comfort hours as the ACH increases, demonstrating how NV is able to discharge the PCM and prepare it for heat flow reduction during the following day. These observations highlight two key aspects: 1) an air exchange rate (≥5 ACH) is essential to maximise the potential of PCM, ensuring its thermal discharge during the night; 2) the addition of a PCM layer offers significant added value, allowing

higher thermal attenuation during daytime hours, even with moderate natural ventilation strategies.

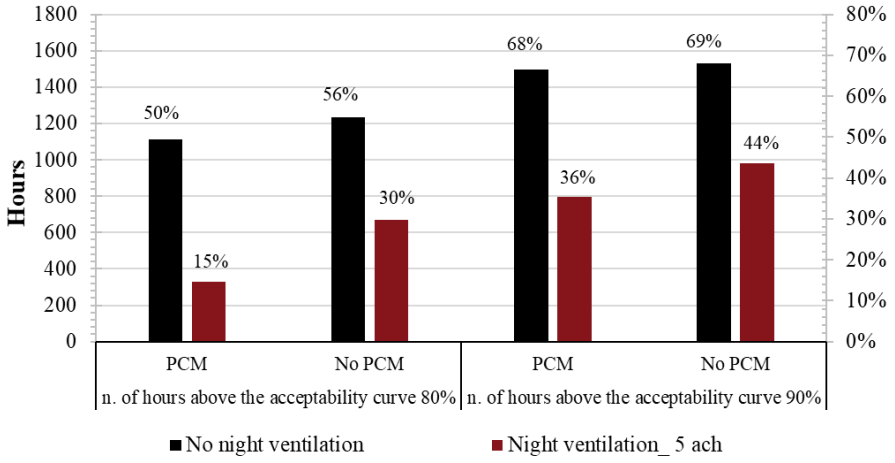

Figure 6. Hours above the upper acceptability limits 80% and 90% following the standard ASHRAE 55-2020.

Figure 7 compares the scatter plot of the adaptive comfort of the two scenarios with PCM, without NV and with 5 ACH. The comfort zone, highlighted in red, represents the range of acceptable conditions according to the ASHRAE 55 standard. Analysis of the results clearly shows that in the absence of night ventilation most of the data is distributed outside the comfort zone, indicating a prevalence of unfavourable thermal conditions. On the contrary, at 5 ACH, a significantly higher proportion of hours fall within the comfort limits due to the nightly PCM unloading and the reduction of thermal fluctuations that maintain more stable indoor temperatures. This demonstrates that an adequate ventilation rate not only exploits the potential of the PCM, but also ensures more stable and prolonged thermal comfort.

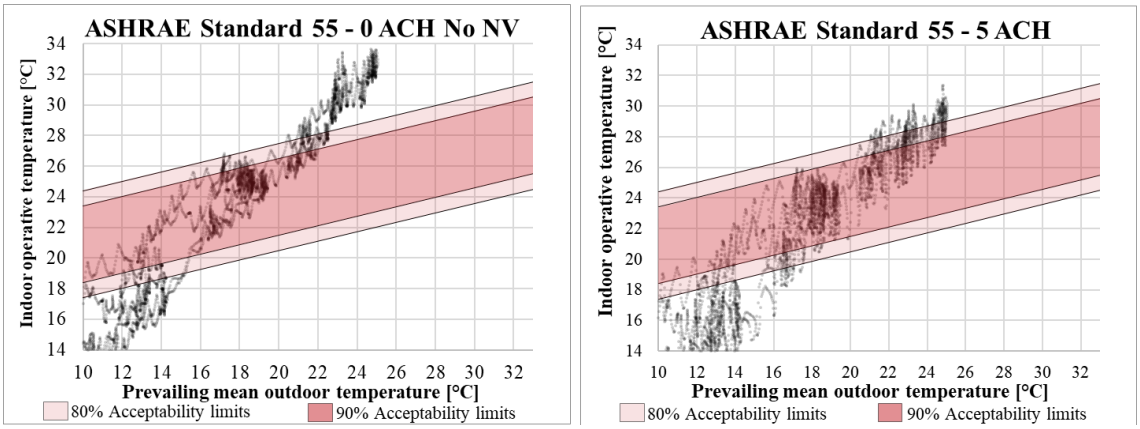

Figure 7. Operating temperature scatter plot as a function of prevailing mean outdoor temperature.

4. CONCLUSIONS

The integration of a PCM-impregnated system in building retrofitting offers significant improvements in thermal comfort and energy efficiency, especially when combined with effective

night ventilation strategies. The study shows that night ventilation, with air exchange rate of 5 ACH, optimises the performance of PCM, ensuring maximum utilisation of its latent heat storage capacity, with exploitation rates reaching 92% during the summer season. Although night ventilation is not necessary in June leading to 99% PCM utilisation, its absence throughout all summer period results in high levels of discomfort. The combination of LTES and night ventilation reduces the number of hours above the upper acceptable limits for indoor temperatures by up to 35% compared to the scenarios without PCM or ventilation, thus improving occupants' thermal comfort. This underlines the remarkable efficiency of PCM systems in reducing the need for excessive insulation during retrofitting processes. These results highlight the potential of PCM-based LTES systems as a sustainable and efficient solution especially for retrofitting existing buildings, but also for new constuctions, contributing to both energy savings and improved occupant comfort.

The developed model will be calibrated and validated by an experimental campaign with a scenario including a PCM layer. Future research will evaluate incremental NV (ACH) values to identify the optimal value that maximises the exploitation of the PCM-B-CRT27 without compromising thermal comfort. Additionally, the study will explore the implementation of ventilation control strategies based on the PCM's thermal response and outdoor temperature. The research will also assess the performance of PCM-B-CRT27 during the winter season by coupling it with an integrated heating system, aiming to enhance energy efficiency while potentially reducing the required insulation thickness.

SUMMARY

The building sector is a major contributor to global carbon emissions and energy consumption. A promising solution to mitigate this impact is the utilization of renewable energy, especially solar energy. However, in a high-density built environment, the application of photovoltaic (PV), especially on the building facades, is often hindered by shading from surrounding structures. To optimize solar energy use in urban area, it is important to understand the influence of key urban morphological parameters on solar energy utilization in densely built environment. This study aims to explore the relationship between urban morphology and building-integrated photovoltaic (BIPV) performance with a typological approach, while ensuring life cycle economic and environmental benefits. The findings are expected to inform design and planning strategies for effectively integrating solar energy into urban environments, thereby promoting more sustainable and energy-efficient cities and supporting long-term carbon neutrality objectives.

Keywords: High-density Urban Morphology, Solar Potential, Block Prototypes, Life Cycle Assessment

1. INTRODUCTION

1.1 Background

As one of the largest contributors to global energy consumption and greenhouse gas emission, cities should play a leading role in the process of energy transition. Thus, Solar energy is now widely used in built environments. Building-integrated photovoltaic (BIPV) integrates photovoltaic (PV) modules into building structures, providing the benefits of both clean energy production and enhanced building performance. However, the widespread application of BIPV faces several challenges. Besides economic barriers, a significant issue lies in the inflexibility of implementation, since the positioning of PV modules is often fixed during the construction phase. In the implementation of BIPV in high-density urban environments, the drawback of fixed-position installation of PV modules is further aggravated, where shading from surrounding structures can significantly decrease the PV performance. Therefore, meticulous planning and evaluation are crucial for the successful deployment and promotion of BIPV systems.

To provide a theoretical foundation for the planning of BIPV, this paper aims to investigate the impact of urban morphology on the potential of BIPV. Focusing on Shanghai as a representative high-density metropolis, this study explored the influence of key urban morphology on the BIPV energy potential at meso scale with the prototypes identified through clustering algorithm. The

findings of this study aim to offer valuable insights for optimizing BIPV integration in urban planning, thereby supporting the development of more sustainable and energy-efficient cities.

1.2 Literature Review

Strategic urban morphology planning has been recognized as a critical factor in maximizing solar energy utilization (Amado et al., 2012). Recent studies have adopted an established methodology that integrates quantitative urban morphology analysis with prototype selection, systematically examining parameter variations and their combinatorial effects on solar performance (Schirmer et al., 2016). One crucial step in this research lies in the identification of appropriate morphological parameters, which directly determines the representativeness of extracted urban block prototypes. The definitions of common parameters and their related literature can be found in Table 1.

Table 1. Morphological parameters commonly used in studies related to solar potential

Parameter	Description	Related Literature
Density / Building Coverage Ratio	Building Footprint Area / Site Area	Basic parameters adopted for the most research
Floor Area Ratio / Plot Ratio	Building Floor Area / Site Area	
Average Building Floor	Building Floor Area / Building Footprint Area	
Average Building Height	Average Building Height × Floor Height	
Sky View Factor	Upper hemisphere visible sky percentage	(Liu et al., 2023) (Poon et al., 2020)
Orientation	Orientation of the main façade of the building	(Mahaya et al., 2022) (Yang et al., 2024)
Open Space Ratio	1/ Floor Area Ratio – 1 / Average Building Floor	(Zhu et al., 2020) (Zhang et al., 2019)
The Form of Single Buildings	Single building form, including slab, tower, courtyard, etc.	(Tian er al., 2021)

The selection of research cases generally follows two approaches: analysis of existing urban configurations (Jareemit et al., 2025) or generation of sample library with different morphological parameters combination (Du et al., 2024). The difficulty with the former is how to select a representative prototype in a number of cases. Limitations of the latter approach in capturing real-world complexity have been shown in previous research. To over this bridge, this study employs real-world urban blocks in Shanghai as research prototypes with a clustering approach, the potential for solar potential will be compared to analyze the impact of morphology on it.

2. METHODOLOGY

This research consists of the following four stages, as shown in Figure 1.

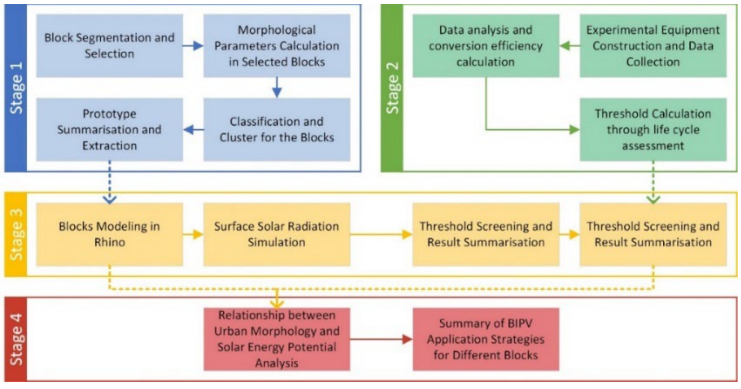

Figure 1. The Framework of this research

From the review of the related research in Section 1.2, 7 key parameters are selected for analyzing urban morphology, as shown in Table 2. Following the Chinese standard GB 50352-2019, we classified buildings into three categories: low-rise (1-3 floors), multi-rise (4-9 floors) and high-rise (≥10 floors). The prototype extraction process was implemented in two sequential stages. First, urban blocks were classified with density and average number of floors. Then, block types were clustered with the percentage of floor area of each building height category as the primary criterion.

Table 2. Selected morphological indicators

Parameter	Unit	Description
Block Area *A*	m^2	The site area of the research block
Building Footprint Area *F*	m^2	The footprint area of buildings in the research block
Building Floor Area *B*	m^2	The total building area in the research block
Density of Block *D*	-	F / B
Floor Area Ratio *FAR*	-	B / A
Average Building Floor N_{Floor}	-	B / F_t
Percentage of Floor Area of Different Type Building Height n_i	%	$S_{Building,\ i} / S_{Building}$

For BIPV performance evaluation, modules were constructed in building surface to evaluate conversion efficiency under real-world conditions. The experimental equipment is listed in Table 3. The radiation threshold is important for the selection of the usable building surfaces, ensuring both environmental and economic benefits. These benefits, noted as $R_{T,en}$ for environmental and $R_{T,ec}$ for economic benefits, can be calculated through Equations (1) and (2) , respectively. Table 4 details the values for each parameter in this study.

Table 3. Experiment devices

Equipment		Function	Sampling Rate
PV panels		Converting solar energy into electricity	-
Kipp & Zonen CMP11		Measuring solar radiation on the ground	-
Kipp & Zonen LOGBOX SE		Record the test data transmitted by CMA11	1 min
DAM3053DC		Measure the actual output power of the PV panel	1 min

$$R_{T,en} = \frac{\sum_{t=0}^{n} \frac{C_t}{(1+d)^t}}{\sum_{t=1}^{n} \frac{LCOE_t \times \eta_t}{(1+d)^t}} \tag{1}$$

$$R_{T,ec} = \frac{\sum_{t=0}^{n} EF_{PV,t}}{\sum_{t=1}^{n} EF_E \times \eta_t} \tag{2}$$

Table 4. Required Parameters for the performance evaluation

Parameter	Values
Life Cycle *n*	25a
Levelized Cost of Energy *LCOE*	0.737 RMB/kWh

Initial Investment C_0	3.0 RMB/W
Subsequent Investment C_t (t is from 1 to 25)	3% of the initial investment
Conversion Efficiency of PV η_t	Calculations based on experiment data. Annual degradation rate: 2.5%/a in the first year and 0.7 %/a thereafter
Discount Rate n	8%/a
Electricity Carbon Emission Factor EF_E	0.581kg/kWh
PV Carbon Emission Factor $EF_{PV,\,t}$	Only the carbon emission during production process is considered with the Report by Deloitte and Envision Group (Deloitee et al., 2024), 1.22 kgCO2/Wc

The block prototypes will be extracted through a clustering approach, then the geometry data of the selected cases are exported from ArcGIS and reconstructed into 3D models with Rhino. The simulation of the solar radiation on the building surfaces was performed with the Ladybug plug-in, enabling the identification of surfaces meeting the predefined application thresholds. Based on these results, a comparative analysis of BIPV application potential was conducted across different block types.

3. CASE STUDY

3.1 Block Prototype Extraction

Urban blocks serve as fundamental elements of urban fabric, enabling the analysis of building interactions and providing insights for larger-scale urban planning and design. This study adopts the three-tier living circle system as the scale of block extraction: 5-minute, 10-minute, and 15-minute walking distances. Given that a 5-minute walk for adults is approximately 400 meters, the block scales within the range of 400 m × 400 m to 1200 m × 1200 m, corresponding to an block area between 0.16 km^2 and 1.44 km^2. Block parcels were generated from urban data by first establishing road buffer zones. Road widths were set at 40 m, 30 m, 25 m, and 12 m, following Technical Standard of Highway Engineering (JTG B01-2014), resulting in 1,515 parcels. These parcels were further categorized into nine groups based on their density and their number of floors. Density classification was performed using the K-means algorithm (K=3), yielding three density clusters: low-density (< 0.18), middle-density (0.18–0.27), and high-density (> 0.27). The distribution of the nine block types is shown in Figure 2.

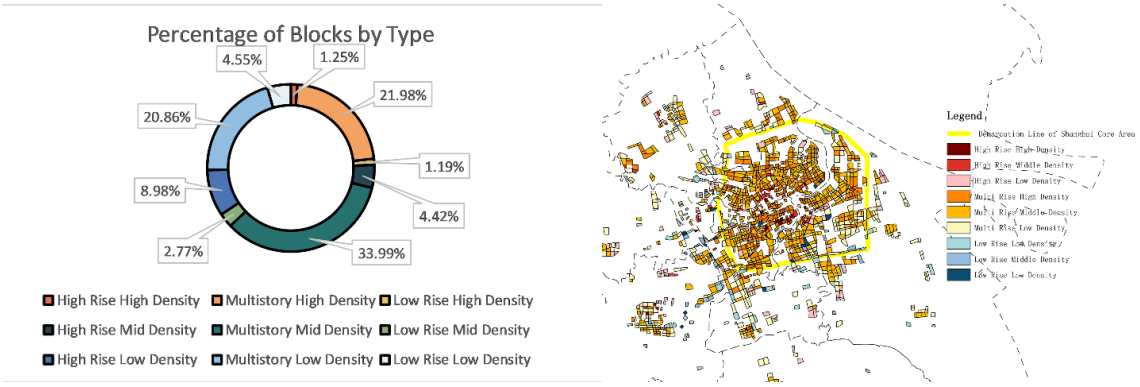

Figure 2. Percentage and Distribution of Blocks by Type (Urban Data Source: Baidu Map, OpenStreetMap)

High-rise high-density (HH), multi-rise high-density (MH), high-rise middle-density (HM) and

multi-rise middle-density (MM) blocks were identified as the dominant types in Shanghai center. Further analysis focused on the mixing ratios of high-rise, multi-rise, and low-rise floor areas within MH and MM blocks. The Affinity Propagation (AP) algorithm was employed to cluster blocks within each type. The MH blocks were further divided into four clusters: multi-rise dominated (MH-A), multi-rise low-rise hybrid (MH-B), multi-rise dominated multi-rise high-rise hybrid (MH-C), and high-rise dominated multi-rise high-rise hybrid (MH-D). Similarly, the MM blocks were classified into five clusters: multi-rise low-rise hybrid (MM-A), multi-rise dominated (MM-B), high-rise dominant mixed (MM-C), multi-rise intercourse mixed (MM-D) and high-rise multi-rise mixed (MM-E). The plot scales were further divided into three intervals of $0.16km^2$~$0.64km^2$ (small plot), $0.64km^2$~$1.00km^2$ (middle plot), and $1.00km^2$~$1.44km^2$ (huge plot).

Table 5. Prototypes used for research

Type	Small Plot (SP)	Middle Plot (MP)	Huge Plot (HP)
High-rise High-density (HH)	√		
Middle-rise High-density A (MH-A)	√	√	√
Middle-rise High-density B (MH-B)	√	√	√
Middle-rise High-density C (MH-C)	√	√	√
Middle-rise High-density D (MH-D)	√	√	
High-rise Middle-density (HM)	√	√	
Middle-rise Middle-density A (MM-A)	√	√	√
Middle-rise Middle-density B (MM-B)	√	√	√
Middle-rise Middle-density C (MM-C)	√	√	√
Middle-rise Middle-density D (MM-D)	√	√	√
Middle-riseMiddle-density E (MM-E)	√	√	√

3.2 Radiation Threshold for BIPV Application

For the performance evaluation, the nominal conversion efficiency of PV panels was assumed to be 17.36% in this study. Our experimental results indicated an average conversion efficiency found of 16.61%. Based on the calculation method described in Section 2.2, the radiation threshold for PV application can be calculated as $404.5kWh/m^2$ because of the economic factors considering the PV feed-in subsidy. This threshold can be reduced to $392.14kWh/m^2$ if carbon quota trading was incorporated into the analysis. For environmental benefits the threshold value is 91.46 kWh/m^2 to meet PV application requirements. Consequently, the threshold of 400 kWh/m^2 for PV application was selected in this study.

3.3 Building Solar Radiation Potential Analysis

Solar radiation analysis was conducted using the Ladybug tool within the Grasshopper plugin. A computational framework was established, as shown in Figure 3, which determines the solar radiation on building surfaces and identifies the areas meeting the specified radiation threshold. Simulations were performed for both roofs and façades across 29 selected urban blocks in Shanghai. The results of these calculations are summarized in Table 6.

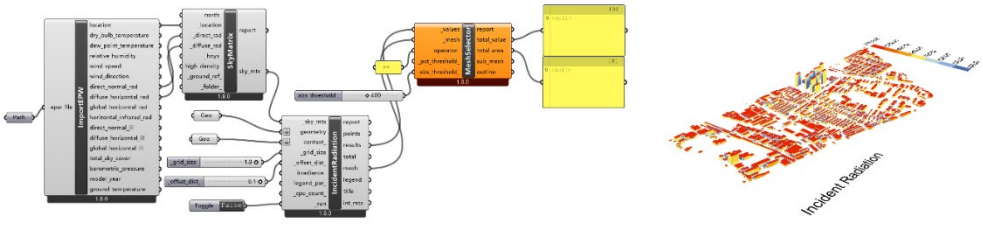

Figure 3. Grasshopper-LB-HB components for BIPV simulations and example of simulation results

Table 6-a. Simulation results (High Density)

Study Case	Radiation per unit area of the roof kWh/m^2	Radiation per unit area of the facade kWh/m^2	Radiation per unit area of all building surfaces kWh/m^2	Proportion of usable building surface area
HH SP	1039.14	563.75	730.40	28.62%
MH-A SP	1146.41	604.29	880.60	40.44%
MH-A MP	1159.95	658.94	988.84	49.38%
MH-A HP	1157.95	575.80	834.72	60.48%

MH-B HP	1152.92	603.12	819.99	60.29%
MH-C SP	1131.72	578.39	814.07	46.90%
MH-C MP	1134.20	591.54	844.84	44.60%
MH-C HP	1156.26	604.05	859.89	47.24%
MH-D SP	1091.25	598.10	812.55	49.94%
MH-D MP	1167.07	590.85	926.42	51.23%

Table 6-a. Simulation results (Middle Density)

Study Case	Radiation per unit area of the roof kWh/m^2	Radiation per unit area of the facade kWh/m^2	Radiation per unit area of all building surfaces kWh/m^2	Proportion of usable building surface area
HM SP	1190.55	588.22	808.59	38.68%
HM MP	1024.34	573.57	706.62	46.93%
MM-A SP	1172.92	652.21	937.50	58.63%
MM-A MP	1146.74	592.35	791.76	53.59%
MM-A HP	1117.65	597.60	804.57	42.96%
MM-B SP	1184.70	628.37	896.98	50.64%
MM-B MP	1162.40	590.76	810.57	42.10%
MM-B HP	1197.37	565.78	945.76	65.37%
MM-C SP	1088.40	583.27	796.80	37.23%
MM-C MP	1117.07	581.21	790.01	35.71%
MM-C HP	1150.87	620.31	866.88	32.65%
MM-D SP	1153.49	563.90	789.24	41.18%
MM-D MP	1163.77	601.10	877.67	46.39%
MM-D HP	1130.74	585.80	787.21	41.57%
MM-E SP	1141.93	609.69	836.52	46.45%
MM-E MP	1147.80	587.00	752.62	45.63%
MM-E HP	1127.02	606.94	826.61	36.56%

4. DISSCUSSION

These block types exhibit significant vertical development intensity, especially for MH-A MP, MM-B SP resulting in façade areas substantially larger than roof areas. This morphological feature highlights the considerable potential for façade-integrated BIPV applications. The analysis of BIPV potential can be categorized into two aspects: irradiation per unit area and the proportion of usable area, which determine the quality and quantity of BIPV deployment.

The solar energy potential of roofs is found to be relatively consistent across 29 study examples and less affected by morphological variations, with the irradiation levels exceeding 1000 kWh/m^2. In contrast, the solar potential of façades is significantly influenced by morphology. Despite the threshold of 400 kWh/m^2, the average radiation intensity on qualifying façade surfaces exceeded 550 kWh/m^2, ensuring both economic viability and substantial coverage of building surfaces. Meanwhile, building height emerged as a critical factor of the overall solar potential, as seen in both HH and HM cases ranking at the bottom in BIPV performance (Table 6-a, 6-b).

Among MH blocks, the MH-A type performed well across all three scales, while MH-B demonstrates the highest radiant intensity. MH-C exhibits optimal performance in compact plots, while MH-D demonstrates better performance only in medium plots. Within MM blocks, MM-B shows consistent suitability across multiple scales. These results suggest that multi-rise-dominated or multi-rise-low-rise hybrid configurations are most suitable for both MM and MH blocks.

In terms of the proportion of usable surfaces, HH blocks consistently showed the lowest values. Among MH blocks, MH-B has the highest proportion of usable surfaces, while MH-C has the lowest. Within MM blocks, MM-A and MM-B achieved the largest proportions of usable surfaces, with MM-D and MM-E demonstrating similar performance with over 40% of usable area. Conversely, MM-C shows the lowest proportion of usable area.

These results reveal that multi-rise-dominated or multi-rise and low-rise mixed-type blocks generally outperform high-rise blocks in solar energy potential within Shanghai's high-density urban context.This suggests that urban planners could prioritize mid-rise developments in area with high solar resources, while reserving high-rise typologies for areas where vertical density provides critical benefits. Such approach would balance the energy efficiency objectives with broader urban development goals.

5. CONCLUSION

This study investigated the impact of urban morphology on building-integrated photovoltaic (BIPV) potential in high-density urban environments, using Shanghai as a case study. With a clustering approach, urban blocks were classified into nine types, with four dominant types identified in the city's core: high-rise high-density (HH), multi-rise high-density (MH), high-rise medium-density (HM), and multi-rise medium-density (MM). These blocks were further subdivided into 29 clusters based on the plot scale and the mixing of various building height types. The solar radiation threshold was determined with a PV life cycle analysis framework. The solar radiation simulations were conducted for 29 selected block samples, and surfaces meeting the threshold were identified and analyzed. The results revealed significant variations in solar potential across different morphological block types, with multi-rise-dominated and multi-rise-low-rise hybrid configurations demonstrating the highest potential for BIPV applications. These insights shall provide valuable guidance for urban planners and policymakers aiming to integrate BIPV systems into high-density urban environments, ultimately supporting the development of more sustainable and energy-efficient cities.

However, this study has several limitations. First, the sample size was insufficient for rigorous quantitative analysis of the relationship between morphology parameters and solar energy

potential. Second, the abstraction process of quantifying the urban morphology was only limited to several parameters, which may not fully capture the complexity of morphology's influence on solar energy potential.

These limitations will be addressed in our future research, by incorporating interpretable machine learning methods based on the expanded sample size to enhance the robustness and generalizability of the findings and so that a quantitative relationship can be addressed for decision-making in the design and urban planning process. The external factors such as air pollution and season will be also considered in a more detailed experimental design to calculate the conversion efficiency to increase the credibility of the results. Furthermore, the spatial-temporal transportability of the results is also significant which determines the value of the application. Migration studies within and across climate zones will be further developed to confirm the validity of the method.

SUMMARY
This study evaluates the thermal performance and energy efficiency of two widely used cooling systems in data centers: ALT-1 (Fan Wall Unit-based Slab Floor) and ALT-2 (CRAH-based Raised Floor). Using CFD simulations, airflow distribution, temperature compliance, and cooling capacity were analyzed under varying supply air temperature (SAT) conditions. ALT-1 demonstrated superior airflow uniformity, stable temperature distribution, and minimal bypass and recirculation, consistently maintaining IT inlet temperatures within ASHRAE's recommended range of 18°C–27°C. In contrast, ALT-2 exhibited greater temperature and airflow variability, leading to localized hotspots and higher cooling capacity deviations. While both systems achieved comparable average net cooling power, ALT-1 proved more reliable and energy-efficient due to its consistent performance. These findings highlight the advantages of FWU-based slab floor configurations for high-density data centers, providing improved thermal management and operational efficiency. Future research could explore optimizing FWU designs for further energy savings and performance enhancement.

Keywords: data center, cooling system, thermal performance, energy efficiency

1. INTRODUCTION

The cooling method of data centers has been a critical topic in the IT industry, particularly regarding the efficiency of different air distribution strategies (Cho et al., 2014). Traditional approaches involve the use of raised floors to supply air through computer room air handling units (CRAH) or the deployment of fan wall units (FWU) to manage airflow within slab floor configurations (Xiong et al., 2021; Wu et al., 2024). This study aims to analyze the performance of these two widely adopted cooling methods in air-cooled data centers by evaluating their airflow distribution, cooling efficiency, and impact on IT equipment inlet temperature.

Energy efficiency and temperature control are essential for maintaining optimal data center operations. The study specifically investigates the differences in supply air distribution between under-floor air distribution (UFAD) with CRAH and slab floor air distribution (SFAD) with FWU. By gradually increasing the supply air temperature from 16°C to 24°C, the effect on IT equipment inlet temperatures is analyzed. A smaller difference between the supply air temperature and the IT inlet temperature signifies improved air distribution efficiency, minimizing bypass and re-circulation. If the IT equipment inlet temperature remains within ASHRAE's recommended range (ASHRAE, 2021), energy efficiency can be enhanced through better system coefficient of performance (COP) and increased economizer operation.

2. METHODOLOGY

To quantitatively assess the cooling performance of these two systems, a computational fluid dynamics (CFD) simulation was conducted using Cadence Reality DC Design.

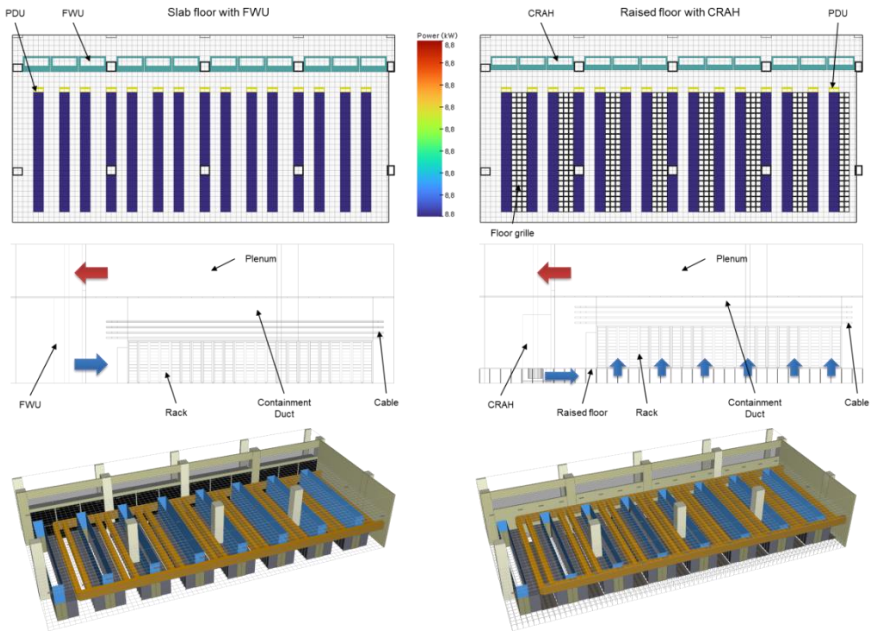

Figure 1. Cooling configurations: raised floor (ALT-2) vs. slab floor (ALT-1).

Table 1. Comparison of cooling strategies: raised floor (ALT-2) vs. slab floor (ALT-1).

Category	Raised Floor (ALT-2)	Slab Floor (ALT-1)
Cooling method	CRAH unit supplying air under a raised floor	FWU supplying air through the walls
Floor structure	Raised floor with 800mm height	Standard slab floor
Airflow pattern	Air supplied through floor grilles	Air supplied through wall-mounted FWU
Containment	Hot aisle containment	Hot aisle Containment
Air return	RA recovery through false ceiling	RA recovery through false ceiling

The study focuses on an IT Hall comprising 339 racks with a total IT load of 2983.2 kW (8.8 kW × 339EA). The comparison is based on key factors such as airflow distribution, temperature uniformity, and cooling performance. The CFD Solver is k-Epsilon turbulence model.

As shown in Figure 1, raised floor and slab floor cooling strategies differ primarily in air supply methodology. The raised floor system uses CRAH units to supply air under an 800 mm high raised floor, distributing it through floor grilles into the white space. In contrast, the slab floor system employs FWUs to supply conditioned air directly through the walls, eliminating the need for raised floors. Both methods implement hot aisle containment and return air collection through false ceilings. The comparison of these two methods is summarized in Table 1.

To ensure accuracy, an unstructured Cartesian grid was used, with ALT-1 containing 5,671,331 cells and ALT-2 containing 8,280,376 cells. The grid size ranged from a maximum of 250mm to a minimum of 25mm. Boundary conditions included an inlet supply air temperature of 16°C to 24°C, a pressure-based outlet discharge condition, and adiabatic walls. The key evaluation metrics were temperature distribution, airflow patterns, and cooling performance, focusing on IT equipment inlet temperature stability within ASHRAE's recommended range.

3. NUMERICAL RESULTS

This section analyzes the simulation results of the cooling strategies for ALT-1 (FWU-based slab floor) and ALT-2 (CRAH-based raised floor), focusing on airflow distribution, temperature compliance, and cooling performance. Key evaluation metrics include ASHRAE temperature compliance, rack mean inlet temperature, airflow distribution, and cooling capacity (Figure 2).

3.1 ASHRAE Temperature Compliance

Compliance with ASHRAE's recommended temperature range (18–27°C) was evaluated for each SAT (Supply Air Temperature) condition (16–24°C). ALT-1 consistently maintained rack inlet temperatures within the recommended range across all SAT conditions, with minimal temperature variation. This highlights the effectiveness of the FWU system in delivering uniform airflow. In contrast, ALT-2 exhibited increased inlet temperatures in racks located farther from the CRAH units, indicating uneven airflow distribution in the raised floor configuration.

3.2 Rack Mean Max Inlet Temperature

The analysis of rack mean inlet temperatures for each SAT condition showed that ALT-1 maintained a consistent temperature range across all racks, demonstrating uniform airflow. ALT-2 exhibited greater temperature variation due to uneven airflow distribution within the raised floor plenum, particularly in racks located farther from the CRAH units (Table 2).

3.3 Airflow Distribution

ALT-1's FWU-based approach effectively separated the cold and hot aisles, minimizing re-circulation while delivering uniform airflow. ALT-2, on the other hand, exhibited uneven velocity distribution in the raised floor plenum, leading to non-uniform air delivery through floor grilles. This was identified as a primary cause of increased temperatures in racks farther from the CRAH units.

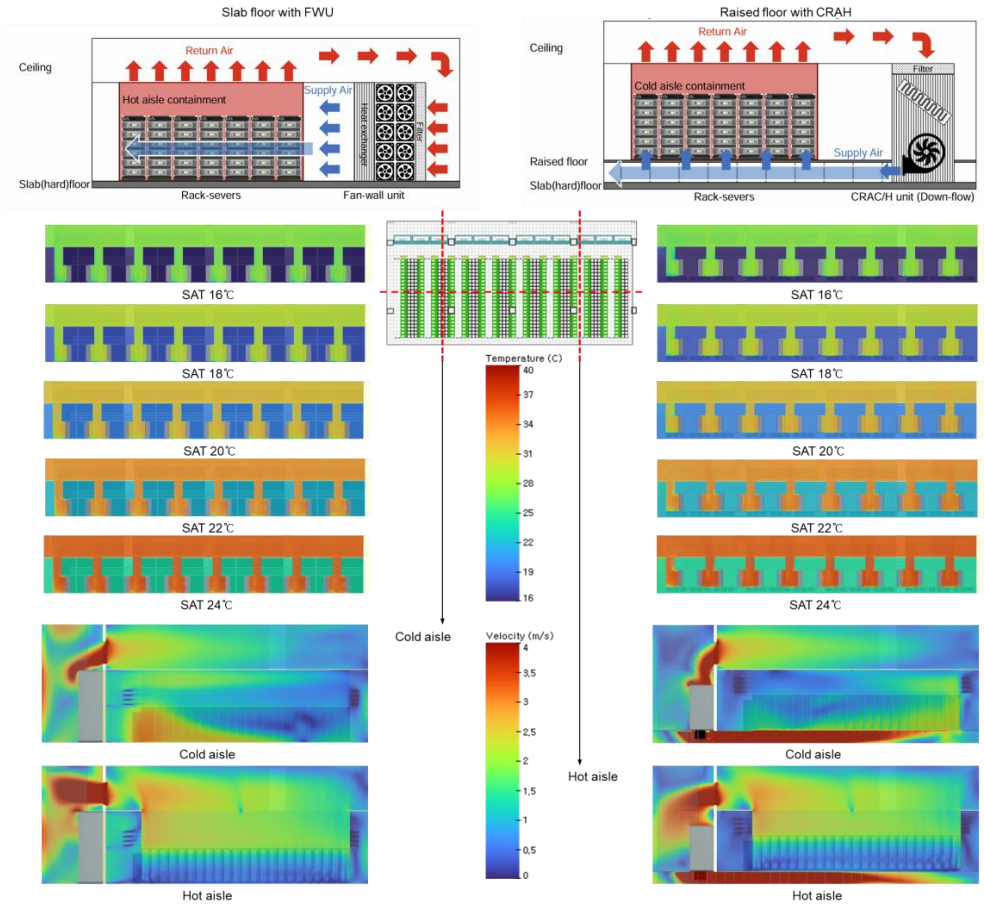

Figure 2. CFD results: ALT-1 vs. ALT-2 temperature and airflow distribution.

Table 2. Mean maximum inlet temperatures for ALT-1 and ALT-2 at different SATs.

SAT (°C)	ALT-1 mean max inlet temp (°C)	ALT-2 mean max inlet temp (°C)
16	16.07985 (+0.50%)	16.18428 (+1.15%)
18	18.07985 (+0.44%)	18.18448 (+1.02%)
20	20.07988 (+0.40%)	20.18469 (+0.92%)
22	22.07988 (+0.36%)	22.18475 (+0.84%)
24	24.07982 (+0.33%)	24.18478 (+0.77%)

3.4 Temperature Distribution by Rack Height

Temperature was measured at three rack height levels: base (0.1m), middle (1.0m), and top (1.8m). ALT-1 maintained consistent temperature profiles across all heights, with minimal variation between racks. In contrast, ALT-2 showed greater temperature differences at the base level due to uneven airflow, although the middle and top levels exhibited improved uniformity.

3.5 Cooling Capacity Analysis

Under identical load conditions, the net cooling power of ALT-1 and ALT-2 was similar on average. However, ALT-2 exhibited greater variation in cooling capacity among units due to differences in airflow distribution. ALT-1 maintained smaller capacity variations thanks to the uniform air distribution achieved by the FWU system (Table 3).

Table 3. Net cooling power comparison between ALT-1 and ALT-2.

Cooling metric	ALT-1	ALT-2
Net cooling power	248.68 kW	248.65 kW
Standard deviation	±2.12%	±4.15%

4. DISCUSSION

This study compared the performance of ALT-1 (Fan Wall Unit-based Slab Floor) and ALT-2 (CRAH-based Raised Floor) in data centers. CFD simulations revealed that ALT-1 maintained uniform airflow and stable temperature distribution, consistently meeting ASHRAE's recommended temperature range. While ALT-2 showed similar average cooling performance, it exhibited greater variability, leading to localized inefficiencies. Thus, the FWU-based slab floor configuration proves to be a more reliable and energy-efficient solution for high-density data centers.

ABSTRACT

This study explores the potential of Phase Change Materials (PCMs) in improving both thermal comfort and energy efficiency in buildings. Nine PCM configurations (S1-S9), varied by melting temperature, thickness, and location (wall, roof, floor), were evaluated using EnergyPlus simulations. Thermal comfort was assessed with the Predicted Mean Vote (PMV) and Percentage of People Dissatisfied (PPD) indices, following ASHRAE Standard 55. The PCM melting temperatures were 18°C, 21°C, and 23°C, representing variations in their thermal behavior under different seasonal conditions. The results of the simulations showed that the integration of PCM in the building envelope reduced energy demand while maintaining thermal comfort. The floor configurations (S3, S5, S7) demonstrated the lowest heating energy demand while achieving acceptable comfort levels. These findings suggest that strategic placement of PCMs in building floors is an effective solution for optimizing energy consumption without compromising occupant comfort. .

Keywords: Phase change materials, whole building simulation, thermal comfort assessment,

1. INTRODUCTION

Building energy efficiency has become a central focus in addressing global energy consumption and reducing greenhouse gas emissions. Buildings account for a significant portion of global energy use, primarily due to the demand for heating and cooling to maintain indoor comfort. According to the International Energy Agency (IEA), buildings contribute to nearly one-third of global energy use and carbon emissions, emphasizing the urgent need for sustainable solutions in buildings (Agency, 2020). The integration of innovative materials, such as Phase Change Materials (PCMs), offers promising solutions to improve thermal performance and reduce energy consumption in buildings. PCMs are materials that absorb or release heat during phase transitions, making them particularly useful in regulating indoor temperatures by storing excess heat during peak periods and releasing it during temperature drops (Sharma et al., 2009).

Thermal comfort in buildings is a crucial factor for occupant well-being and energy efficiency. The design and operation of buildings must balance these two aspects, ensuring that thermal conditions fall within acceptable limits for occupants while minimizing energy demand. Standards such as ASHRAE Standard 55 provide a framework for assessing indoor environmental quality, using indices like the Predicted Mean Vote (PMV) and Percentage of People Dissatisfied (PPD) to quantify comfort levels (ASHRAE, 2017).

In recent years, PCM integration has gained attention as a viable solution to address both energy demand and thermal comfort. Strategically incorporating PCMs in building envelopes (walls, roofs, and floors), has shown great possibilities in shifting the thermal response of the building, reducing the need for mechanical heating and cooling systems. Previous studies have investigated PCM performance under different climate conditions, highlighting the potential of the material to reduce energy consumption during peak cooling and heating periods (Cabeza et al., 2010; Kalogirou, 2009). However, the application of PCMs in buildings remains complex, as the performance is highly dependent on several factors, including the PCM's melting temperature, thickness, and placement within the building structure (Zhang and Liu, 2015).

Thermal comfort in buildings is also influenced by the dynamic interaction between building design, indoor climate, and external environmental factors. While PCM integration has been studied for its energy-saving potential, its effect on indoor comfort remains an area of active research, with results varying based on building type and local climate conditions (Yang et al., 2016). Understanding how to optimize PCM configuration in buildings is critical to maximize both energy savings and occupant satisfaction.

While previous studies have primarily focused on PCM energy-saving potential, this study uniquely examines multiple PCM variables and their effect on both thermal comfort and energy demand. This study employs a Taguchi L9 orthogonal array to systematically evaluate nine configurations combining three melting temperatures (18°C, 21°C, and 23°C), thicknesses (0.06m, 0.04m, and 0.02m), and locations (wall, roof, and floor). We further assessed both thermal comfort, using the ASHARAE-55 standard and energy demand pattern, providing insights on optimal configuration for PCM integration in buildings.

2. METHOD

This section provides an overview of the simulation setup used to evaluate the impact of various PCM configurations on energy consumption and thermal comfort in buildings. The building was designed in DesingBuilder with simulations run on Energyplus Engine to evaluate the building's thermal performance with different PCM con- figurations. The results of these simulations were then fed into a thermal comfort tool to assess the thermal comfort levels for the various configurations. Figure 1 below summarizes our work process, the key simulation parameters, and the tools used in the study.

2.1. Simulation Setup

The simulation process involved using DesignBuilder and EnergyPlus to model the energy performance of the building. These tools provided the platform for simulating the building and evaluating the effects of different PCM configurations on thermal behavior and energy demand. Simulations were conducted for a full year (January 1 to December 31) 2002, using EnergyPlus weather data of Eindhoven's climate sourced from the EnergyPlus database for accurate representation of local conditions.

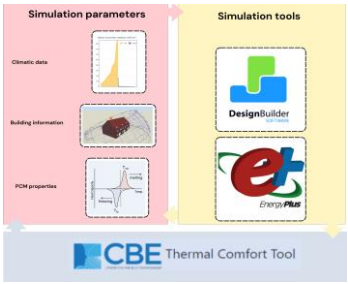

Figure 1. Simulation study.

2.1.1. Simulation tool

EnergyPlus has proven to be particularly effective for modeling buildings with PCMs, as it enables precise calibration and validation of PCM models. The tool allows for detailed simulations of PCM's ability to absorb and release heat, using a one-dimensional conduction finite difference (CondFD) algorithm that accounts for the thermal transfer and storage processes of PCMs (see equation 1). This capability is critical for evaluating the energy-saving potential of PCMs, as the software can dynamically update temperature-dependent properties, such as specific heat, based on phase change energy. These features make EnergyPlus an invaluable tool for simulating PCM integration in buildings. (Feng et al., 2022; Tabares-Velasco et al., 2012).

$$c_p \rho \Delta x \frac{T_i^{j+1} - T_i^j}{\Delta t} = \frac{1}{2}\left(k_W \frac{T_{i+1}^{j+1} - T_i^{j+1}}{\Delta x} + k_E \frac{T_{i-1}^{j+1} - T_i^{j+1}}{\Delta x} + k_W \frac{T_{i+1}^{j} - T_i^{j}}{\Delta x} + k_E \frac{T_{i-1}^{j} - T_i^{j}}{\Delta x}\right) \quad (1)$$

Where:

T = node temperature, Δx = calculation time step, Δx = finite difference layer thickness, C_p = specific heat of material, k_W = thermal conductivity for interface between node i and node $i+1$, k_E = thermal conductivity for interface between node i and node $i-1$, ρ = density of material.

with superscripts and subscripts: i = node being modeled, $i+1$ = adjacent node to the interior of the construction, $i-1$ = adjacent node to the exterior of construction, $j+1$ = new time step, i = previous time step.

2.1.2. Building Model

To evaluate the impact of various PCM configurations on the building, a detailed residential building model was developed using DesignBuilder software (see Fig. 2). The study specifically focuses on terrace buildings constructed between 1940 and 1980, which represent a significant portion of

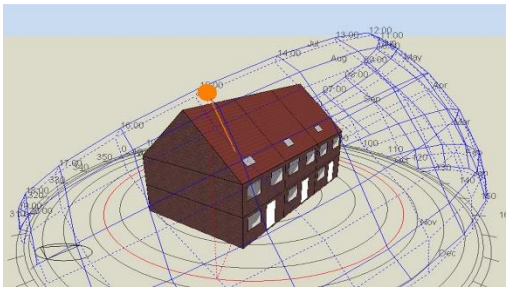

Figure 2. Building model.

the building stock in Eindhoven. The building dimensions, material properties, and other relevant details are based on standardized references (Ondernemend Nederland (RVO), 2017). These properties were used to simulate the thermal behavior of the building and assess the performance of PCM integration in the envelope. The Infinte PCM used for the simulation was sourced from Insolcorp LLC, 2023 with different melting temperatures as described in Section 1.

2.1.3. PCM Configurations

Nine PCM configurations (S1-S9) were designed using a Taguchi L9 orthogonal array, a standardized experimental design method that efficiently evaluates multiple factors and their interactions with a minimal number of runs (Liu et al, 2019). Three factors were considered: melting temperature (18°C, 21°C, 23°C), PCM thickness (0.02m, 0.04m, 0.06m), and location (wall, roof, floor), each at three levels. The matrix of variables (σ) shown in eqn (2), was used to generate the Taguchi L9 array in Table 1. Taguchi systematically combines these factors to assess their combined and relative effects on thermal comfort and energy demand.

$$\sigma = \begin{bmatrix} T_1 & T_2 & T_3 \\ x_1 & x_2 & x_3 \\ c_1 & c_2 & c_3 \end{bmatrix} \qquad (2)$$

where T_1 is the melting temperature =18°C, which is T_2 is the melting temperature =21°C, and T_3 is the melting temperature of =23°C.

while x_1 = 0.06, x_2 = 0.04, x_3 = 0.02. and c_1, c_2 and c_3, corresponds to wall roof and floor respectively. Each configuration was integrated into the EnergyPlus model, allowing the simulation of the building's thermal response to different PCM configurations across a full year.

2.2. Thermal Comfort Assessment

According to ANSI/AHSRAE Standard 55, thermal comfort is defined as the mental state reflecting an individual's satisfaction with the thermal environment, typically assessed through subjective evaluation (Kim et al., 2019). Since thermal comfort varies by individual, creating a universally satisfying thermal environment is challenging. What is comfortable for one group may be uncomfortable for another (Su et al., 2024). Thermal comfort was assessed using the PMV and PPD indices, as outlined in ASHRAE Standard 55. The PMV ranges from -3 (cold) to +3 (hot), with a neutral comfort value of 0. However, ASHRAE 55 makes it clear that it considers the acceptable comfort range to be a PMV score in the range of -0.5 to +0.5. The PPD index estimates dissatisfaction, with values under 10% deemed acceptable for comfort. EnergyPlus simulations provided hourly data, which was used to calculate PMV and PPD, considering factors like air temperature, mean radiant temperature, air velocity, relative humidity, clothing insulation and metabolic rate. The CBE Thermal Comfort Tool was employed to calculate these indices, essential for evaluating occupant satisfaction with indoor conditions (Tartarini et al., 2020).

2.3. Assumptions

For this simulation, we modeled a residential building with gas heating, mechanical ventilation, and natural ventilation for winter heating and summer cooling. Metabolic rates were set at 1.0 for men, 0.85 for women, and 0.75 for children and a clo of 0.5 (Ioannou and Itard, 2015; Ioannou, Itard, and Agarwal, 2018). The heating system is activated when the room temperature drops below 18°C, and cooling begins at 25°C, with a setback temperature of 30°C. The building uses both gas heating and mechanical ventilation, complemented by natural convection. It was also assumed that the building had four occupants: two adults and two teenagers.

3. RESULTS

In this section, we present the results of the thermal comfort assessment and heating energy demand for the different PCM integration configurations in the building. The simulations were conducted with various configurations, each characterized by distinct melting temperatures, PCM thicknesses, and locations within the building. These configurations were evaluated to assess their effectiveness in improving thermal comfort and reducing heating energy demand. Table 1 below summarizes the different simulation runs, providing a detailed overview of the configurations tested.

Table 1. Summary of building simulation runs.

Simulation run	Temperature (T)	Thickness	Configuration (c)
S1	T_1	x_1	c_1
S2	T_1	x_2	c_2
S3	T_1	x_3	c_3
S4	T_2	x_1	c_2
S5	T_2	x_2	c_3
S6	T_2	x_3	c_1
S7	T_3	x_1	c_3
S8	T_3	x_2	c_1
S9	T_3	x_3	c_2

The simulation runs can be categorized into three groups based on the PCM location within the building: wall configurations (S1, S6, S8), roof configurations (S2, S4, S9), and floor configurations (S3, S5, S7). Each category represents distinct placements of PCM in the building's envelope, and the performance results for each category will be discussed in the subsequent subsections.

3.1. Wall Configuration

The thermal comfort assessment for the wall configurations (S1, S6, and S8) shows that all configurations comply with the ASHRAE 55-2023 standard as shown in Fig. 3. The Predicted Mean Vote (PMV) values for the three configurations are -0.28, -0.09, and 0.25, respectively, all indicating a neutral thermal sensation. Similarly, the Percentage of People Dissatisfied (PPD) values for the wall configurations are within the acceptable range of 5-7%, with S1 showing the highest PPD at 7%. The Set Effective Temperature (SET) for each configuration varies slightly, with S1 having a

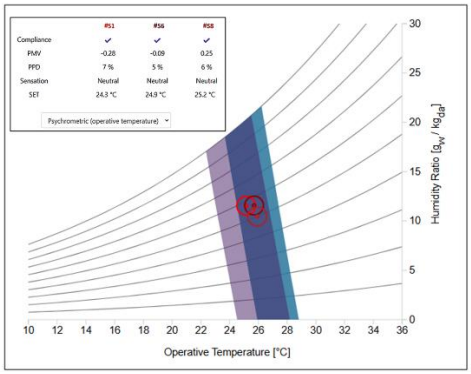

Figure 3. Thermal comfort assessment for wall configurations

SET of 24.3°C, S6 at 24.9°C, and S8 at 25.2°C, all remaining within the range of comfort. These results suggest that the wall configurations, despite differences in PCM mass and location, provide a neutral thermal environment for occupants, aligning well with ASHRAE 55 standards.

3.2. Roof Configuration

The thermal comfort assessment for the roof configurations (S2, S4, and S9) shows varying levels of compliance with ASHRAE 55-2023 standards shown in Fig. 4. S2 complies with the standard, showing a PMV of 0.28, PPD of 7%, and a neutral sensation. The SET is 26.0°C, indicating

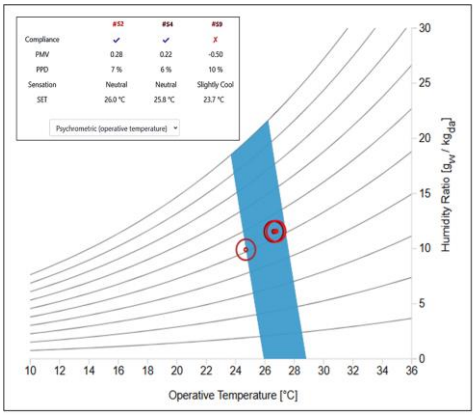

Figure 4. Thermal comfort assessment for roof configurations

a comfortable thermal environment for occupants. Similarly, S4 also complies with ASHRAE 55, with a PMV of 0.22, PPD of 6%, and a neutral sensation. The SET for S4 is 25.8°C, indicating a comfortable indoor temperature. However, S9 does not fully comply with the standard, as it shows a PMV of -0.50 and PPD of 10%, indicating a slightly cool sensation and a higher level of dissatisfaction. The SET for S9 is 23.7°C, which is below the ideal comfort range.

3.3. Floor Configuration

The thermal comfort assessment for the floor configurations (S3, S5, and S7) presented in Fig. 5 shows that all configurations comply with ASHRAE 55-2023 standards. S3 shows a PMV of 0.36, PPD of 8%, and a neutral sensation with a SET of 26.2°C. S5 shows a PMV of -0.17, PPD of 6%, and a neutral sensation, with a SET of 24.7°C. Similarly, S7 also complies with the standard, with a PMV of 0.05, PPD of 5%, and a neutral sensation. The SET for S7 is 25.3°C.

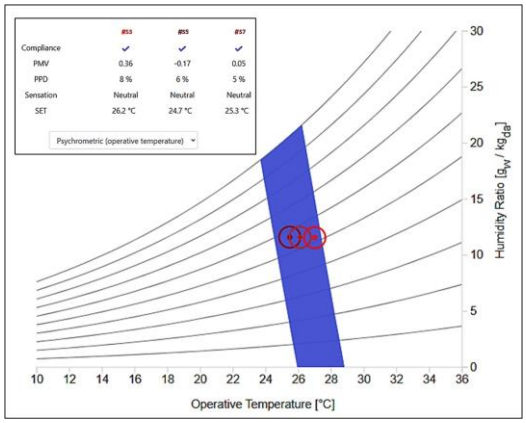

Figure 5. Thermal comfort assessment for floor configurations.

3.4. Heating Energy Demand Across Simulation Runs

Figure 6 presents the mean heating energy demand across the different simulation runs, with each configuration representing different placements of PCM in the building. This plot is critical in illustrating the energy trade-offs associated with maintaining thermal comfort. As the results show, although some configurations met the ASHRAE 55-2023 thermal comfort standards, they were more energy-efficient than others.

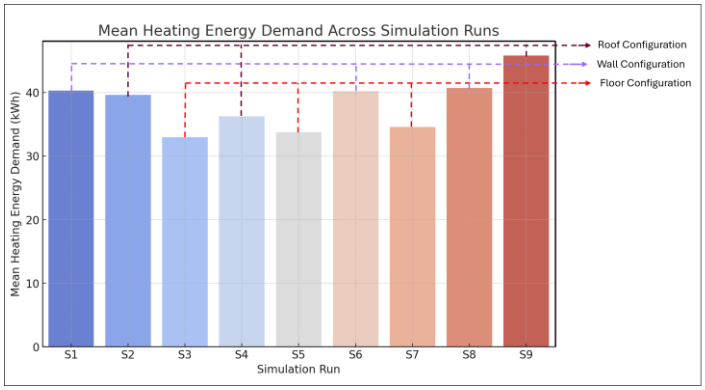

Figure 6. Heating energy demand across simulation runs for different PCM configurations.

For example, while configurations such as S1, S6 and S8 complied with thermal comfort standards, their heating energy demands were relatively high compared to others. Also evident from the result is that S9 does not meet the thermal comfort standards; this is because it has the least PCM density, is located on the roof, and has the highest energy demand, indicating that this configuration is the least suitable for the building with a net heat loss to the ambient. The graph also shows that the floor configurations maintained thermal comfort with lower energy demand, providing information on the energy-efficient benefits of strategic PCM integration.

4. DISCUSSION

PCM integration offers energy and comfort benefits but faces challenges like high initial costs, especially for retrofits, degradation over time, and maintenance needs, potentially limiting adoption. The Taguchi L9 design reveals that lower melting temperatures (e.g., 18°C in S3) enhance thermal storage, improving PMV (0.36) and reducing energy demand, while thicker layers (0.06m in S3, S7) and floor placement minimize heat loss, explaining why floor configurations outperform roof (e.g., S9: 0.02m, 23°C, highest demand) and wall setups. However, further research is needed on wall orientation and PCM-to-surface ratio effects. Statistical methods like ANOVA can isolate individual parameter effects for sensitivity analysis.

5. CONCLUSION

This study shows that PCM configurations significantly impact thermal comfort and heating energy demand, with floor configurations (S3, S5, S7) achieving the lowest energy demand while maintaining ASHRAE 55-2023-compliant comfort. S3 (18°C, 0.06m) performed best, due to minimal ambient heat loss, enhanced thermal storage from lower melting temperatures, and better heat retention with thicker layers. These findings highlight floor PCM integration as an efficient solution for reducing energy consumption without compromising comfort. Future research should explore wall orientation effects and use statistical methods like ANOVA to isolate parameter impacts.

Interface characteristics of PVDF membrane used for dehumidification by liquid desiccant

Tingting Chen [1], Zhimin Chang [1], Yang Li[2]

[1]*China University of Mining and Technology, Xuzhou, China, chenttmail@cumt.edu.cn*
[2]*Suzhou Zhonghuiyun Engineering Technology Limited Company, Suzhou, China, 1312837151@qq.com*

SUMMARY
Polyvinylidene fluoride (PVDF) membrane is used to separate the liquid desiccant and air for avoiding corrosion during dehumidification. The contact angle of the liquid droplet on the PVDF membrane was simulated by taking lithium bromide (LiBr) aqueous solution as the liquid desiccant. Interface characteristics of liquid-PVDF-gas systems were simulated using molecular dynamics. Interface thickness and hydrogen bond distribution of liquid-PVDF-gas systems were further analyzed and compared. Results show that the cube droplet on the PVDF membrane firstly transforms into a spherical shape rapidly and then spreads along the PVDF surface slowly. The simulated contact angle of LiBr solution on the PVDF membrane is about 93° when the concentration is 50%. It is found that the thickness of the interface between the LiBr solution and PVDF membrane is much larger than that of the interface between the LiBr solution and air especially for conditions with high solution concentration. Hydrogen bonds are formed between PVDF and water in the interface zone and PVDF tends to be the acceptor.

Keywords: dehumidification, contact angle, interface thickness, hydrogen bonds.

1. GENERAL INSTRUCTIONS

Liquid desiccant dehumidification has attracted much attention to realize thermal comfort with low energy consumption in the past decades (Yin et al., 2014; Gurubalan et al., 2021). However, the application of the liquid desiccant dehumidification is limited in some situations due to the corrosion which occurs inevitably when the liquid desiccant absorbs water in air by direct contact.

Membrane based dehumidification using liquid desiccant is proposed to solve aforementioned problems by applying membranes to separate the liquid desiccant and air (Liu et al., 2019). But the use of membranes increases mass transfer resistance simultaneously. PVDF (polyvinylidene fluoride) is a commonly used membrane material but usually suffers from problems of fouling and solution leakage. All drawbacks depend on the interface characteristics between phases to some degree regardless of mass transfer, fouling or solution leakage. Promoting membrane performance plays an important role in enhancing dehumidification, bringing about the energy conservation and emission reduction. Investigation from the microscopic level helps develop and propose superior membrane because some crucial details cannot be achieved from the macroscopic level. With the rapid development of computers, molecular simulation has been widely used to study gas-liquid interface characteristics and reveal the microscopic mechanism of chemical processes (Nagata et al., 2015; Weng et al., 2016). Björneholm et al. discussed the density profile and h-bond distribution of the gas-liquid interface for pure water (Björneholm et al., 2016). The mixed matrix membrane using PVDF as the matrix was investigated by molecular dynamics simulation. It was verified that the addition of zwitterion and TiO_2 improved the hydrophilicity and oil resistance of

the membrane (Bui et al., 2021). Relevant researchers also used molecular dynamics and Monte Carlo simulation to obtain the density, free volume fraction, diffusion, permeability and selectivity of PVA-PVDF membranes (Liu et al., 2022).

Membrane based dehumidification using liquid desiccant is related with the mass transport through the gas-solid interface, the membrane and the liquid-solid interface. Studying the interface and interactions of the liquid-PVDF-gas system at the microscopic level is beneficial for developing novel membrane materials and enhancing dehumidification process essentially. The contact angle has obvious effects on dehumidification and fouling (Wen et al., 2018) and hydrogen bonds are often non-negligible as to interactions. So in this paper, the interface characteristics of liquid-membrane-gas systems were analyzed by molecular dynamics simulation. The lithium bromide (LiBr) aqueous solution was taken as the liquid desiccant and PVDF was taken as the membrane to separate the liquid desiccant and air here. The contact angle of LiBr solution on the PVDF membrane was simulated and calculated. The distributions of density and hydrogen bonds for liquid-PVDF-air systems were also obtained. Liquid-gas interfaces and liquid-solid interfaces were further compared. This study sets foundation for further disclosing the mechanism of membrane based dehumidification by molecular dynamics.

2. METHOD

All simulations were performed based on GROMACS 5.1.1 software and periodic conditions were applied in three directions. SPC/E water model was used and OPLS-AA force field was adopted for PVDF considering precision and compatibility. Parameters of force fields for ions were listed in Table 1, which were validated with good performance in our previous work (Chen et al., 2019). All atoms or ions were considered as Lennard-Jones (LJ) particles with charges. The intermolecular potentials were the summation of LJ potentials and Coulombic potentials. LJ interactions between different kinds of atoms were produced by Lorentz-Berthelot combining rules. The cutoff distance was set as 1.2 nm for Lennard-Jones potential and short-range electrostatic interactions. Potentials switched smoothly to 0 between 1.0 nm and 1.2 nm and PME solver was applied to calculate long-range electrostatic interactions. Water molecules were constrained by SETTLE algorithm and all bonds of PVDF were constrained by LINCS algorithm. Center of mass translation was removed every 500 time steps. Newtonian equations of motion were solved by the leap-frog algorithm with the timestep of 1 fs.

Table 1. Parameters of force fields for ions

Ions	ε (kJ/mol)	σ (Å)	q (e)
Li^+	0.6904	1.505	1
Br^-	0.4184	4.539	-1

2.1. Simulation of Contact Angle

The simulation system for computing contact angle is shown in Fig. 1. The simulation box was 10 nm in length, 10 nm in width and 12 nm in height. As shown in Fig. 1, the simulated system mainly consisted of three parts including the fixed layer on the bottom, the PVDF layer in the middle and the square droplet of LiBr aqueous solution. Before constructing the system, an annealing simulation of 6 ns was conducted for the PVDF layer with the temperature between 300 K and 500 K. The size of the droplet was 4 nm in all directions and the initial density was set corresponding to one atmosphere. The system was run in the NVT ensemble for 20 ns with the output interval of

2 ps after energy minimization. 2D number-density maps were derived from GROMACS when reaching equilibrium. The density contour was further fitted by equation of a circle and the contact angle was calculated finally (Kitabata et al., 2018).

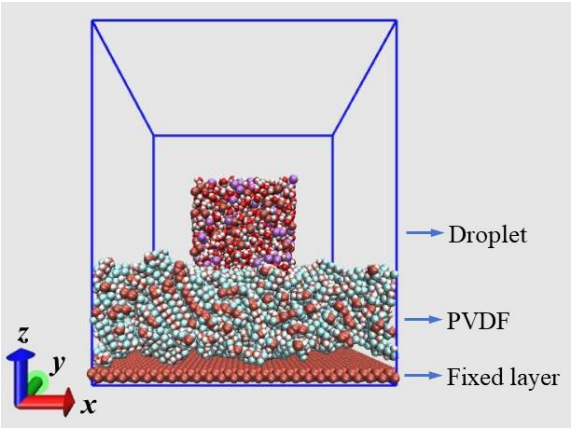

Figure 1. System for simulating contact angle

2.2. Simulation of Density Profiles and Interface Thickness

Fig. 2 illustrates the liquid-PVDF-air system using LiBr solution as the liquid desiccant. The simulation box was 5 nm in width, 5 nm in length and 15 nm in height. PVDF was formed by 19 single chains with the polymerization degree of 50. Solid-liquid interface and liquid-gas were produced simultaneously due to periodic conditions. LiBr aqueous solution had 2000 water molecules and corresponding ions according to the concentration. Air is represented by empty zone for simplification. All initial configurations were provided by Packmol software. After an equilibration run of 1000 ps under NVT ensemble of 300 K, thermodynamics data and trajectories of atoms were output every picosecond during the production run of 500 ps.

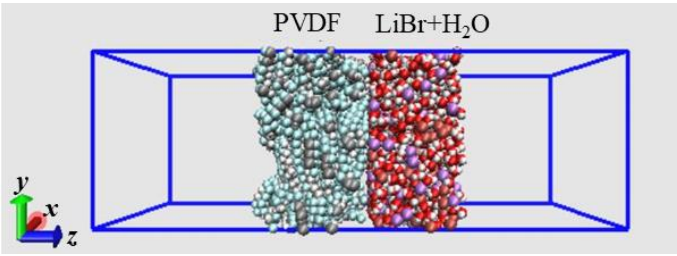

Figure 2. Liquid-PVDF-gas systems

The simulation system was divided into slices with the thickness of 0.1 nm along *z* direction and the density for every slice could be computed using the built-in programs of GROMACS software. The interface thickness could be achieved after correlating the density profiles using hyperbolic tangent functions.

2.3. Analysis of Hydrogen Bond

The number of hydrogen bonds were analyzed based on VMD software and Python codes. Trajectories from GROMACS were input in VMD software and data of hydrogen bonds were output. The distance between acceptors and donors was set as 0.35 nm. The number of hydrogen

bonds for every slice was half of the summation of the donor number and the acceptor number. The final result adopted the average value of the production run.

3. RESULTS AND DISCUSSION

3.1. Contact Angle of LiBr Solution on PVDF membrane

The concentration of the LiBr aqueous solution was 50% here and the contact angle of the aforementioned solution on the PVDF membrane was simulated. Fig. 3 gives the root mean square deviation (RMSD) by comparing two structures at different times. This indicates that at least 12 ns is needed for system equilibration and the followed data is used to calculate the contact angle accurately.

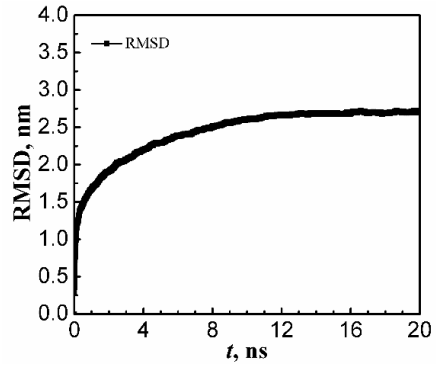

Figure 3. RMSD of simulation

Fig. 4 illustrates the droplet change as the simulation goes on. It seems that the droplet change can be divided into two periods. The droplet changes from the cube shape to the spherical shape rapidly due to the effects of interactions during the first period. The contact area between the droplet and the PVDF membrane as well as the height of the droplet almost keeps unchanged. Compared with the first period before 500 ps, the second period proceeds more slowly. The droplet of LiBr solution spreads along the PVDF surface during the second period. The contact area between the droplet and the PVDF membrane increases gradually and the height of the droplet decreases till equilibration.

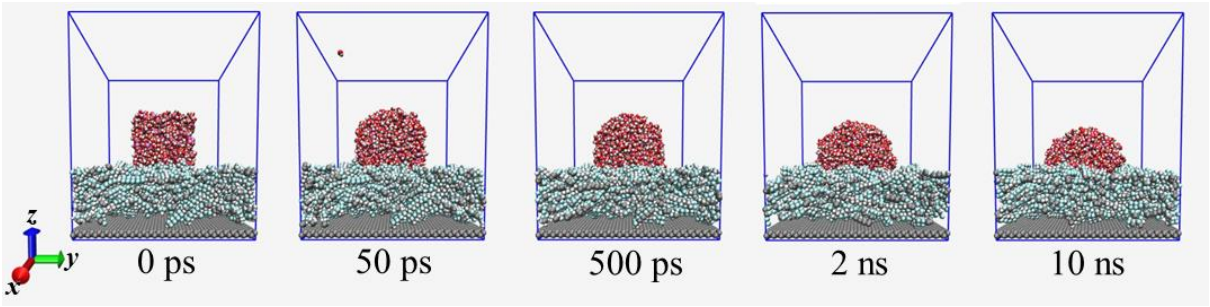

Figure 4. Droplet variation with time

The number density map of *yz* plane is shown in Fig. 5. Fig. 5(a) presents different density contours.

The data set in Fig .5(a) with the density of 5 nm^{-2} is extracted and is further fitted using the equation of a circle. The contact angle can be calculated according to the circle parameters and the position of the liquid-solid interface. The final result is the average value of *yz* plane and *xz* plane. The contact angle of the LiBr solution on the PVDF membrane is about 93^o by simulation calculation here, which agrees well with the experimental results. This means the molecular dynamics and the used force field could investigate phenomena involving liquid-PVDF-gas systems with satisfied accuracy. Further, molecular dynamics can be relied on to verify whether the novel membranes can enhance dehumidification and anti-fouling or not.

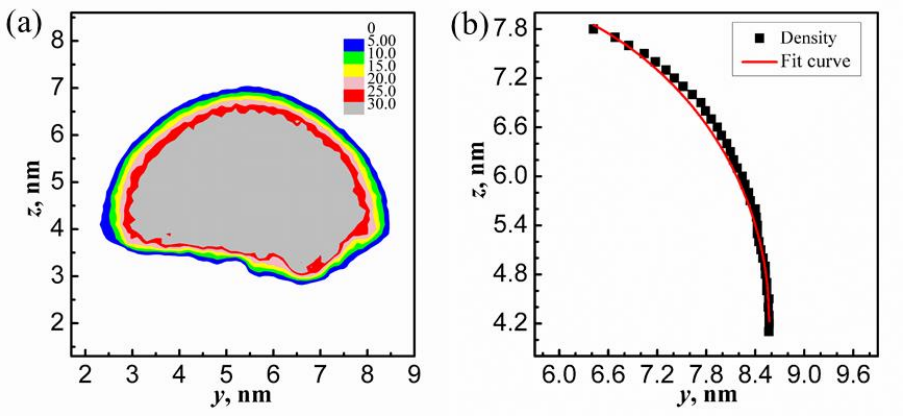

Figure 5. Density map: (a) 2D density contour; (b) circle fitting

3.2. Density Profiles and Interface Thickness of Liquid-membrane-gas Systems

The mass density profile of liquid-PVDF-air system for pure water is shown in Fig. 6. Two different interfaces can be seen from Fig. 6(a) where the left shadow area is the solid-liquid interface and the right shadow area is the liquid-gas interface. The PVDF density reduces from 1555 kg/m^3 to 0 along the interface normal direction in the zone of the solid-liquid interface. The water density rises from nearly 0 to 993 kg/m^3 in the zone of the solid-liquid interface while drops from nearly 993 kg/m^3 to 0 in the zone of the liquid-gas interface. The thickness of interfaces is calculated by fitting density profiles of water (Fig. 6(b)). The thickness of PVDF-water interface is about 0.455 nm. The thickness of water-air interface is about 0.392 nm, reduced by 16% compared with the PVDF-water interface.

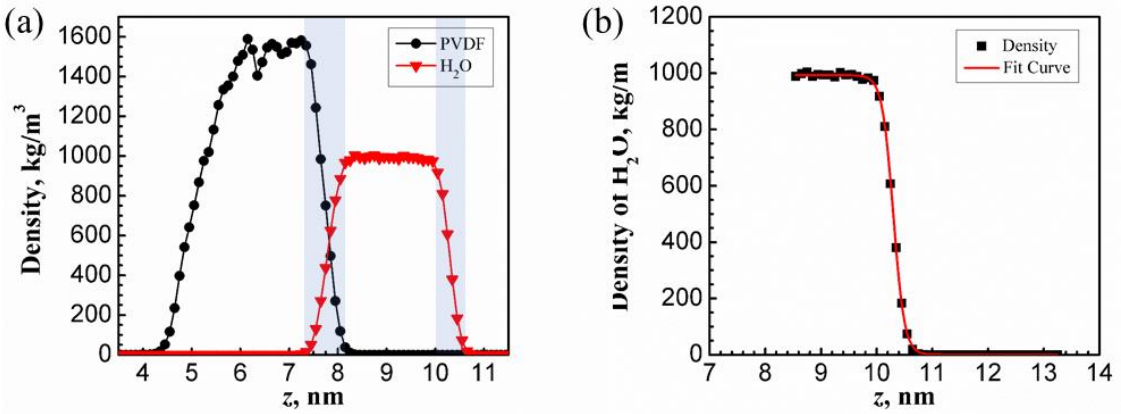

Figure 6. Density profiles of water-PVDF-air system: (a) mass density; (b) hyperbolic tangent fitting

Density profiles of liquid-PVDF-air system for LiBr aqueous solution are shown in Fig. 7. With an increase in concentration, the water density decreases while the ion density increases (Fig. 7(a) and Fig. 7(b)). Compared with the system using pure water, the density profile of LiBr aqueous solution fluctuates more significantly because of the ion accumulation position.

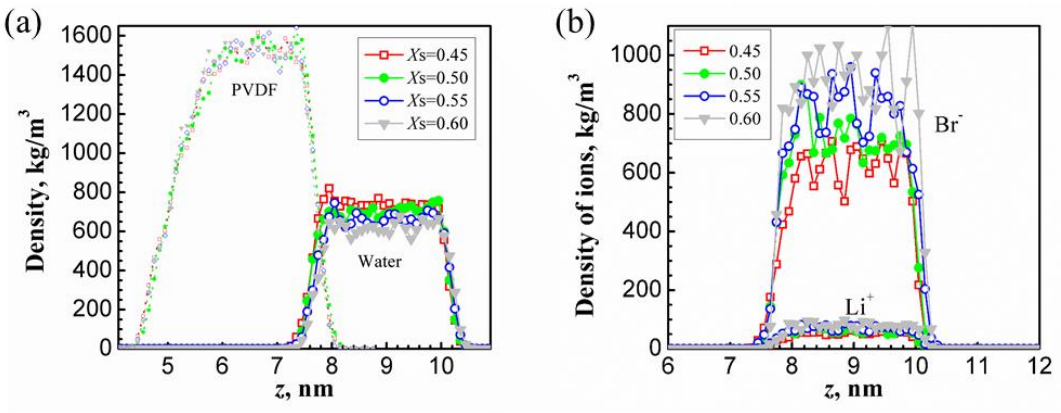

Figure 7. Density profiles of solution-PVDF-air systems: (a) PVDF and water; (b) ions

The thickness comparison between the liquid-solid interface and liquid-gas interface using LiBr aqueous solution is shown in Fig. 8. The thickness of the liquid-air interface declines from 0.345 nm to 0.260 nm with an increase in the concentration of LiBr solution. The stronger interactions from the liquid phase can account for the shrink of interface. But for the thickness of the solid-liquid interface, it seems a minimum value of 0.382 nm emerges with the solution concentration of 50%. This may be because different interactions predominate within different concentration ranges.

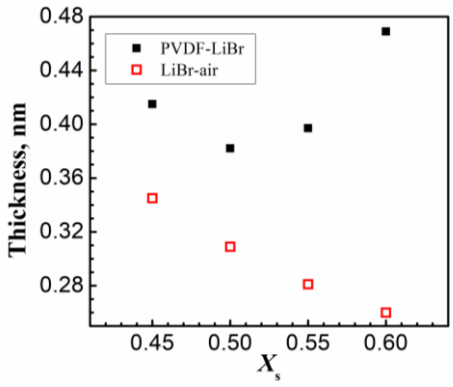

Figure 8. Thickness of liquid-solid interface and liquid-gas interface

As a result, the thickness of liquid-solid interface is much higher than that of liquid-air interface especially for LiBr solution with the concentration larger than 50%. The extension of liquid-PVDF interface may be attributed to larger interactions from PVDF than gas. When the concentration of LiBr solution is 55% and 60%, the PVDF-liquid interface is 41% and 80% thicker than the liquid-air interface respectively. This implies that using PVDF to separate air and LiBr solution produces higher resistance for transport prominently even without considering membrane resistance. This is

because the membrane based dehumidification is related with the solid-liquid interface while the conventional liquid desiccant dehumidification is related with the liquid-air interface. Develop novel membrane materials for dehumidification could resort to reducing the thickness of solid-liquid interface.

3.3. Hydrogen Bond of Liquid-membrane-gas Systems

Fig. 9 describes the distribution of hydrogen bonds for liquid-PVDF-air systems. Fig. 9(a) is the system adopted pure water of 300 K and Fig. 9(b) is the system adopted LiBr aqueous solution with the concentration of 60%. As depicted in Fig. 9(a), the hydrogen bonds in the zone of PVDF-water interface consist of three parts. Hydrogen bonds can be formed between PVDF and PVDF, between PVDF and water, and between water and water respectively. Hydrogen bonds formed between PVDF and water can also include two types in terms of water as the acceptor or donor. In the zone of PVDF-water interface, the number of hydrogen bonds formed between PVDF and PVDF becomes less and less along *z* direction. The number of hydrogen bonds formed between water and water increases sharply. This is consistent with the density distribution of each component in the interface zone. Moreover, almost all hydrogen bonds formed between PVDF and water are types of water as the donor and PVDF as the acceptor. The number of hydrogen bonds formed between PVDF and water firstly reaches the maximum and then decreases in the interface region. Compared with the liquid-PVDF-air system using water, the total number of hydrogen bonds for systems using LiBr aqueous solution decreases by more than half according to Fig. 9(b). However, it must be mentioned that the number of hydrogen bonds formed between PVDF and water is nearly the same in the interface zone regardless of liquid types. This may be due to the fact that the number of hydrogen bonds formed between PVDF and water is dominated by the number of available acceptors.

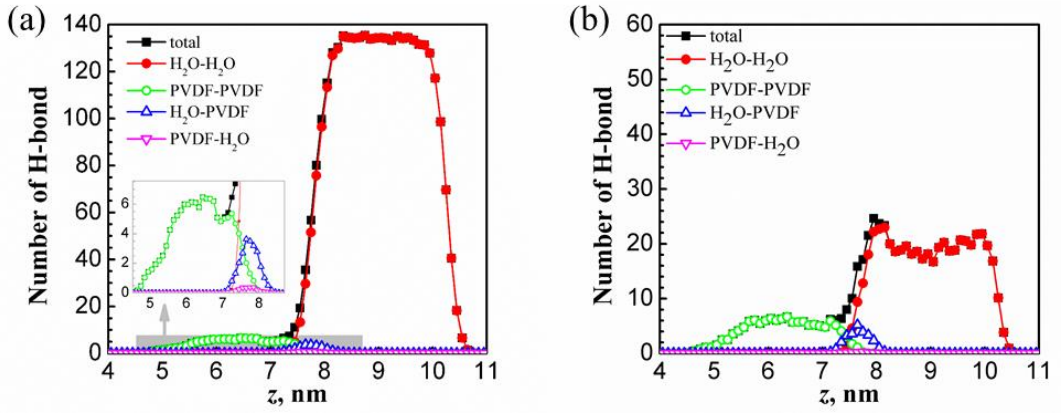

Figure 9. H-bond profiles of liquid-PVDF-air systems: (a) water; (b) 60% LiBr solution

In addition, the total number of hydrogen bonds in the zone of PVDF-liquid interface is higher than that in the zone of liquid-air interface. This can be attributed to the contribution of PVDF membrane, which participates in the formation of additional hydrogen bonds. The water transport through PVDF membrane and PVDF-liquid interface deserves further study from aspects of the formation and destruction of hydrogen bonds.

4. CONCLUSIONS

Interface characteristics of liquid-solid-gas systems were obtained using molecular dynamics by taking PVDF as the membrane to separate the LiBr aqueous solution and air. This study sets foundation for developing novel membrane materials with excellent performance and enhancing dehumidification process essentially. Main findings are summarized below:

(1) The cube droplet of LiBr solution on the surface of PVDF membrane was simulated by molecular dynamics. The change of droplet can be divided into two periods. The former is the rapid period of spherize while the latter is the slow period of spread on the surface. The simulated contact angle of LiBr solution on the PVDF membrane is about 93^{o}.
(2) Density profiles of liquid-PVDF-air systems were compared and interface thicknesses were further obtained. In general, the thickness of liquid-PVDF interface was much higher than that of liquid-air interface especially using LiBr aqueous solution with high concentration. The thickness of PVDF-liquid interface could increase by more than half compared with the liquid-air interface when the concentration of LiBr aqueous solution is over 0.55. This indicated higher interface resistance of the membrane based dehumidification.
(3) Hydrogen bond distribution of liquid-PVDF-air systems were discussed and the composition of hydrogen bonds in the interface zone was analyzed. Hydrogen bonds can be formed between PVDF and water for liquid-solid interfaces between LiBr solution and PVDF membrane. PVDF usually acted as the hydrogen bond acceptor in the interface zone, which meant PVDF had important effects on molecular transport through the interface.

SUMMARY
Reducing building energy consumption is crucial due to growing concerns about global warming. Architecture and urban planning actively embrace sustainable development, with policies promoting energy efficient spaces. However, unique structures such as large convention spaces pose HVAC design challenges. Achieving a balance between healthy air, thermal comfort, and energy efficiency requires a multifaceted approach. This study focuses on an 1804 m² two story convention space that has been certified by the Ecology, Energy Saving, Waste Reduction, and Health (EEWH) the Taiwan green building evaluation system. We used ANSYS FLUENT to conduct a detailed analysis of thermal comfort standards and energy optimization. We realistically simulated temperature and airflow under varying loads and assessed occupant perception and acceptance through thermal comfort evaluations (Predicted Mean Vote, PMV). We also simulated thermal comfort to evaluate potential improvements, including air conditioning optimization and energy saving strategies. Key findings: (1) The numerical technique used accurately predicted the airflow and temperature distribution in high rise air conditioned spaces. (2) The study found that supply air velocity and temperature, diffuser count, and space height significantly impact thermal comfort. (3) Case2, which had optimal supply air velocity and diffuser configurations, achieved the best system performance and thermal comfort. These results provide valuable operational and design guidelines for large convention spaces, enabling a win-win scenario of enhanced thermal comfort alongside energy savings. This contributes to sustainable development and provides insights for managing the thermal environment of similar venues.

Keywords: Thermal comfort, Energy saving, CFD, Large Exhibition spaces, Air conditioning.

1. INTRODUCTION

In contemporary society, expansive exhibition spaces are essential not only for cultural exchange but also for commercial activities and art exhibitions. With the continuous development of modern building technology, people's living environments are increasingly evolving towards larger spaces and higher ceilings. Simultaneously, architectural structures are also incorporating more innovative artistic design elements. People spend more than 90% of their time indoors, making indoor thermal environment and thermal comfort crucial(Cheng et al., 2012). This is particularly important for large exhibition spaces, such as venues, where the air conditioning system load, heat transfer properties, airflow organization, and indoor air quality control face significant challenges. Large exhibition spaces pose unique challenges for controlling the internal environment due to frequent entry and exit of unspecified individuals, uncertain retention times, and drastic changes in peak loads. Therefore, it is crucial to have a flexible air conditioning system and prioritize energy efficiency. Therefore, achieving appropriate airflow organization in large exhibition spaces

to ensure that the indoor environment meets the needs of users has become an important research topic for contemporary designers(Tu et al., 2023).

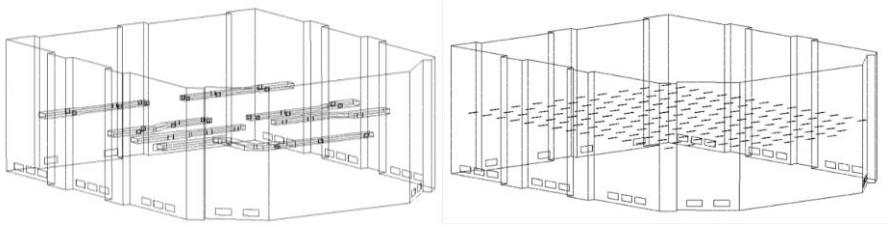
The fear from cold draft formation leading to unaccepted indoor conditions, and pose significant challenges for indoor air quality control due to the air conditioning system load, heat transfer properties, and airflow organization(Youssef et al., 2018). It is important to address these challenges to ensure optimal indoor air quality. Additionally, the frequent entry and exit of unspecified individuals and the uncertainty of crowd retention time contribute to more drastic changes in peak loads. The internal environment of a building can be difficult to control due to its complex characteristics(Kwon, 2016). Therefore, it is important to focus on flexible operation of the air conditioning system and energy saving measures. Contemporary designers must research how to achieve appropriate air flow organization in large exhibition spaces to ensure that the indoor environment meets the needs of users.

2 MODELING

To accurately simulate the thermal comfort environment, the following basic assumptions are used:

1. Steady, incompressible turbulent flow
2. Ignore radiation effects
3. Gravitational forces
4. Pressure-based solver, and the k-ε RNG model
5. The design and location of the air conditioning system. For example, the direction and volume of air supply will have a direct impact on airflow and comfort.

Environmental thermal comfort can be modelled and predicted based on these factors, and the model can be used to determine appropriate strategies for optimizing comfort. The functional design of the ground floor and the simulation model is shown in Figure 1.



(a) (b)

Figure 1. Various air duct designs (a) Side blow systems (Case1) (b) Downdraft System (Case2).

2.1 Model boundary conditions

This study focuses on a large convention space with three as the research subject. Case1 employs the originally designed side blow system, while Case2 uses a downdraft system. Both cases are supplied by seven on site air conditioning units, with three units providing an air volume of 25,200 cubic meters per hour (CMH), three units providing 31,500 CMH, and one unit providing 15,800 CMH. As the space is located in the center of the building and serves as the main activity area, it is surrounded on all sides by lobby corridors or adjacent office spaces. Therefore, the walls are

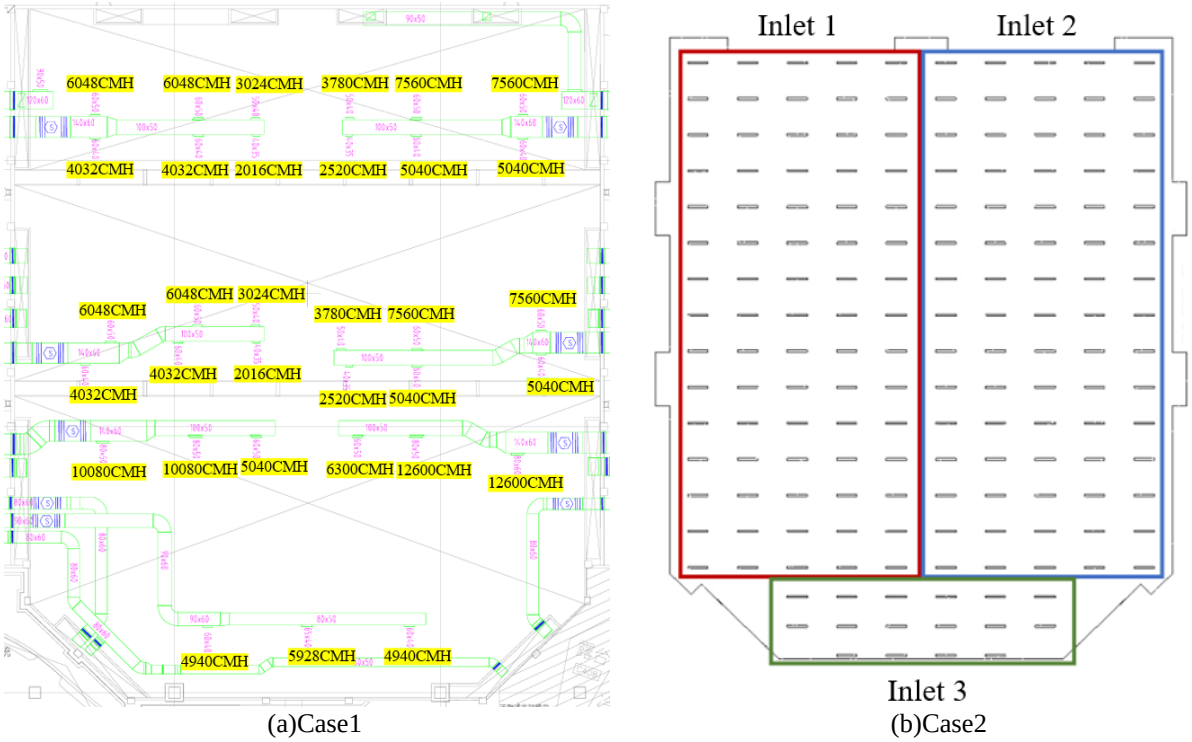
defined as adiabatic in the simulation. The boundary conditions are shown in Table 1. The ISO 14505-4:2021 standard (International Organization for Standardization, 2021) proposes three conditioning principles for thermal human models, including a constant skin surface model, a constant heat flux model and a comfort equation model. In these models, the human body boundary conditions of Cheng et al.(Cheng et al., 2012) will be utilized in this study, with detailed settings including a constant skin temperature of 34°C. The detailed settings are shown in Table 2 and Figure 2.

Table 1. The boundary conditions of CFD simulations.

Type	CFD simulation
Dimension	1804m^2 × 15.21m
Occupants	0.4m × 0.4m× 1.7m
Supply air duct	6.7m above the floor
Exhaust air duct	2m×0.8m / 0.5m above the floor
Walls / Ceiling / Floor	Adiabatic

Table 2. Case2 air volume design.

Supply air duct	Inlet 1	Inlet 2	Inlet 3
Air volume (m^3/h)	1008	1260	988
Supply air duct size (m^2)	1.5m×0.15m		
Air velocity (m/s)	1.24	1.5	1.22



(a)Case1 (b)Case2

Figure 2. Supply air duct design.

In this study, the mass, momentum, and energy conservation equations are considered along with the time averaged equations for the incompressible flow can be expressed in a general form including four terms, transient, convective, diffusive and source terms, denoted as Eq (1):

$$\frac{\partial}{\partial t}\int_{v} \rho\phi \, dV + \oint_{A} \rho\phi V \cdot dA = \oint_{A} \Gamma_{\phi} \nabla\phi \cdot dA + \int_{V} S_{\phi} dV \quad (1)$$

Where ρ is the fluid density $\emptyset$ represents the dependent variable, which could represent either a velocity component, $\vec{V}$ denotes the velocity vector, Γ represents the diffusion coefficient, and $S_{\emptyset}$ stands for the source term.

Solving the Reynolds-averaged Navier-Stokes (RANS) equations requires the use of turbulent models. Studies comparing these models (Cheng et al., 2012) have shown that the RNG k-ε turbulent model performs the best in predicting indoor airflow properties. This is because it can handle both low velocity and high velocity airflow effectively.

2.2 Air Diffusion Performance Index

The Air Distribution Properties Index (ADPI) is a formula developed in accordance with ANSI/ASHRAE Standard 113(ANSI/ASHRAE Standard 113-2013, 2013), as defined in Eqs.(2) and (3). It is primarily used to evaluate air diffusion performance and quantify the cooling system's impact on thermal comfort. ADPI is the percentage of eligible Effective Draft Temperature (EDT) divided by the number of test points, where the EDT is calculated from the air temperature and air velocity. ASHRAE recommends higher ADPI values to indicate better air distribution performance. Generally, an ADPI value of 80% or higher is considered acceptable. This ensures efficient and even distribution of air throughout the interior space, providing good thermal comfort. A high ADPI value indicates even air movement, reducing temperature variations and improving overall indoor air quality.

$$\boldsymbol{ADPI = \frac{N_{EDT}}{N} \times 100\%} \quad (2)$$

$$\boldsymbol{EDT(\theta) = (T_X - T_I) - 8(V_X - 0.15)} \quad (3)$$

Where EDT(θ) is between -1.7 °C < EDT < 1.1 °C, which is comfortable for most people; N_{EDT} is the number of test points when the EDT is between -1.7 °C < EDT < 1.1 °C; N is the total number of test points; T_X is the temperature at the test point (°C); T_I is the average indoor temperature (°C); and V_X is the Air velocity at a point in the working area (m/s).

2.3 Concept of Grid Independence

Grid independence refers to the state in which the results of a numerical simulation do not change significantly as the mesh is refined. When the mesh is sufficiently fine, the solution stabilizes, and further mesh refinement leads to negligible changes in the results. The goal of a grid independence study is to identify this threshold at which the mesh provides a sufficiently accurate representation

of the physical system, while avoiding unnecessary computational effort.

The grid division in this study can be roughly categorized into four parts: the large space, personnel, supply air vents, and return air vents, each assigned different grid sizes. The analysis was conducted by proportionally reducing the grid sizes, as shown in Figure 3. Ultimately, a grid count of 8.3 million was used for simulation, where all test points maintained an error below 5%, compared to a reference grid count of 10.6 million.

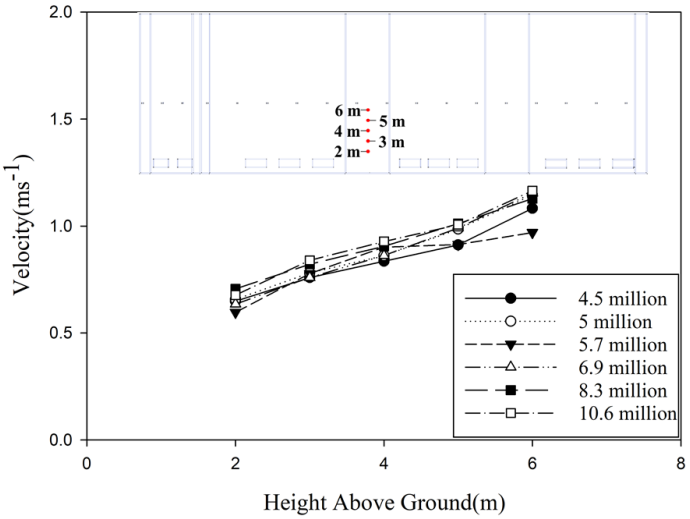


Figure 3. Grid Independence Test.

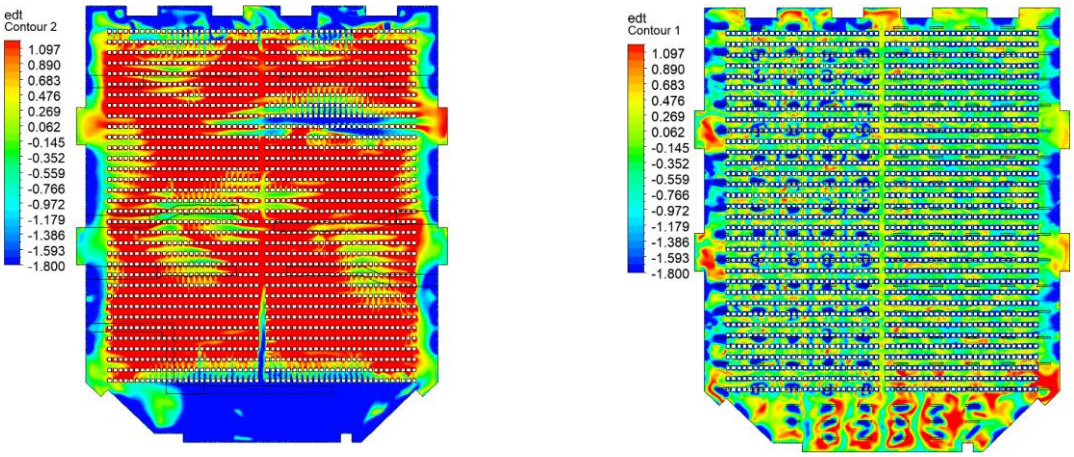
3 RESULTS AND DISCUSSION

Upon further analysis, it was discovered that in the Case1 design, the supply air duct was arranged horizontally with the floor. As a result, the simulated air velocity data for work points located at the lower bottom of the large space was low. This low air velocity reduces the effective ventilation of the air to the human body and increases the likelihood of localized air stagnation, which affects the EDT values, are shown in Figure 4. In contrast, Case2 utilizes a downdraft design, which is more effective at improving airflow, particularly in the bottom areas of large spaces. This improves ventilation and reduces discomfort and air quality issues.

Additionally, the velocity of inlet 1 in Case2 is slightly lower than that of inlet 2, resulting in EDT results slightly below the comfort range (-1.7~1.1) for the area directly below the inlet 1 air inlet in Case2. The ADPI's overall performance is slightly reduced in this situation. Although the EDT value is lower below the inlet 1 air duct in Case2, the overall ADPI value still exceeds the standard requirement, indicating a comfort advantage.



(a)Case1 (b)Case2

Figure 4. EDT on 1.4m plane.

4 CONCLUSIONS

Based on the data extracted from 86 working points on the plane from Figure 4, the following conclusions were calculated:

1. In Case1, the supply air duct was arranged horizontally, resulting in low air velocity at lower areas of the space. This reduced ventilation and increased air stagnation, leading to an ADPI value of 45.35%, far below the 80% recommended by ANSI/ASHRAE Standard 113. Personnel may feel discomfort due to poor air quality and low comfort levels.
2. The ADPI value for Case2 is 87.21%, which complies with the recommendations of ANSI/ASHRAE Standard 113. The study indicates that utilizing a downdraft design is more effective in improving airflow, particularly in the lower regions of large spaces. As a result, personnel are typically comfortable in Case2 environments due to the high level of air quality and comfort.

In conclusion, the results highlight the importance of proper airflow design in large spaces to ensure air quality and comfort. Effective ventilation and air conditioning measures are essential to enhance air circulation, reduce discomfort, and promote the health and wellbeing of personnel.

NudgeFlow – the next generation of residential ventilation (13:30-15:00 h)

6th International Conference on Building Energy and Environment
Eindhoven University of Technology, The Netherlands
6 - 10 July 2025

A distributed control framework for residential ventilation system: "NudgeFlow"

Douaa Al-Assaad[1,2], Hilde Breesch[1]
[1]KU Leuven, Gent, Belgium, douaa.al-assaad@kuleuven.be, [2]TU Eindhoven, Eindhoven, the Netherlands

SUMMARY

The COVID-19 pandemic exposed serious shortcomings in existing residential ventilation systems, which struggled to meet new demands for higher airflow to prevent virus spread. This was soon followed by an energy crisis, requiring these systems to also become more energy-efficient—creating conflicting demands. Most current systems lack true "smart" capabilities, as defined by the Air Infiltration and Ventilation Centre (AIVC). Meanwhile, the market is shifting toward performance-based, robust, and distributed ventilation solutions. New room-based systems have emerged, but they often fall short in controlling airflow throughout an entire building. In the framework of the Flemish VLAIO Flux50 project, we propose a smart novel decentralized residential ventilation system consisting of low pressure drop components connecting zones directly to each other and to the outdoors. This system coined as "NudgeFlow" would adjust airflow dynamically based on room conditions, user needs, and environmental factors, serving as a potential breakthrough for the Flemish ventilation industry and making it an adequate renovation solution. The following paper discusses a potential distributed control framework for such a system.

Keywords: NudgeFlow system, residential ventilation, passive components, distributed control architecture

1. INTRODUCTION

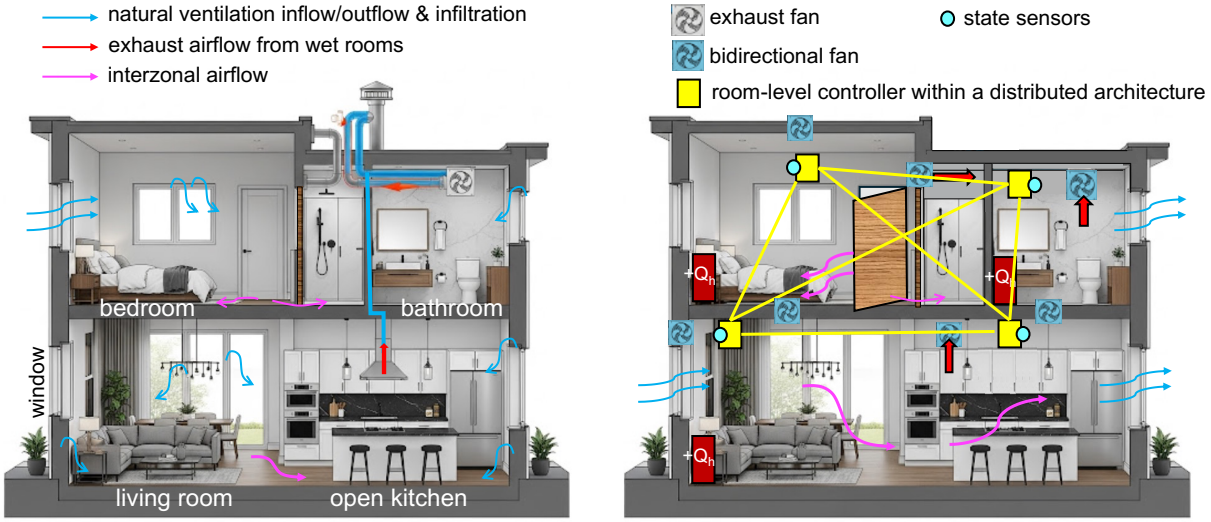
1.1 Challenges facing residential ventilation

The residential ventilation market is continuously evolving due to shifting performance demands. The SARS-CoV-2 pandemic emphasized the importance of indoor air quality (IAQ), prompting systems to prioritize airflow and responsiveness. This was quickly followed by an energy crisis, challenging systems to maintain IAQ while reducing energy consumption. Simultaneously, the EU's "Renovation Wave" initiative is pushing the market from traditional, prescriptive standards toward performance-based design approaches. Renovation constraints, such as limited space for ducts and a focus on sustainable, circular solutions, have renewed interest in decentralized ventilation systems. These must be user- and context-aware, with some incorporating local heat recovery via compact units like push-pull systems and rotary exchangers.

1.2 NudgeFlow system: A potential solution

The previous VLAIO Flux50 cluster for energy project "SmartVent" (Breesch et al., 2022) introduced a holistic, performance-based framework that allows for more flexible and robust ventilation designs. This approach avoids the single points of failure found in systems like MEV and MVHR, paving the way for more distributed solutions. In this context, the NudgeFlow system is proposed as the next generation of residential ventilation: decentralized, intelligent, and minimally invasive—ideal for renovation. It ensures high IAQ and low energy use by smartly guiding natural airflow through a dwelling. Using local, low-pressure components and adaptive control, the system responds to changing conditions and user needs, offering a resilient and future-ready solution. **Figure 1** illustrates the difference between a typical residential ventilation system and a NudgeFlow system for a typical Belgian dwelling. The typical system is equipped with exhaust fans in wet polluted areas (bathroom, WC, kitchen). When operated, this drives outdoor

airflow to infiltrate through the building envelope (cracks, unintended window opening). The airflow can subsequently circulate in the house in between zones driven by pressure and temperature differences. Such airflows are often left unguided and may result in increased cooling or heating loads (e.g., unintentional flow of cool outdoor air to an unoccupied living room increasing heating energy demand) or an untapped ventilation and energy saving potential (e.g., a flow of fresh air from the hallway to the bedroom is not taken advantage of if door remains closed). On the other hand, the impact of occupant disturbances (opening of windows or leaving doors half open) and outdoor weather fluctuations on system performance is often left unchecked. On the contrary, NudgeFlow is a context aware intentional system that taps into the potential of interzonal airflows and guides and distributes airflows throughout the dwelling where it is needed through bidirectional fans with adjustable flow rates and intentional window and door opening and by taking advantage of occupant behaviors in its control loop. For example, a NudgeFlow system would redirect flow from unintentional opening of window from an unoccupied room to a room where it is needed or it would open the door between the hallway and bedroom for energy efficient ventilation. **Table 1** shows sample scenarios comparing both system behaviors applied to the dwelling in **Figure 1**.



(a) typical mechanical ventilation system: Exhaust from wet polluted areas and infiltration through building envelope/intentional openings and fixed interzonal airflow path with outdoor and occupant disturbances not considered.

(b) NudgeFlow system: Controlled zonal and interzonal airflows and airflow paths through intentional opening of windows and considering outdoor dynamic disturbances and uncontrolled leakages

Figure 1. Illustration of a reference Belgian dwelling equipped with (a) a typical mechanical ventilation system and (b) the novel NudgeFlow system

Table 1. Scenarios showing differences between typical and NudgeFlow system response & performance

Scenario	Typical system	NudgeFlow system
Occupants are away. Cold wind is blowing on the façade of the unoccupied dwelling and infiltrates to a room through a trickle vent	No response. Increased heating energy demand. Situation is worse if occupants leave internal doors open. Potential thermal discomfort during occupancy	System will close trickle vents to minimize ventilation losses. Potential discomfort reduced

Occupants sleeping in the bedroom with internal doors closed during winter. Increased CO_2 levels.	Cold air comes in through trickle vents due to activation of bathroom exhaust fan. Increased heating energy demand	Activates inter room fan from hallway where the air is clean but warmer than the outdoors. Energy saving potential
Occupant cooking in the kitchen with internal door to living room open	Extracts from the kitchen but may let odors spread if airflow paths are imbalanced	Senses pressure/CO_2/temp rise in the kitchen and actively redirects flow to the hallway or adjacent room to contain and evacuate the air more quickly
Occupant taking a shower increasing humidity levels after use and left their damp clothing in the bathroom	Extracts moist air but water vapor can still spread in the house if humidity is too high	Detects high humidity and boosts airflow temporarily, using interzonal fans or windows to rapidly dry the space, then scales back to save energy.

1.3 A promising control approach for NudgeFlow

Centralized controllers are impractical for multi-zone dwellings with dynamic conditions, especially in systems like NudgeFlow. Central control requires complete system data and assigns actions to each component, making data collection costly and fault detection difficult (Ygge et al. 1999). A single component failure can disrupt the entire system and require manual intervention. NudgeFlow systems add complexity due to their spatial and temporal dynamics and inter-zone connectivity, making centralized control even less viable. Carbonare et al. (2021) demonstrated an occupant-centric, self-learning controller with decentralized micro-controllers for room-specific fan control based on discomfort models. However, their system did not manage airflow across the entire dwelling, and they reported significant issues with central-to-local communication—issues likely worsened in NudgeFlow setups. Advancements in IoT sensing and open building automation now make distributed control a feasible solution for NudgeFlow. Distributed, model-based controllers—like those proposed by Walker et al. (2017) and Li and Wang (2022) —have shown robust performance and efficiency in HVAC applications. Zhao et al. (2018) introduced the Insect Intelligent Building (I^2B) architecture, where each node is autonomous, sensing, communicating, and making decisions locally. Studies confirm this approach outperforms centralized control in flexibility and energy efficiency, making it ideal for NudgeFlow.

2. PROBLEM SETUP & FORMULATION

In a distributed control architecture, subsystems include the room controllers (each room has a controller solving locally for its own objectives), the coordinating agent which has its own global objective which is to find consensus between the zones since they share components (fans, doors). Each room $i \in \mathcal{R}$ is characterized by complex thermal, acoustics and air quality dynamics (temperature $T_i(t)$, species' concentrations $C_{s,i}(t)$, noise level $A_i(t)$) resulting from the presence of heaters and bi-directional fans, operable windows (both controlled and occupant-driven), solar gains through the envelope, and internal acoustic sources (appliances, voices, fans). **Table 2** presents the different variables and parameters involved in a NudgeFlow system and **Figure 2** presents a graphic representation of the physical problem for the first floor of the dwelling. Each room is represented by one node assuming fully mixed conditions. It is connected (edge

representation) to the outdoor node and adjacent indoor nodes (other rooms) via thermal and mass couplings. The coupling with the outdoors is due to the external walls and controlled or occupant-driven window openings while the coupling with the indoors is due to the internal walls, bidirectional fans operation and uncontrolled leakages through doors.

Table 2. The different types of variables and parameters in a NudgeFlow system.

State variables (quantities describing current state of each room and its evolution over time and measurable via sensors)	$T_i(t)$: indoor temperature (°C) $C_{s,i}(t)$: indoor pollutant concentration (ppm) $\omega_i(t)$: indoor water vapor content (g/kg) $A_i(t)$: indoor sound pressure level (dB)
Control variables (actuator inputs that can be directly manipulated to influence system performance)	$Q_{i,h}$: heater power (W) $\dot{m}_{ij,fan}(t)$: fan airflow between rooms (kg/s) $W_i(t)$: window opening fraction (0 to 1)
Disturbance inputs (external or occupant driven influences not directly controlled that can be measured)	$W_{i,occ}(t)$: occupant-induced window state (0 to 1) $D_{i,occ}(t)$: occupant-induced door state (0 to 1) $T_{out}(t)$: outdoor temperature (°C) $C_{s,out}(t)$: outdoor pollutant concentration (ppm) $\omega_{out}(t)$: outdoor water vapor content (g/kg) $A_{out}(t)$: outdoor sound pressure level (dB) $a_{int}(t)$: internally generated noise (dB)

In a distributed controller, each room solves its own objective function real-time. The objective function per room is shown in equation (1):

$$\min J_i = \omega_1\left(\max(0, \left|T_i - T_i^{comf}\right| - \delta)^2 + \max(0, \left|DR_i - DR_i^{comf}\right|)^2\right) + \omega_2 \max(0, C_{s,i} - C_{s,i,th})^2 + \omega_3 \max(0, A_i - A_{i,th})^2 + \omega_4 \left(Q_{i,h} + \sum_j \left|\frac{\dot{m}_{ij,fan}\Delta P}{\eta}\right|\right) \quad (1)$$

The first term in equation (1) is a penalizing deviation from an adaptive thermal comfort range as defined in EN 15251. The adaptive comfort model defines a comfort band that depends on the outdoor temperature T_{out}. δ is the half-width of acceptable comfort range (e.g., ± 2.5°C). The second term is the penalizing deviation from the draft risk according to ISO 7730 that depends on the air velocity and turbulence. The second term is the penalizing deviation from the threshold concentration of pollutants *s* of interest in the dwelling. The third term is the deviation from acoustic thresholds, and the final term is the energy consumption due to fans and heaters. Different rooms can have different thresholds of comfort, air quality and acoustics depending on their usage. The objective function in equation (1) is subject to following hard and soft constraints:

- Hard (enforced via inequality constraints): (a) components' control bounds within physical limits (heater, fan speeds, window and door positions) (b) bi-directional shared fan between zones flow conservation ($\dot{m}_{ij,fan}(t) = \dot{m}_{ji,fan}(t)$) , (c) connectivity constraints: preventing opposing shared fan, window and door states, (d) acoustic resistance defines hard constraints to limit sound transfer during fan operation or select airflow paths that balance ventilation without exceeding noise thresholds.
- Soft (imposed objective penalties via quadratic functions): (a) thermal comfort according to the adaptive comfort band and draft discomfort, (b) IAQ,

The weighting factors multiplying the different terms in equation (1) should be adequately tuned per room and time depending on its requirements at the current state (e.g., prioritizing IAQ during cooking events in the kitchen) or even user preferences. This is expected to be the most challenging task in minimizing the objective function.

The state variables in equation (1) can be solved iteratively and dynamically using an adequate state space model of the dwelling and an adequate solver. Temperature and concentration dynamics are described in equations (2) and (3):

$$T_i(t+1) = T_i(t) + \frac{\Delta t}{C_i}.\left[Q_{h,i}(t) + Q_{envelope} + Q_{Internal\ gains} + Q_{leakage+ventilation\ losses}\right] \quad (2)$$

$$C_i(t+1) = C_i(t) + \Delta t.\left[\frac{1}{V_i}\left(\sum_{j=1}^{N}(d_{ji}^{leak}(t) + \dot{m}_{fan,ji}(t))C_j(t) - \sum_{j=1}^{M}(d_{ij}^{leak}(t) + \dot{m}_{fan,ij}(t))C_i(t) + \dot{m}_i^{window}(t).C_{out,t}\right) + G_i(t)\right] \quad (3)$$

$G_i(t)$ is the generation rate of pollutant in question (e.g., CO_2 from people or VOCs from cooking, etc.). d_{ij}^{leak} is the inherent leakage through passive components between room i and j (door slits, cracks). They are expressed in equation (4) where k_{ij} is the leakage conductance function of the geometry and door opening fraction.

$$d_{ij}^{leak}(t) = k_{ij}^{leak}\Delta P_{ij}(t) \quad (4)$$

The model should be able to capture all relevant physics influenced from control actions and uncontrolled disturbances (**Table 2**). This includes handling inter-room couplings; arising nonlinearities and discretizing the continuous dynamics with an appropriate sampling time matching the system dynamics and eventually control hardware capabilities to support real-time operation. Literature has shown that tools such as Modelica can be promising as it supports detailed modelling of pressure and buoyancy-driven airflows in multi-zone buildings connected by doors, cracks, leaks, windows and vents. Moreover, it allows a direct coupled thermal and airflow simulations in addition to possibility of coupling with control algorithms. However, limitations exist in its assumption of lumped parameters, simplifications of 3D geometries (i.e., openings are represented as ports or flow resistances), calibration requirements of flow coefficients (i.e., leakages, discharge coefficients). Consequently, thorough testing of this tool and its solvers is needed.

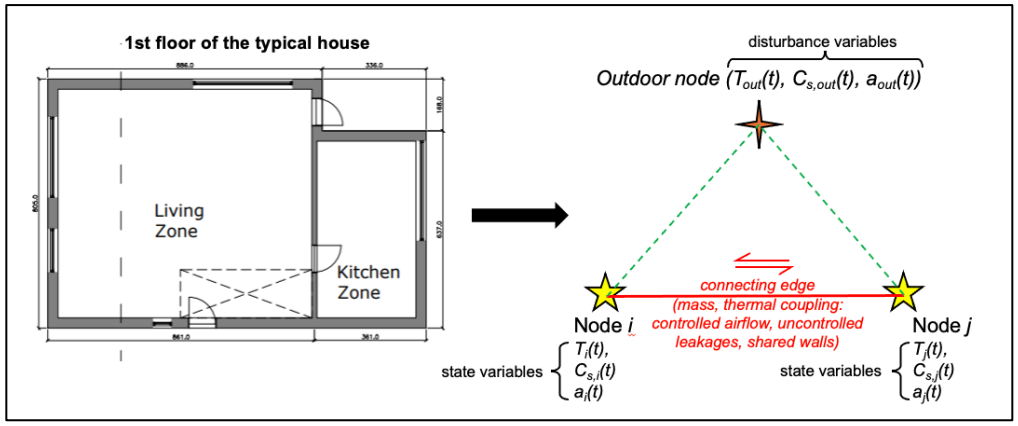


Figure 2. Graphical representation of the NudgeFlow equipped dwelling

3. CHALLENGES OF A DISTRIBUTED CONTROL

To coordinate control across zones in real time without relying on a fully centralized controller, an effective distributed optimization approach needs to be defined. The framework decomposes the global control problem into smaller local problems for each zone, enabling independent optimization with local states and controls, while enforcing consensus constraints on shared coupling variables through a coordinator. The risk remains that a consensus would be difficult to

reach between rooms on shared variables. In this case, the coordinator can still change its function encouraging cooperation between zones rather than finding a single consensus. Cooperation can include prioritizing zones over others over time depending on the context. Thus, year-round performance can still be achieved. For example, the bedroom and bathroom are both occupied, and a bidirectional fan is shared between them. The bedroom wants to operate the fan to discharge pollutants into the bathroom, but the bathroom controller wants to operate the ceiling fan only and prevent additional pollutants from being discharged into the bathroom to reach its IAQ objectives as the ceiling fan cannot further increase flow rates. A cooperation between zones means prioritizing the bedroom due to its longer occupancy periods and compromising the bathroom IAQ for the short duration of time during which the shower is in use.
Other functions that the coordinator can take is a supervisory role setting hard constraints over certain airflow path or variables (power use, comfort, acoustics) which can facilitate the cooperation between rooms by eliminating certain control actions. For example, if both bedroom and bathroom are occupied, the coordinator can set a hard rule prohibiting local agents from operating the bidirectional fan. In this case, the agents must use other NudgeFlow components (e.g., windows) to reach their local objectives.

SUMMARY
The impact of vegetation, more specifically trees, is analyzed across three different climates: continental climate in Montreal, Canada, tropical climate in Singapore, and arid climate in Morocco. Based on the pedestrian thermal comfort assessed by the Universal Thermal Climate Index (UTCI), two new heat indices are proposed: heat exposure and cooling efficiency by mitigation measures. Trees yield local improvements in all three cases. In tropical climate, air cooling by vegetation is largely canceled out by an increase in relative humidity, resulting in a reduced thermal comfort impact. The primary factor of trees contributing to improvement in pedestrian thermal comfort in all climates is shading. However, apart from local cooling, trees show a nonlocal heating effect due to blocking of wind and an increase in relative humidity due transpiration from leaves.

Keywords: Urban microclimate model, Vegetation, Heat exposure, Cooling efficiency

1. METHODOLOGY

The urban microclimate is modeled using the high-fidelity open-source model urbanMicroclimateFoam (2024), developed by the authors based on OpenFOAM. It solves for turbulent and buoyant flow in the air domain, coupled heat and moisture transport in porous urban materials, and solar and longwave radiation between the urban surfaces and the sky (Kubilay et al. 2020). The different models have been validated separately and the urban micromodel for the case of a patio with and without trees. Environmental boundary conditions are downscaled from the mesoscale meteorological model WRF (Weather Research and Forecasting) for a typical heatwave. Vegetation is modeled as porous zones characterized by a leaf area density introducing source/sink terms for momentum, heat, moisture, producing shadowing and evaporative cooling. Leaf heat balance is based on the sensible, radiative and latent heat fluxes. Impact of vegetation is analyzed for three different climates: continental climate in Montreal, Canada (Nevers et al., 2025), tropical climate in Singapore, and arid climate in Oujda, Morocco. Thermal comfort is assessed using the Universal Thermal Climate Index (UTCI), which represents the human thermal sensation with an equivalent temperature, accounting for long-wave radiation from surfaces, solar radiation, humidity, air speed, and air temperature. To provide a metric of the cumulative heat stress an individual might experience, we introduce the heat exposure index, defined as the integral of UTCI exceeding a specified threshold over a given time period. This metric incorporates a weighting factor based on the dynamic thermal sensation to take into account the higher impact of extreme heat stress on a person. Heat exposure is expressed in UTCI_degree_hours (UTCI_DH). Additionally, the cooling efficiency (CE) by vegetation is defined as the relative

improvement/deterioration in terms of the heat exposure index achieved by vegetation compared to a mineral case without vegetation. The simulations are conducted on a high-performance computing cluster and took around 30 hours.

2. LOCAL HEAT EXPOSURE AND COOLING EFFECT OF VEGETATION DURING HEATWAVE IN MONTREAL (CANADA), SINGAPORE AND OUJDA (MOROCCO)

In Montreal (continental climate), a typical neighborhood of Plateau-Mont-Royal, a late 19th-century working-class area, is studied. The simplified urban layout consists of six urban lots each with four buildings of 10 m height arranged around an inner courtyard (Figure 1a). Trees in streets are medium-aged, evenly distributed, with foliage 6 m high and wide at 3 m from ground, while backyard trees are taller, more mature, with foliage of 8 m high and wide at 4 m, reaching above the buildings. To study the urban microclimate in a tropical climate, we focus on Sun Plaza Park and its neighboring 12-story apartment buildings, some with open ground floors, in Tampines neighborhood in Singapore, a densely populated residential area (Figure 1b). The girth size, location, species of trees in the park are extracted from the National Parks Service of Singapore database, while foliage height and diameter are determined using allometric equations. Trees between buildings have a height of 8 m and crown diameter of 5.5 m at 12 m spacing. For the arid climate we focus on the El Qods neighborhood in Oujda (Figure 1c), a border city in the north-east of Morocco. In the area of interest, trees are only present in the local park and around the school courtyard. Foliage height and crown diameter are classified into four categories: 2m, 3.5m, 5m and 7m, with the majority of trees falling within the first two categories. The built environment mostly consists of two-story buildings with a height of 7m.

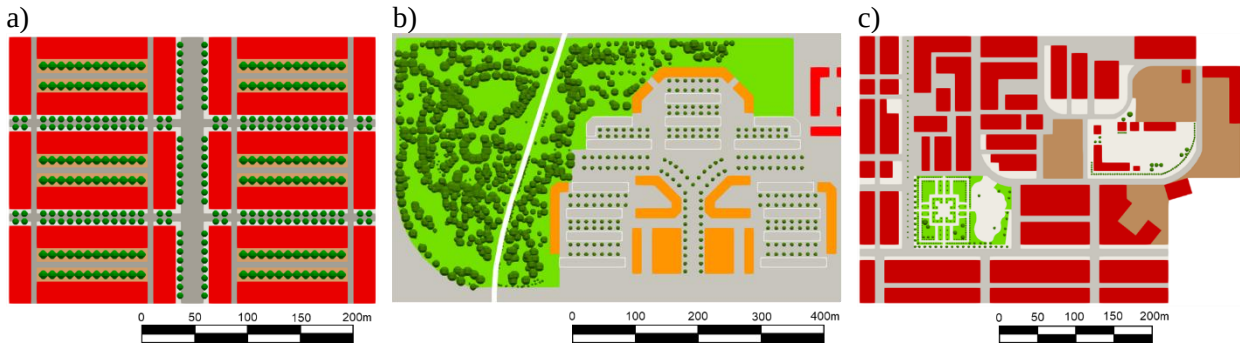

Figure 1. Layout of the neighborhoods (a) in Montreal (Canada) with trees in streets and courtyards, (b) in Singapore with an urban park and adjacent buildings, (c) in Oujda (Morocco) in a residential area with park.

Figure 2 shows the map of heat exposure expressed in UTCI Degree Hours (UTCI_DH with units °C·h) for present situation with existing vegetation. We remark that the UTCI_DH ranges differ for different climates with lower values between 200 – 500°C·h for Montreal case study, higher values between 300 – 700°C·h for Singapore case study and extreme values between 550 – 850°C·h for Oujda case study, as expected for continental, tropical and arid climates, respectively. In all the three climates, we observe lower heat exposure locally around and under trees due to shadowing effect of trees. The highest heat exposure is observed in unshaded zones in the park, courtyards and streets not shaded by trees. For Montreal case study (Figure 2a) wind flowing from south cools the main boulevard which is along the wind direction (250 – 300°C·h), while the unshaded parts in the courtyards and small streets exposed to low winds experience higher heat

exposure (~350°C·h). For Singapore case study (Figure 2b), the part shaded by trees experiences less heat exposure (~400°C·h) compared to unshaded parts in park and in between the buildings (600 – 650°C·h). For Oujda case study (Figure 2c) extreme heat exposure is observed in streets in densely built areas (~800°C·h), while lower heat exposure values are attained in zones open to wind flow and shaded by trees (550 – 700°C·h).

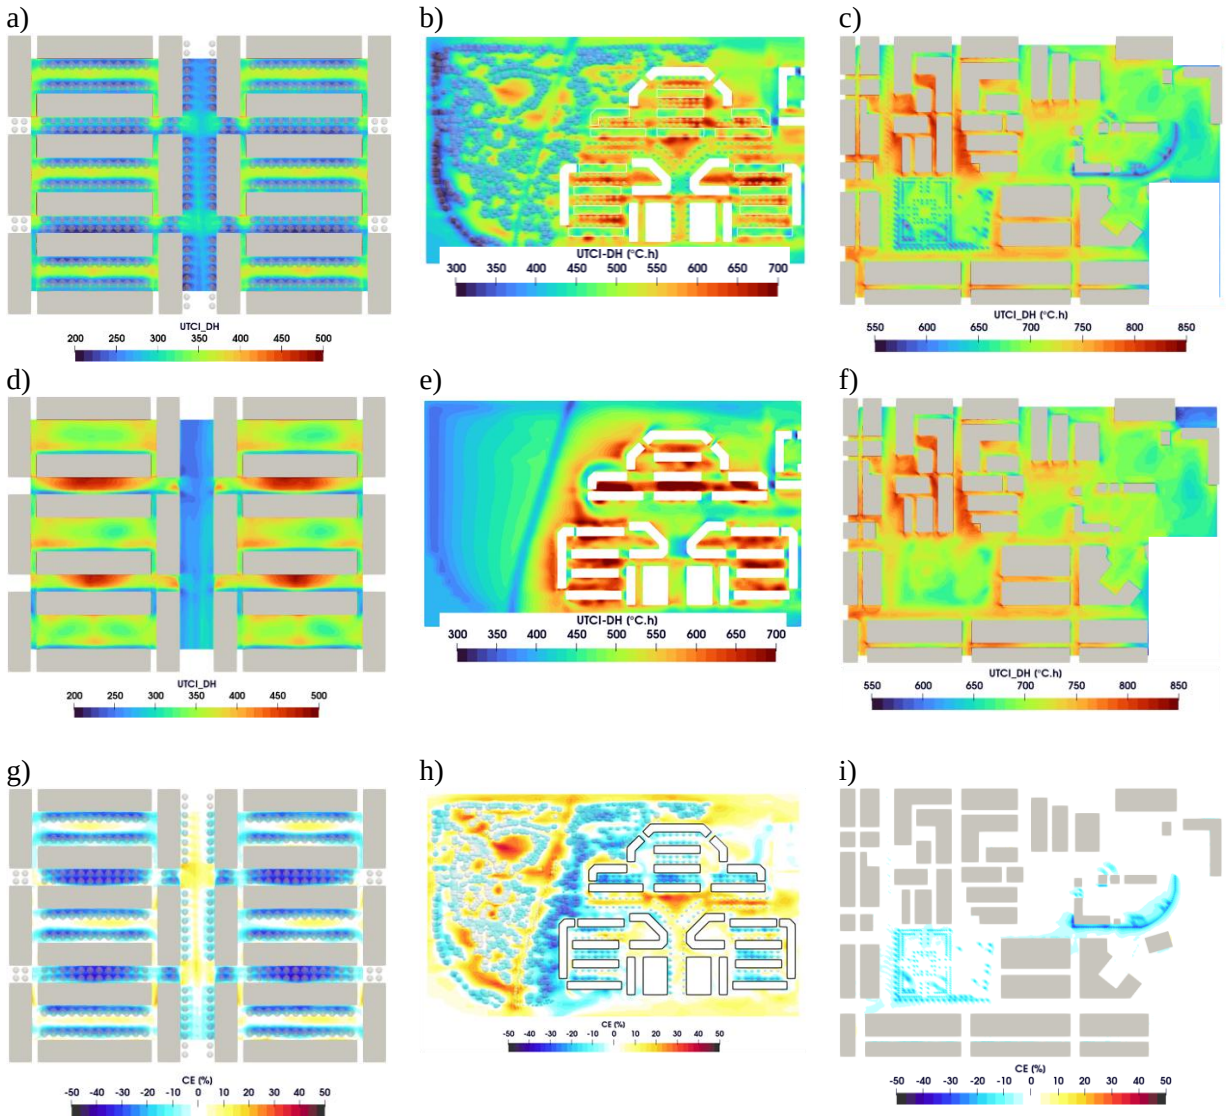

Figure 2. Heat exposure map expressed in UTCI_ DH for existing situation with vegetation in (a) Montreal, (b) Singapore, (c) Oujda. Heat exposure map for mineral case without vegetation in (d) Montreal, (e) Singapore, (f) Oujda. Map of Cooling Efficiency (CE) in (g) Montreal, (h) Singapore, (i) Oujda.

Figures 2d-f show the heat exposure map for the mineral cases without trees. We observe in general that heat exposure increases in zones where trees are removed. For Montreal case study (Figure 2d), this occurs mainly in transverse streets reaching ~450°C·h and to a lesser degree in courtyards (350 – 400°Ch). For Singapore case study (Figure 2e), heat exposure in the park increases along the wind direction coming from west, starting at approximately 350°C·h and reaching up to 650°C·h nearing the building blocks. The space between building blocks experiences very high

heat exposure, with values exceeding 700°C·h. For Oujda case study (Figure 2f), we see only local increases in heat exposure where trees are removed, i.e. in the park and along the school yard (up to 700°C·.h).

Comparing the situation with and without trees in Montreal and Singapore case studies, some hotter zones appear in the existing case with vegetation compared to the mineral case. To understand the cause of these hotter zones and to quantify the cooling and heating effects by trees, the cooling efficiency is determined as shown in Figures 2g-i. For Montreal case study, we see cooling effects by trees especially in the transverse streets with a reduction of -40% and in the courtyards under the trees of -25% indicating the positive effect of trees by shadowing and air cooling by transpiration. However, we also observe heating effects reaching +15% in some areas, referred to as nonlocal heating. This nonlocal heating is mainly caused by the blocking of wind due to the presence of trees in areas not shaded by trees, and to a lesser extent by increase in relative humidity by transpiration from leaves, which deteriorate the thermal comfort. For Singapore case study (Figure 2h) we see local cooling effects of trees in the park ranging from -15% in the west side of the park to -40% in the transition zone between the park and the building blocks. The lower CE in the west side of the park is due to the reduction of incoming wind speeds and increase in relative humidity due transpiration by trees, while in the transition wind hits the higher buildings and is guided down. We also observe strong non-local heating effects of +10% to +25% in unshaded zones within the park and between the building blocks. These high nonlocal effects are due to blocking of wind and, especially, due to the increase in relative humidity by transpiration from trees. The baseline relative humidity in Singapore is already high reaching ~70%RH, which further increases to almost 90%RH when passing through the park due to transpiration from leaves, which significantly deteriorates the thermal comfort. For Oujda case study, cooling effects by trees are relatively lower with values between -10% to -25%, which is mainly due to shadowing effects and transpiration cooling. Unlike in tropical climates, in arid context, where the baseline relative humidity is ~10%, a moderate increase in humidity is beneficial for thermal comfort. The lower CE values are attributed to the low numberof sparsely placed trees with also small foliage volume, resulting in a smaller impact on both air cooling by transpiration and shading.

In conclusion, our findings demonstrate the dual nature of trees providing both positive and negative benefits on thermal comfort. While trees provide local cooling through shading, they can also deteriorate thermal comfort non-locally by increasing relative humidity and blocking wind. Trees significantly cool in Montreal via shading and evapotranspiration. In Singapore, high humidity and low wind reduce their impact by 50%. In Morocco, trees enhance comfort through shading, though soil moisture is a limiting factor.

SUMMARY
In this paper we use the urban microclimate model 'urbanMicroclimateFoam' developed by the authors to compare the thermal comfort during a heatwave in three neighborhoods in Switzerland, two in Geneva and one in Fribourg, with different topography, urban form and green cover. The local thermal comfort is found mainly to depend on the interaction of shadowing by buildings, vegetation and wind flow. In a second study, the impact of high-rise buildings on the wind and thermal comfort in a square is analyzed, showing that zones with higher wind speeds are more susceptible to wind discomfort, while offering higher thermal comfort during heatwaves.

Keywords: Urban microclimate model, thermal comfort, wind comfort, wind driven rain

1. DESCRIPTION OF THE MODEL

A multiscale numerical approach is developed to model the urban climate with one-way coupling between the scales (Kubilay et al., 2020). At mesoscale, the climate is predicted by a nested meteorological weather prediction model, such as WRF (Weather Research and Forecast Model), for cities and their surroundings with a domain size around 50 km (Strebel et al., 2024). At microscale, the climate is predicted for urban neighborhoods with a domain size around 1-2 km using a solver developed by the authors, urbanMicroclimateFoam (2024), which is based on OpenFOAM libraries. The solver employs consecutive calculations of air flow with steady Reynolds-averaged Navier-Stokes (RANS), coupled with an unsteady heat and moisture (HAM) transport model for urban materials considering dynamic heat and moisture storage. Direct solar irradiation is modeled with ray casting to capture shading. The long-wave and the reflected short-wave radiative exchanges are calculated with view factors using a radiosity approach with multiple reflections. Foliage of trees is modeled as porous zones with leaf area density (LAD), introducing source/sink terms for momentum, heat, moisture and shadowing. Leaf heat balance is based on the sensible, radiative and latent heat fluxes. In a postprocessing step, the outdoor thermal comfort is assessed using the Universal Thermal Climate Index (UTCI) which represents the human thermal sensation with an equivalent temperature considering long-wave radiation from surfaces, solar radiation, air relative humidity and air speed in addition to the air temperature.

2. THERMAL COMFORT DURING A HEATWAVE

In this case study we simulate the outdoor thermal comfort during a heatwave in three neighborhoods in two Swiss cities, two neighborhoods in Geneva and one in Fribourg. The neighborhoods differ in topography, urban form, and green cover (Figure 1a-c). *Jonction* is a neighborhood in Geneva that sits near the confluence of the Rhône and Arve rivers and has a mix of residential, industrial, and green spaces, with a building footprint ratio of 33%, a grass area ratio

of 9%, a tree cover ratio of 10% and impervious area ratio of 48%. *Carouge* is a neighborhood south of the historic center known for its 18th-century buildings, with a building footprint ratio of 32%, a grass area ratio of 18%, a tree cover ratio of 19%, and an impervious area ratio of 50%. *Schoenberg* is a residential neighborhood, located at the eastern side of the river on a plateau outside the city of Fribourg characterized by a mix of modern and older buildings, with a building footprint ratio of 15%, a grass area ratio of 35%, a tree cover ratio of 16% and an impervious area ratio of 50%.

We examine the meteorological conditions associated with the heatwave that occurred from June 24-26, 2019, as simulated by the mesoscale Weather Research and Forecasting (WRF) model. Figures 1d-f show the maps of the UTCI at a height of 2m at 4 pm on June 24, 2019, in the core of three domains. All three neighborhoods show zones with moderate, strong and very strong heat stress. Zones shadowed by trees and buildings, and ventilated streets show moderate heat stress. In Jonction and Carouge, courtyards and streets without shadowing from trees and buildings and with low wind speed show very strong heat stress. Interestingly, Schoenberg, characterized by a lower building density compared to Carouge and Jonction, shows larger zones of strong and very strong heat stress. Built areas and streets without trees experience the highest heat stress when they are also less ventilated by wind. This means that the cooling effect by trees and wind depends on the complex interaction of factors such as street orientation, wind patterns, building morphology and tree planting patterns.

2. WIND AND THERMAL COMFORT BETWEEN HIGH-RISE BUILDINGS

In a second study, the wind and thermal comfort in and around an urban square, Place Étoile near the neighborhood Carouge, Geneva, is assessed. The city of Carouge is planning to transform the industrial area La Praille-Acacias into a new urban area, with Place de l'Etoile in the heart of the new development surrounded by some high-rise buildings (Figure 2a). To support an architectural competition, wind and thermal comfort are assessed to identify mitigation measures.

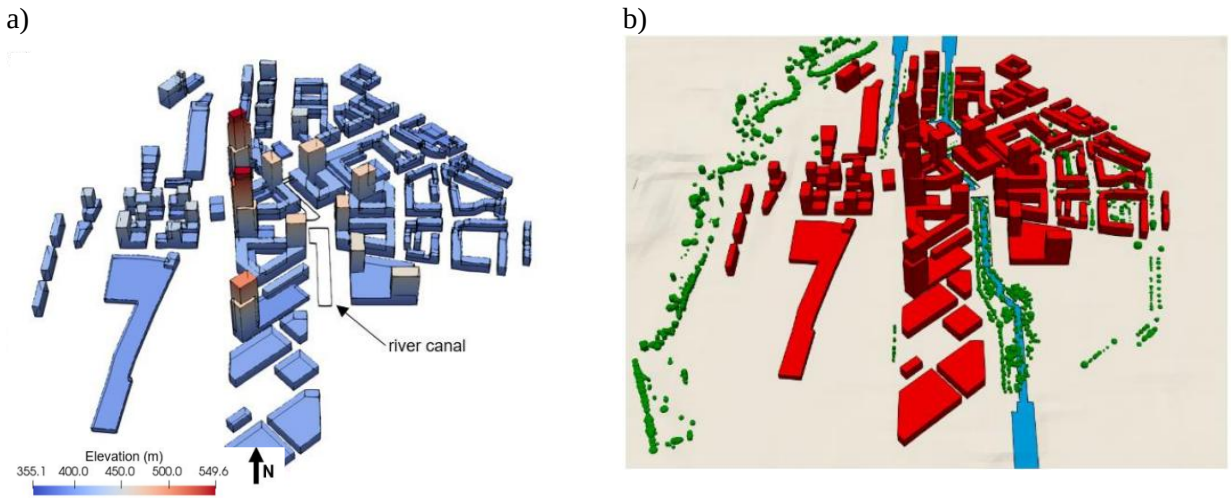

Figure 2. a) Place Etoile and surrounding buildings with elevation for wind comfort study. b) Domain for thermal comfort study with trees and water.

The assessment of wind comfort around buildings is based on aerodynamic information, statistical meteorological data and wind comfort criteria (Blocken et al., 2004). The wind comfort criteria according to Isyumov and Davenport (1975) and grades ranked from A to E are used to distinct for different activities, such as traversing, strolling and sitting. Figure 3a shows the wind rose data, with the most frequent wind directions and highest wind speeds from southwest and northeast. Figure 3b shows the local wind-amplification factor at pedestrian height, i.e. the ratio between wind speed at pedestrian height around buildings and a reference wind speed without presence of buildings. We observe that flow separation with accelerated wind speeds occurs at the upstream corners of the buildings, low wind speed regions in the wake of buildings, downflow due to the high-rise buildings around the plaza leading to corner streams with high wind speed, and channeling flows between the buildings oriented southwest-northeast.

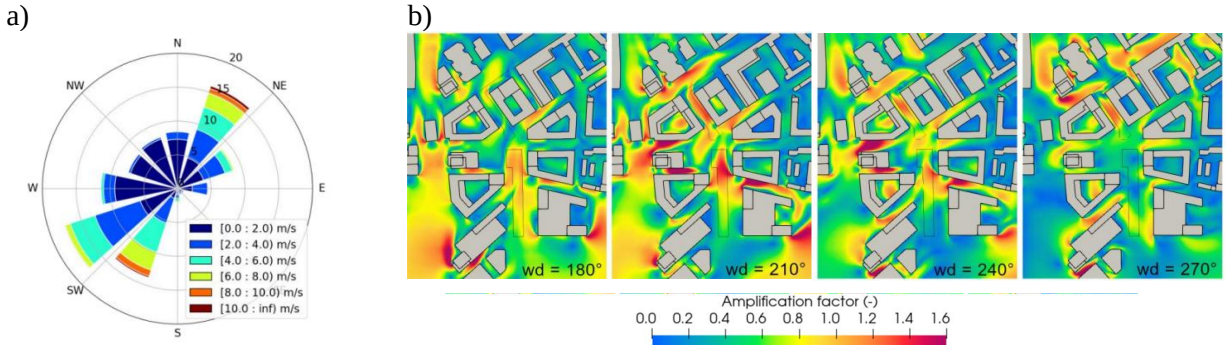

Figure 3. a) Wind rose obtained from MeteoSwiss weather station Genève / Cointrin. b) Wind-amplification factor at 2m for winds from south (180°), west (270°) and two in-between directions.

Based on the amplification factor calculation for 12 wind directions and statistical meteorological data, a map with wind comfort grades is determined (Figure 4a), where A being the most comfortable. Some regions with higher wind discomfort (grade C) can be distinguished especially around high-rise buildings in the west center of the plaza, along the river canal and at the southeast of the plaza. Figure 4b shows the thermal comfort levels at 2 m based on UTCI on June 24, 2019, at 4 pm. The highest values are observed in courtyards and near facades facing south indicating higher thermal stress. Figure 4c combines the regions showing wind discomfort (grade B and higher, in lavender), thermal discomfort (UTCI threshold of 32°C, in pink) and overlapping wind and thermal discomfort (in purple). Zones with higher wind speeds are clearly more susceptible to wind discomfort, while zones with lower wind speeds are characterized by lower thermal comfort. During heatwaves, high-rise buildings provide shade and downflow bringing cooler air to street level, enhancing thermal comfort. **In conclusion**, wind is found to be a complex phenomenon that significantly influences wind and thermal comfort, and to the best of our knowledge, no research has combined them in a comprehensive way as in this study. At the conference we will also present wind drive rain results showing that high-rise buildings increase wind exposure and rain at pedestrian level,

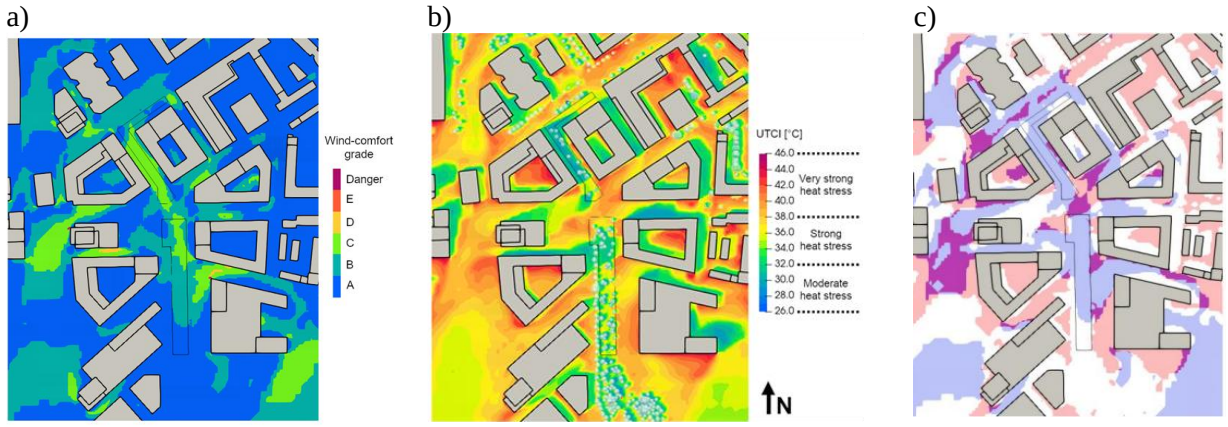

Figure 4. a) Wind-comfort grades. b) UTCI map at 2 m on June 24, 2019, at 4 pm. c) map of wind discomfort (grade B and higher, in lavender), thermal discomfort (UTCI threshold of 32°C, in pink) and overlapping wind and thermal discomfort (in purple).

ACKNOWLEDGEMENTS

The authors would like to thank the financial support of project SWICE (Sustainable Wellbeing for the Individual and the Collectivity in the Energy Transition) within the funding program SWEET of the Swiss Federal Office of Energy. SUMMARY
Investigating outdoor airflow and pollutant dispersion in building areas is crucial for protecting public health. The inherent variability of wind conditions introduces significant uncertainty into airflow and pollutant dispersion around buildings. Previous studies addressed this variability by performing multiple simulations under different wind conditions, which substantially increases computational time. To address this challenge, this study employs the Polynomial Chaos Expansion (PCE) method to develop surrogate model for predicting outdoor airflow velocity and pollutant concentration under varying wind conditions. The surrogate model approximates velocity and concentration by expanding orthogonal polynomials, with wind direction and wind speed as input variables. The correlation coefficient between the surrogate model and the original simulation results ranges from 0.95 to 0.98, verifying the model's accuracy. This surrogate model enables rapid calculations of airflow velocity and pollutant concentration, establishing the response surface of these variables with respect to wind conditions. By avoiding the necessity for repeated, computationally demanding simulations, this method facilitates direct and efficient predictions of outdoor environments. Consequently, it provides a fast, comprehensive, and accurate tool for predicting airflow and pollutant dispersion in urban environments.
Keywords: Urban airflow and pollutant, Varying wind conditions, Surrogate model.

1. INTRODUCTION

With the advancement of industrialization, emissions of pollutants such as CO, SO_2, and NO_x have significantly increased (Li et al., 2018). These pollutants disperse into the surrounding environment, infiltrating buildings and degrading air quality (Li et al., 2020). Research indicates that air pollution can irritate the respiratory system, contributing to chronic diseases, and premature mortality (Saleh et al., 2020). According to a 2016 report by the World Health Organization, air pollution is responsible for approximately 4.2 million deaths annually, ranking it as the sixth leading cause of death worldwide (WHO, 2016). Therefore, investigating pollutant dispersion in urban areas is essential for mitigating health risks and enhancing living conditions.

Computational fluid dynamics (CFD) is widely recognized as an efficient method for simulating airflow and pollutant dispersion in outdoor environments (Liu et al., 2022; Dai et al., 2022, 2023). Studies have simulated airflow and pollutant dispersion around buildings under various scenarios

(Oaks et al., 2021). Previous simulations often rely on prevailing wind direction and speed. However, actual wind conditions are dynamic and frequently fluctuate, introducing uncertainty into outdoor wind environments (Yassin et al., 2005). Simulations based on prevailing wind conditions may provide probable outcomes but fail to capture the impact of wind variability. Thus, investigating airflow and pollutant dispersion under varying wind conditions is essential.

Methods for investigating outdoor environment under varying wind conditions include the local expansion method, sampling methods, and surrogate models (Paudel et al., 2022; Wang et al., 2021). The local expansion method linearizes responses near a reference point using a Taylor series, providing statistical insights into the results (Paudel et al., 2022). However, it tends to amplify uncertainties, limiting its applicability to scenarios with high nonlinearity (Wilson et al., 2013). Its accuracy declines under strong nonlinear variations, such as those induced by fluctuating wind conditions. Sampling methods are approaches which conduct simulation under various wind conditions and evaluate the corresponding result (Wang et al., 2021). A study uses simulations under varying wind directions to analyze pollutant dispersion distribution (Jon et al., 2023). However, these studies are often constrained by limited sample sizes, leading to predominantly qualitative conclusions. Additionally, re-simulations for new conditions are required, which are computationally inefficient in large-scale outdoor environments. In contrast, surrogate models are efficient method for studying airflow and pollutant dispersion under varying wind conditions. Common surrogate models include Kriging, neural networks, and Polynomial Chaos Expansion (PCE), with PCE distinguished by its lower computational demands and physical interpretability, making it widely adopted in built environment research (Wiener, 1938; Mohamed, 2025).

Surrogate models based on polynomial chaos expansion have been increasingly applied to predict building environments (Sun et al., 2017). It establishes relationships between outdoor velocity, pollutant concentration, and wind conditions to quantify the impact of wind variability. For instance, it was employed to compare numerical simulations with field experiments conducted in downtown Oklahoma City under uncertain inflow conditions and to evaluate the impact of inflow variability on airflow within urban canopies (Garcia-Sanchez et al., 2014, 2017). However, these studies demanded numerous simulation results, leading to significant computational costs Therefore, further optimization of this method is necessary to improve prediction efficiency.

In conclusion, prior research on airflow and pollutant dispersion under varying wind conditions has predominantly relied on extensive and repetitive simulations, which limits its applicability to real-world scenarios. This study aimed to apply surrogate models based on polynomial chaos expansion to enhance efficiency and broaden practical applications. Significant advancements were achieved through the implementation of an innovative truncation scheme, which effectively reduced simulation times. The validity of this method was demonstrated using two benchmark building cases different degrees of building geometric complexity. This approach enables direct and rapid predictions of air velocity and pollutant concentration while avoiding repeated simulations under varying wind conditions, thereby significantly enhancing computational efficiency. Consequently, this method offers more comprehensive insights into airflow and pollutant dispersion in outdoor building environments.

2. METHOD

The surrogate model based on polynomial chaos expansion is an effective tool for evaluating air velocity and pollutant concentration under varying wind conditions. This section introduces the method, emphasizing its four key components: the determination of orthogonal polynomials, hyperbolic truncation, coefficient calculation, and practical application. In this approach, velocity and concentration are represented as polynomial expansions of wind direction and speed (Wiener, 1938; Cameron et al., 1945):

$$R = F(x) = c_0\Phi_0 + \sum_{i_1=1}^{\infty} c_{i_1}\Phi_{i_1}(x_1) + \sum_{i_2=1}^{\infty} c_{i_2}\Phi_{i_2}(x_2) + \sum_{i_1=1}^{\infty}\sum_{i_2=1}^{i_1} c_{i_1 i_2}\Phi_{i_1 i_2}(x_1, x_2) \quad (1)$$

where R are the velocity and concentration results; x_1 and x_2 represent the variables of wind direction and speed, respectively; $\Phi_{i_1}(x_1)$ and $\Phi_{i_2}(x_2)$ represent the two orthogonal polynomials corresponding to the wind direction and speed, respectively. Here $\Phi_{i_1 i_2}(x_1, x_2)$ is the product combination of these two orthogonal polynomials of order i_1 and i_2, which are determined through a hyperbolic truncation scheme. c are the coefficients calculated with regression method.

2.1. Determination of Orthogonal Polynomial

The determination of orthogonal polynomials is a crucial step in polynomial chaos expansion. Various types of orthogonal polynomials are available, and their selection depends on matching the weight function with the probability density distribution of the variables (Xiu et al., 2002). For cases where wind direction and speed follow ideal distributions, previous studies have identified their corresponding orthogonal polynomials, as summarized in Table 1 (Xiu, 2010).

Table 1. Summary of orthogonal polynomials corresponding to ideal distributions

Distribution type	Normal distribution	Uniform distribution	Beta distribution	Index distribution
Corresponding orthogonal polynomial	Hermite $H_i(x)$	Legendre $P_i(x)$	Jacobi $J_i(x)$	Laguerre $L_i(x)$

For non-ideal distributions, the λ-PDF distribution (Ma et al., 2004) is a general framework for probability density functions that are unimodal, bounded, and symmetric within the interval [-1,1]. Its formulation, along with the corresponding Gegenbauer orthogonal polynomial (Fang et al., 2004), are defined as follows:

$$f_\xi^\lambda(\xi) = \begin{cases} k_\lambda(1-\xi^2)^{\lambda-1/2}, & |\xi| \le 1 \\ 0, & |\xi| > 1 \end{cases} \quad (2)$$

$$G_i^\lambda(\xi) = \sum_{d=0}^{i} \frac{1}{d!(i-d)!} \frac{(2\lambda)_i (2\lambda+i)_d}{(\lambda+1/2)_d} \left(\frac{\xi-1}{2}\right)^d, \quad i = 0,1,2,\ldots \quad (3)$$

2.2. Hyperbolic Truncation Scheme

The expanded polynomial for velocity and concentration initially comprises an infinite number of terms with varying degrees of influence. While increasing the number of terms improves accuracy, it also requires a larger number of samples. To address this, a hyperbolic truncation scheme (Montgomery, 2004) is applied to reduce the expansion to a finite set of terms by retaining influential low-order terms while eliminating less significant high-order ones, thereby achieving a balance between accuracy and computational efficiency. In this scheme, the q-norm of the variable order vector is constrained to remain below the overall truncation order (Blatman, 2009):

$$||i||_q = (i_1^q + i_2^q)^{\frac{1}{q}} \le d \quad (4)$$

where d is the overall truncation order, $i = (i_1, i_2)$ the order vector of the orthogonal polynomial corresponding to wind direction and speed, and q the truncation norm, in the range of [0, 1]. The orthogonal polynomials, whose orders satisfy the aforementioned relationship, are substituted into Expression (1), thereby completing the fundamental structure of the truncated polynomial.

2.3. Coefficient Determination

The above procedures establish a formula relating velocity, concentration, and wind conditions with undetermined coefficients. By substituting wind conditions and their corresponding

simulation results into the formula, a system of equations is obtained. These coefficients are determined by solving this system through regression method, minimizing the residual mean squared error between the simulated and predicted results. (N$\ddot{a}$ther, 2010):

$$c = argminE[\varepsilon^2] = argmin\frac{1}{N}\sum_{i=0}^{N}[(Y - \sum_{i=0}^{N} c_i\Phi_i)^2] = (\Phi^T\Phi)^{-1}\Phi^T\mathrm{Y} \quad (5)$$

where ε^2 represents the squared residuals; Y the simulation result; Φ the orthogonal polynomial corresponding to the wind variables; and N the number of simulations. The simulations are performed using FFD with the ANN dynamic Smagorinsky model (Dai et al., 2023) in OpenFOAM (Weller et al., 1998).

2.4. Application of the Method

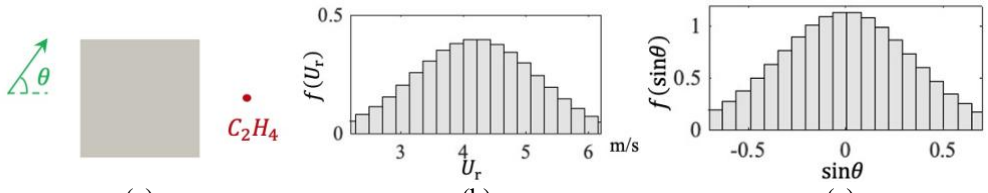
By substituting the determined coefficients into the expression, surrogate models are constructed to represent velocity and concentration as functions of wind conditions. These models enable the rapid prediction of velocity and concentration under varying wind scenarios. Their accuracy is validated through comparisons with experimental and simulation data. Overall, this approach offers an efficient and comprehensive framework for investigating airflow and pollutant dispersion in outdoor environments.

3. RESULT

This section evaluates the performance of the surrogate model based on polynomial chaos expansion under varying wind conditions in both single-building and three-building scenarios.

3.1. Single Building Case

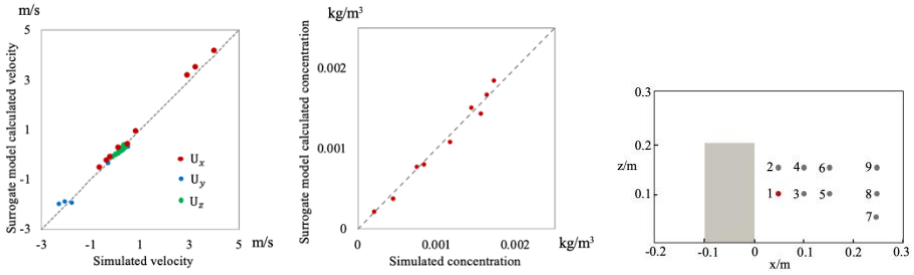
The single-building case, shown in Fig. 1(a), is a classic benchmark for outdoor environment studies (Tanaka et al., 2006). The airflow follows a power-law profile with an exponent of α = 1/4. To analyze airflow and pollutant dispersion under varying wind conditions in this case, wind speed and the sine of the wind direction are assumed to follow a normal distribution, as shown in Fig. 1(b, c).



(a) (b) (c)

Figure 1. (a) Geometric configuration and probability density distributions of the (b) wind speed and (c) sine value of the wind direction in the single-building case.

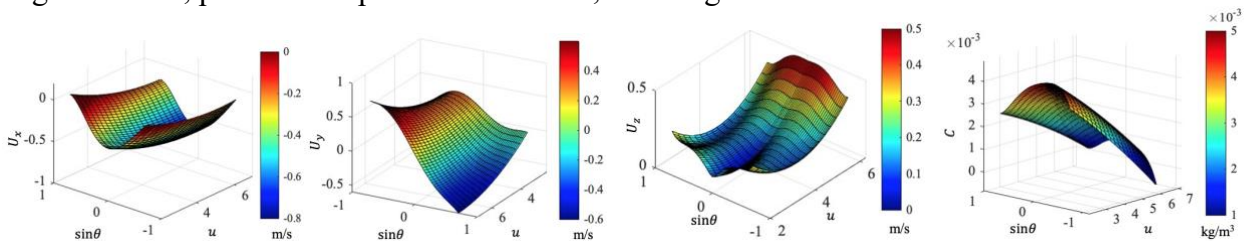
Figure 2 presents the correlation analysis between surrogate model and simulation results for the three velocity components and concentration at sampling points 1–9 (Fig. 2c). The inflow wind velocity was 4.74 m/s, with a wind direction angle θ = -21.1°. The figure demonstrates a strong correlation between the surrogate model and simulation results, with correlation coefficients for velocity and concentration exceeding 0.98 for velocity and 0.97 for concentration. In the wind tunnel experiment, the wind speed was 4.2 m/s, and the wind direction angle was 0°. A comparison between the experimental and surrogate model results under this condition showed errors of 5.1% and 8.4% for velocity and concentration, respectively. These results validate the surrogate model's high accuracy and reliability.



(a) (b) (c)

Figure 2. Correlation analysis between surrogate model calculated results and simulation results for (a) velocity components in three directions, (b) concentration at 9 sampling points, and (c) locations of the sampling points.

After deriving accurate surrogate model, the distributions of velocity components and concentration with respect to wind speed and direction were analyzed. Taking point 1 (0.1, 0, 0.1) as an example, Fig. 9 illustrates the distribution of its velocity and concentration, with the two horizontal axes representing wind speed and the sine of the wind direction. Since point 1 is located on the center plane of the recirculation zone behind the building and the wind direction varies within the range of [-45°, 45°], U_x remains negative and symmetric about the 0° wind direction plane. The reverse velocity decreases with increasing direction angle but increases with higher wind speed. For U_y, its absolute value increases with both wind speed and wind-direction angle. U_z increases with wind speed and remains positive, as this point is situated in the upwelling airflow region near the building's leeward side. The concentration decreases as wind speed and direction angle increase. At low wind speeds and small wind-direction angles, pollutants accumulate in the recirculation zone behind the building. In contrast, as wind speed and direction angle increase, pollutant dispersion intensifies, reducing concentration at this location.

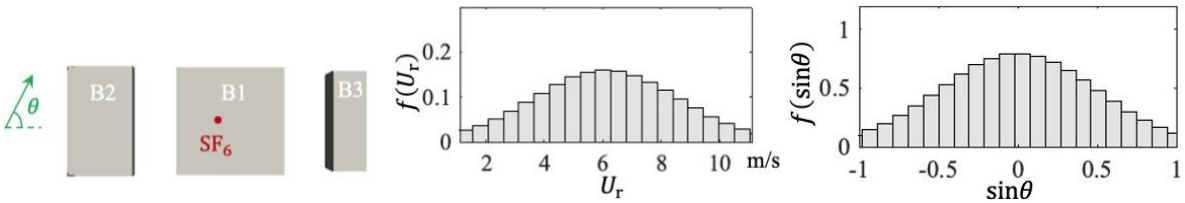


(a) (b) (c) (d)

Figure 3. Distributions of (a)U_x, (b)U_y, (c)U_z, and (d) concentration with respect to wind speed and direction.

3.2. Three-building Case

The geometry of the three-building case (Chavez et al., 2011) is shown in Fig. 4(a). The geometry is more complex, considering interactions between buildings, making it closer to real urban environments. The airflow followed a power-law profile with α = 1/3. To analyze the airflow and pollutant dispersion under varying wind conditions in this case, wind speed and the sine of wind direction were assumed to follow a normal distribution, as illustrated in Fig. 4(b, c). Compared to the single-building case, the three-building case demonstrated a wider range of wind speeds and directions, allowing for evaluation of the surrogate model under more diverse conditions.



(a) (b) (c)

Figure 4. (a) Geometric configuration and probability density distributions of the (b) wind speed and (c) sine value of the wind direction in the three-building case.

Fig. 5 presents a correlation analysis between the surrogate model predictions and simulation results. The analysis includes the three velocity components and concentration at the red sampling points shown in Fig. 5(e) under three different wind conditions. In these validation cases, wind speeds range from 4.8 m/s to 8.7 m/s, while wind direction angles vary between -14° and 8°. As illustrated in the figure, the velocity and concentration values predicted by the surrogate model show a strong correlation with the simulation results, with correlation coefficients exceeding 0.95, thereby confirming the model's accuracy. Since the wind-tunnel experiments measured concentration values at only a few wall points, which were not representative, no comparison with the surrogate model predictions was conducted.

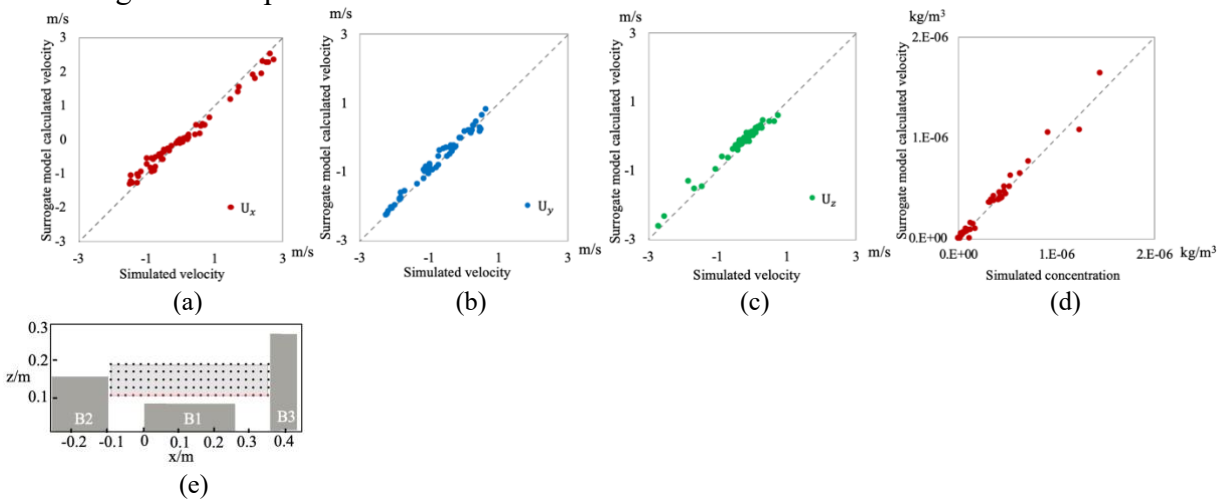


Figure 5. Correlation analysis between surrogate model calculated results and simulation results for(a) U_x, (b) U_y, (c) U_z, and (d) concentration under three different wind conditions, and (e) the locations of the sampling points.

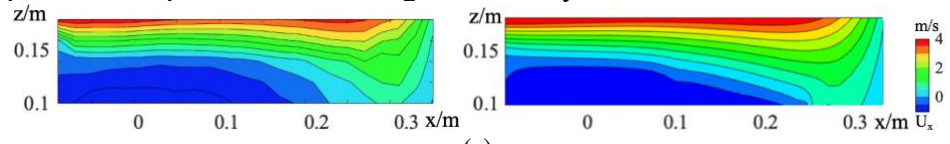
Figure 6 illustrates the velocity and concentration contours obtained from surrogate model calculations and simulations within the shaded region of Fig. 5(e). The surrogate model contours were generated based on the results of sampling points. The wind condition was a velocity of 6.77 m/s and direction angle θ of -3.4°. A recirculation zone formed in this case due to the influence of the B2 building. In the U_x contour, the flow transitioned from forward to reverse as altitude decreased, with smaller values observed in the rear due to obstruction by the B3 building. In the U_y contour, the negative direction angle produced negative values in the rear, while recirculation flow generated small positive values in the front. For U_z, the recirculation created downward velocities in the rear and upward velocities in the front, with higher vertical velocities near the chimney due to its high release velocity. In the concentration contour, pollutants spread forward with the reverse airflow and dispersed along the recirculation zone, as the chimney was located at the bottom of this zone. These results demonstrate that the surrogate model accurately captures airflow and pollutant dispersion, confirming its accuracy.



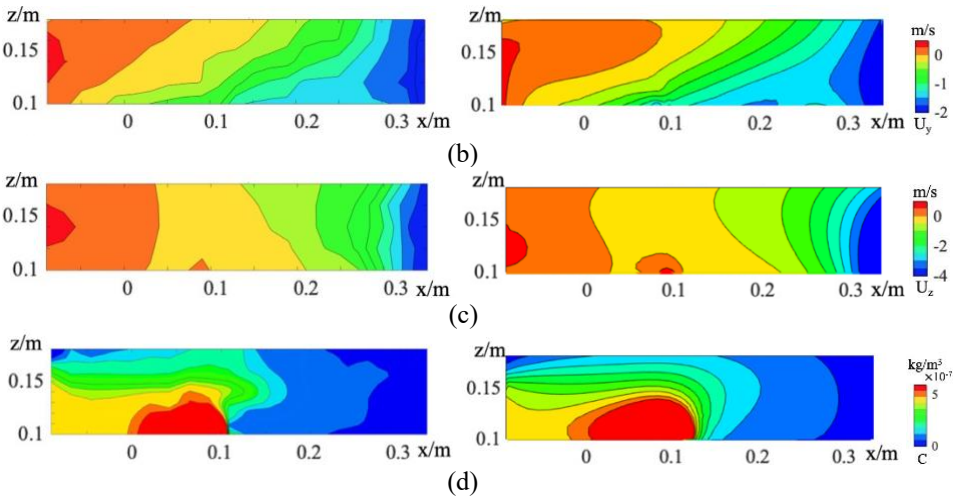


Figure 6. Contours for (a) U_x, (b) U_y and (c) U_z, and (d) the concentration obtained from surrogate model calculation (left) and simulation (right).

4. CONCLUSION

This study utilized surrogate model based on polynomial chaos expansion to investigate the effects of varying wind conditions on air velocity and pollutant concentration. The surrogate model was constructed to represent air velocity and pollutant concentration as functions of wind conditions. Correlation coefficients between the surrogate model and simulation results, ranging from 0.95 to 0.98, demonstrate the model's high accuracy. This approach enables rapid predictions and facilitates uncertainty analysis of airflow and pollutant concentration in outdoor environments under varying wind scenarios.

Due to space limitations, this study focused on validating the model using idealized cases with specific wind distributions. Future work can extend the model's application to more complex real-world building scenarios under actual wind conditions, incorporating measurements and case studies for further validation.

In conclusion, this method allows for direct and efficient predictions of outdoor airflow and pollutant dispersion, eliminating the need for repeated simulations under varying wind conditions and significantly improving computational efficiency. In summary, it provides comprehensive insights into airflow and pollution dispersion in urban environments.

Influence of modelled urban features in CFD simulations for wind microclimate assessments

N.J.V. Vlaun [1], R.P.W. Maas [1], T.C. Fahner [1]

[1] *Actiflow B.V., Breda, The Netherlands, contact@actiflow.com*

SUMMARY
This investigation compares several CFD simulations of a given urban high-rise context (downtown Rotterdam), where the environment is represented differently in each model variant. An assessment region is defined that includes building geometries, while the surroundings within the computational domain are described by roughness parameters. The dimensions of the domain and assessment region are changed in each variant to assess the influence of modelled urban features on the simulated flow fields. The results of this study show that models set up according to known guidelines, where the assessment region is typically limited to a few hundred metres across, significantly overestimate both the wind speeds and exceedance probabilities, compared to a model in which the entire city district is reconstructed. This research serves to expand on procedures and guidelines for urban wind microclimate assessments.

Keywords: urban microclimate, pedestrian wind comfort, computational fluid dynamics (CFD), 3D city modelling.

1. INTRODUCTION

With increasing attention to urban microclimate, driven in part by continuous urbanization and the subsequent densification of major cities, wind microclimate assessment has become critical to urban planning and design. Especially high-rise buildings are known to cause high wind velocities at the pedestrian level frequently leading to uncomfortable and even dangerous wind conditions in urban areas (Hågbo & Giljarhus, 2024). Such wind microclimate assessments are generally performed on physical scale models through wind tunnel testing or full-scale digital models through computational fluid dynamics (CFD) of an urban configuration. The study area is typically limited to a few hundred meters (Blocken, 2015; Liu et al., 2018). Model dimensions vary based on the height of a given target building, the composition of its surroundings and the detail needed to capture local flow phenomena to adequately predict wind comfort or distress and, traditionally, size restrictions of an atmospheric boundary layer wind tunnel. As only a limited area is tested in a typical assessment, wind flow patterns on a district or city level are inherently not captured.

The use of CFD simulations has become the dominant approach in urban microclimate studies, due to advancements in high-performance computing, which makes CFD increasingly accessible and affordable (Abu-Zidan et al., 2021; Yang et al., 2023; Hågbo & Giljarhus, 2024). Its application is however not trivial and requires many choices to be made by the user – including but not limited to the geometrical implementation of the model, sizing the computational domain, and setting appropriate boundary conditions – all of which can have a large impact on the accuracy of the results (Blocken, 2015). For purposes of quality assurance, best practice guidelines for the application of CFD have been established in scientific literature, such as Franke et al. (2007), Tominaga et al. (2008) and Blocken (2015). The question arises whether these are fully applicable

to district-scale assessments when the size of the modelled area and the number of geometries considered are both drastically increased. In this investigation we thus focus on the size of the assessment region and how buildings within are represented. Existing guidelines mostly define a minimum area to be explicitly modelled around a given target building. Tominaga et al. (2008) suggests that all buildings within the region to be assessed should be clearly reproduced and that said assessment region typically has a radius of 1 to 2 times the height of the target building, plus one additional street block in each direction. Tong et al. (2016) defines the influence region as typically two or three layers of surrounding buildings to be modelled depending on urban configuration and wind direction. Liu et al. (2018) concludes that the region within a radius of at least 3 times the maximum dimension of the target building should be simulated with detailed building structures. The Dutch NEN 8100 (2006) standard for the classification of wind comfort, defines a 'sphere of influence' as the area with a radius 6 times the height of the target structure and mandates that the surrounding buildings within a radius of at least 250 m to 300 m be modelled. Maximum dimensions for neither the assessment region nor domain boundaries are given in literature as increasing either is generally considered to be laborious and computationally inefficient (Abu-Zidan et al., 2021; Pađen et al., 2022). The effects of urban features outside the assessment region are instead accounted for through prescribing aerodynamic roughness lengths (Blocken et al., 2007; Liu et al., 2018; Ricci et al., 2020).

In this study we investigate the influence of modelled urban features, such as surrounding buildings and terrain, on the simulated flow fields of a typical pedestrian wind comfort study. This is done by comparing several CFD models of the same location, each set up with different domain sizes and varying number of buildings (i.e. varying the size of the assessment region). As such, we aim to quantify this influence and assess the applicability of existing guidelines to wind microclimate assessments conducted in complex urban contexts at larger scales.

2. RESEARCH METHOD

2.1 Geometric model

A detailed geometric model of downtown Rotterdam, the Netherlands serves as our base model. This model, shown in Fig. 1, covers a total area of roughly 20 km² and includes several districts with distinct urban morphologies from low-rise residential and industrial zones to the city centre with high-rise buildings up to 215 m tall.

The computational model is a cylindrical domain with a height of 800 m and a radius of 4.0 km. In its centre, within a 5.5 km wide circular area, all buildings (3,200 in total) and trees are modelled explicitly. The input geometry is constructed from open geodata including topographical maps, aerial photos, LiDAR scans and building model databases. Structures were added manually where data was missing or resulted in overly complex geometries. In the remaining outer region, the built environment is represented by roughness lengths assigned to the bottom of the domain. This outer ring serves as upstream or downstream region depending on the wind direction. The assigned roughness lengths, shown in Fig. 2, are in accordance with Dutch guideline NPR 6097 (2006) and generally categorize subregions by building height, terrain typology and urban density.

Figure 1. Base model and mesh section for the wind assessment of downtown Rotterdam, the Netherlands.

For the purposes of this study, two more models were created from the base model in Fig. 2(a). In the variant shown in Fig. 2(b) the assessment region (AR) is decreased to a radius of 300 m while the size of the computational domain is unchanged. Buildings outside the assessment region are simplified into flat terrain with roughness lengths assigned. In the third variant, see Fig. 2(c), the domain is decreased to 3.0 km diameter, which is a typical setup for a pedestrian wind comfort study following the NEN 8100 standard, also adhering to best practice guidelines on domain sizing (Franke et al., 2007). Directly comparing these three cases provides insight into the effects of domain size and building geometries on the results of microclimate assessments.

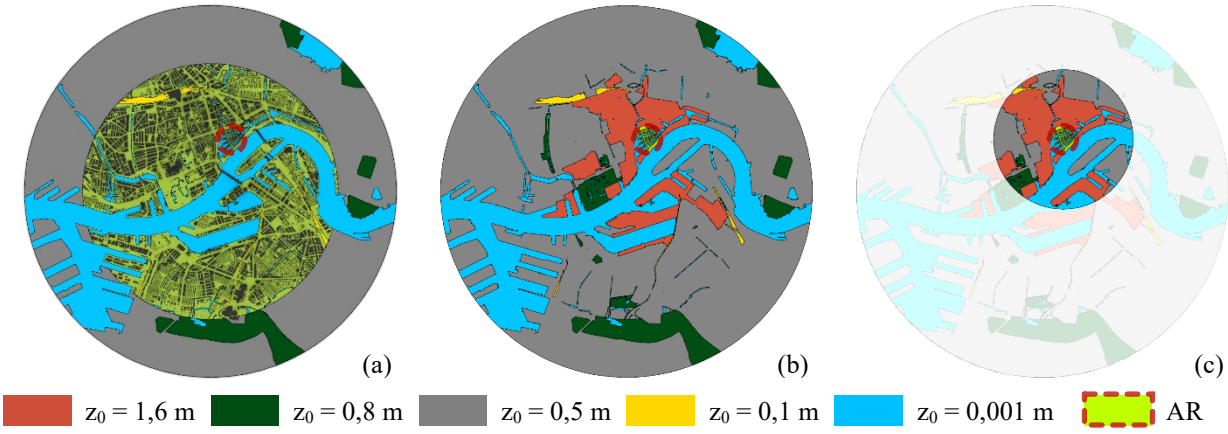

Figure 2. Roughness lengths assigned to the geometric models.

2.2 Computational mesh

The computational meshes for the CFD simulations of each case were generated using snappyHexMesh from OpenFOAM v2312. A conformal hexcore mesh with polyhedral cells between different levels of refinement is utilized in each model variant. The maximum grid size is 64 m near the domain perimeters, and the smallest surface cells have an edge length of 0.25 m to describe detailed features. Edge sizes on the bottom plane in the assessment region are 1 m to 2 m wide. Cell sizes on the buildings in the centre of the domain typically vary between 0.5 m to 4 m,

except for the small 0.25 m features mentioned above. Prismatic layers are added on all walls, of both terrain and buildings. Vegetation is modelled using porous zones that are created at the meshing stage, with cell sizes that vary between 0.5 m and 2 m. This resulted in a final mesh of 583 million cells for the base model. Using the same method, the mesh sizes for the models in Fig. 2(b) and Fig. 2(c) are 20.6 million and 18.6 million, respectively.

2.3 Boundary conditions

A neutral atmospheric boundary layer (ABL) profile is prescribed at the inflow boundary of the cylindrical domain, while the outflow boundary is prescribed as a pressure outlet. Turbulence profiles for the ABL are added at the inflow boundary, with a zero normal gradient outflow. Turbulence close to walls is modelled using wall functions. On the implicitly modelled areas, roughness was used to maintain the ABL up to the explicitly modelled assessment region. Turbulence is modelled using the k-ω SST model (Menter et al., 2003). Velocity profiles and turbulence quantities are set according to the following expressions (Richards & Hoxey, 1993; Yang et al., 2009):

$$U = \frac{u^*}{\kappa} \ln\left(\frac{z + z_0}{z_0}\right) \tag{1}$$

$$u^* = \frac{U_{ref}\,\kappa}{\ln\left(\frac{z_{ref} + z_0}{z_0}\right)} \tag{2}$$

$$k = \frac{(u^*)^2}{\sqrt{C_\mu}} \tag{3}$$

$$\omega = \frac{u^*}{\kappa\sqrt{C_\mu}} \frac{1}{z + z_0} \tag{4}$$

In the simulations, a reference wind speed U_{ref} of 5 m·s^{-1} is set at the domain boundary at a reference height z_{ref} of 60 m. Eq. 1 and Eq. 2 describe the velocity profile, where U is the horizontal wind speed, u^* is the friction velocity, z is the height from ground level, z_0 is the aerodynamic roughness length and κ is the "von Kármán" constant (= 0.41). The turbulent kinetic energy k and specific turbulent dissipation rate ω profiles at the inflow part of the domain are calculated using Eq. 3 and Eq. 4. C_μ is a turbulence model constant (= 0.09).

2.4 CFD model

The simulations are performed using the simpleFoam solver from OpenFOAM v2312. This is a steady-state solver for turbulent incompressible flows. For the base model, convergence is determined by monitoring the forces acting on the various bridge structures within the model. When the drag coefficient of these bridges varied by less than 1 count the solutions were considered converged. An additional 500 iterations were run and averaged to reach the presented results. Per model 24 (2×12) simulations are performed to account for all wind directions and different vegetation states. The simulations for the base model had a computational cost of around 7,300 core-hours each on Actiflow's cloud cluster using AWS parallelCluster technology. For models 2(b) and 2(c), the simulations ran on Actiflow's in-house HPC cluster, where each simulation had a cost of approximately 150 core-hours.

2.4.1. Numerical setup

The SIMPLEC algorithm was chosen for the pressure-momentum coupling, while the pressure equation was solved using the Geometric agglomerated algebraic multi-grid (GAMG) method with Gauss-Seidel smoothing. The momentum and turbulence equations were solved using the Preconditioned Bi-conjugate gradient stabilised solver using the Diagonal-based Incomplete Lower-Upper preconditioner.

2.4.2. Post-processing with historical wind data

To assess ground-level wind conditions each model variant is simulated from 12 wind directions, in increments of 30°, as outlined by the NEN 8100 standard. The simulated velocity fields are processed using statistical meteorological data for Rotterdam taken from two different datasets: the Dutch Offshore Wind Atlas (DOWA) time series files from 2008-2017 (Wijnant et al. 2019), and wind statistics from the NPR 6097 guideline covering the period of 1963-2002. The latter specifically takes land use into account and its use is mandated for pedestrian wind comfort studies in the Netherlands.

3. RESULTS

The simulation results are shown in Table 1 and Fig. 3 at a height of 1.75 m above ground level, for the same assessment region (r = 300 m) in each model variant. To clarify, the base model is thus the only variant in which surrounding buildings outside of this region are modelled explicitly. Models 2(b) and 2(c) show both a significantly higher average wind speed (increase of 18-32%) and a significantly higher exceedance probability for the 5 $m \cdot s^{-1}$ threshold wind speed (mean value increase of 81-113%) in the assessment region, compared to the base model.

Table 1. Simulation results: mean values within r = 300 m assessment region of the average local wind speed (U_{loc}) and exceedance probability of 5 $m \cdot s^{-1}$ threshold wind speed (p), at 1.75 m height.

		DOWA		NPR 6097	
	base model	model 2(b)	model 2(c)	model 2(b)	model 2(c)
Local wind speed U_{loc} $[m \cdot s^{-1}]$	1.64	2.16	2.15	1.93	1.93
Difference ΔU_{loc}	--	+ 0.52	+ 0.51	+ 0.29	+ 0.29
Exceedance probability p [%]	2.96	6.31	5.96	5.58	5.37
Difference Δp	--	+ 3.35	+ 3.00	+ 2.62	+ 2.41

The average wind speed across the assessment region is visualised in the first row of Fig. 3(a1-d1) with the second row, Fig. 3(b2-d2), showing the deviation of the results from the base model for each variant. In models 2(b) and 2(c) average wind speeds are overpredicted by up to 1.5 $m \cdot s^{-1}$ compared to the base model. The exception to this is the southeastern part of the assessment region, where the predicted wind speeds are less than those found in the base model simulation. A similar trend is found for the exceedance probability, which is visualised in the third row of Fig. 3(a3-d3). The final row, Fig. 3(b4-d4), displays the relative difference of the exceedance probabilities between the base and comparison models, showing a deviation up to 15 % in some areas.

The comparison indicates that explicit modelling of features outside the assessment region in the base model has a significantly higher influence on the approach flow than those cases where the surroundings are solely described by roughness. As models 2(b) and 2(c) only differ in the distance from the assessment region to the domain boundary, while both have a close match in their results, increasing the surrounding areas does not seem to notably alter the outcomes.

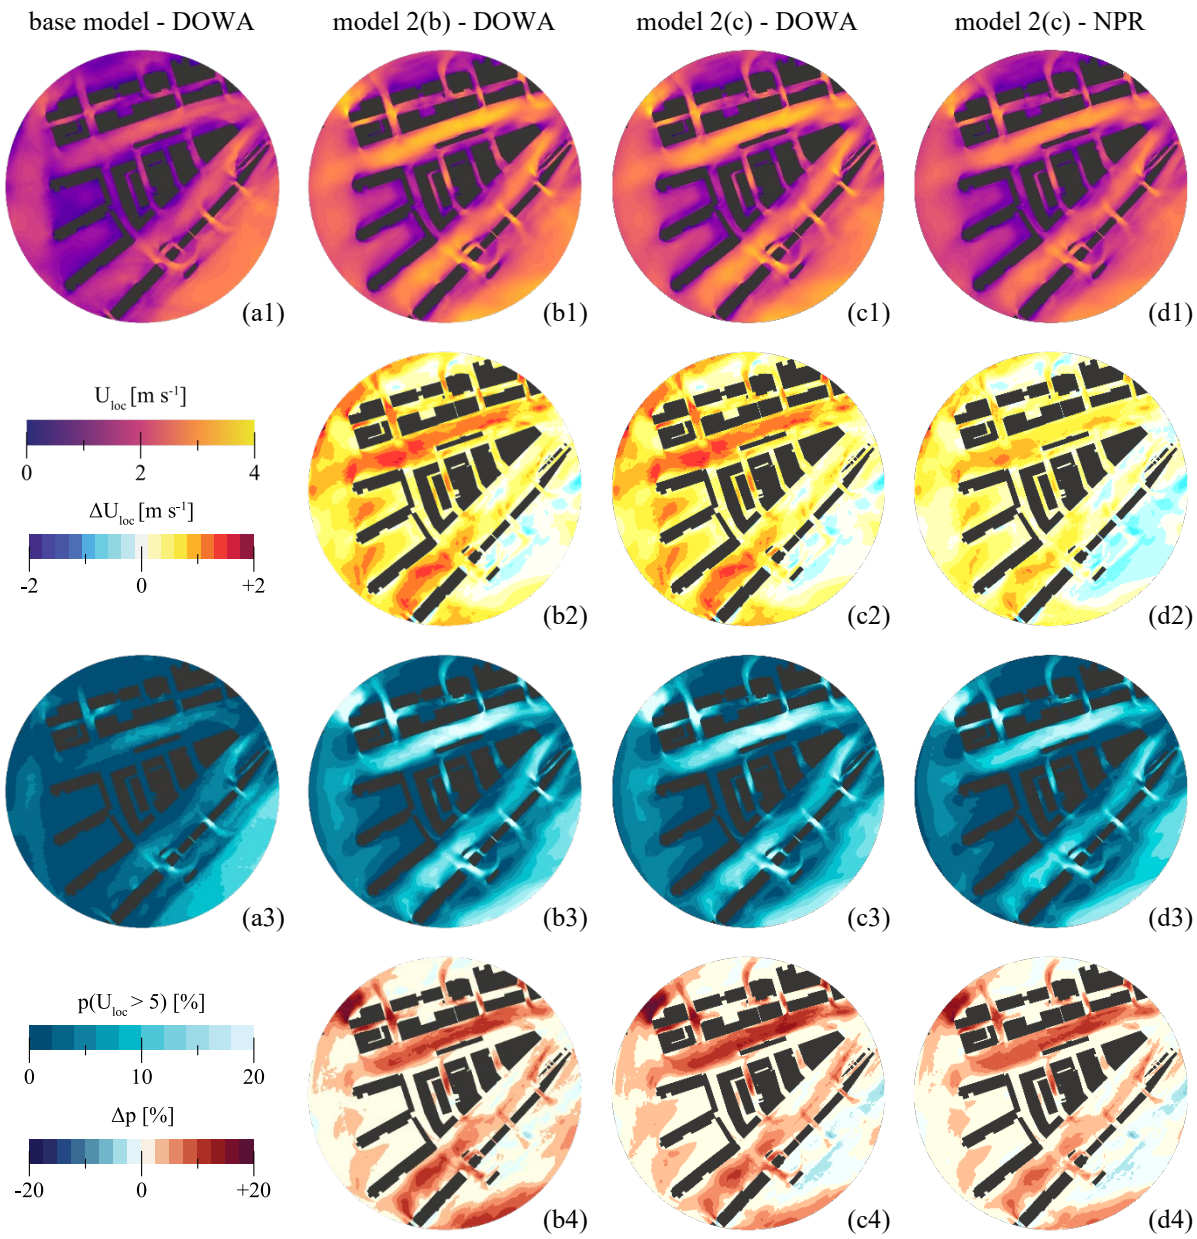

Figure 3. Simulation results for r = 300 m assessment region.

In Fig. 4, pedestrian wind comfort classification according to the Lawson LDDC and NEN 8100 criteria is projected onto the simulation results. These maps show a discrepancy between the models of up to 2 (Lawson LDDC) or 3 (NEN 8100) wind comfort classes.

4. DISCUSSION

As the results shown in Fig. 3(a1-c4) are processed from the same wind statistics, the differences between the variants are found in the calculated wind velocities. Care must also be taken when interpreting these results, as the relationship between local wind speed and exceedance probability

is not linear. The biggest differences in average wind speeds are found in street canyons with their axis aligned to the prevailing southwestern wind direction. The assessment region is relatively open when isolated from its surroundings. In reality, and as shown in the base model, this region is situated within a densely built-up urban centre, several kilometres wide, including multiple clusters of high-rise buildings. Shielding effects from buildings close or adjacent to the assessment region do not seem to be captured properly by parameterization into roughness lengths.

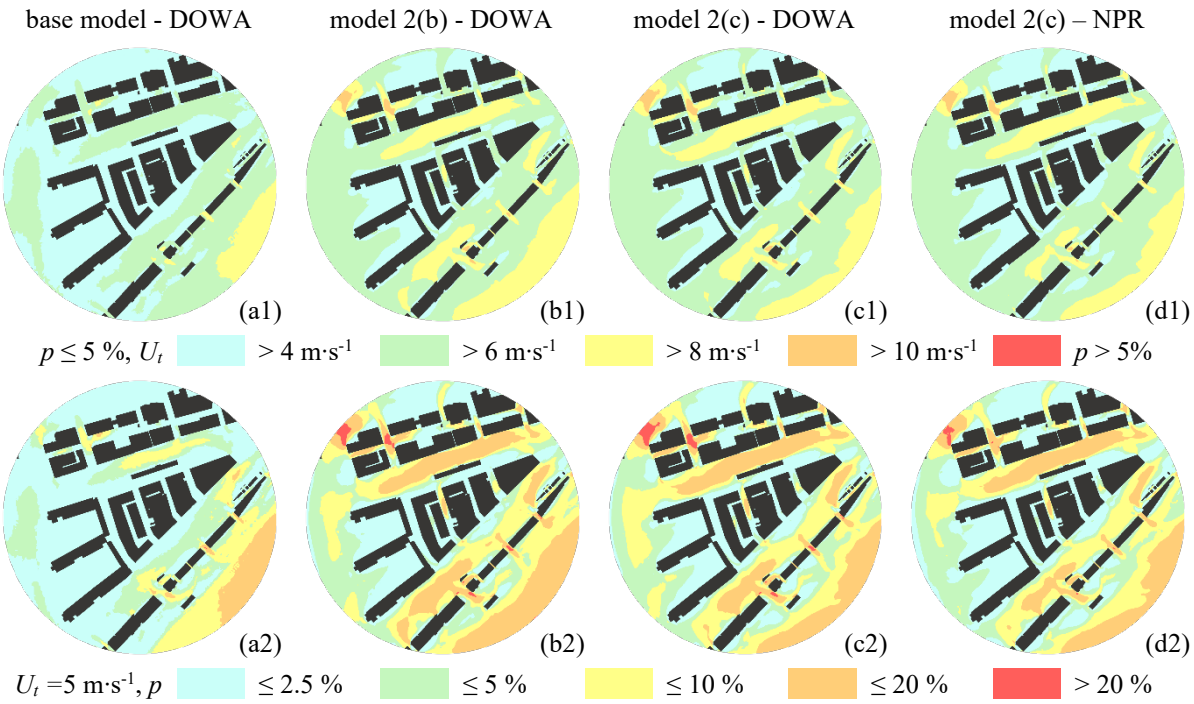

Figure 4. Pedestrian wind comfort maps based on Lawson LDDC (above) and NEN 8100 (below) comfort criteria.

The effect of the utilized wind statistics is also considered. The NPR 6097 guideline provides statistical wind data for any location in the Netherlands, based on a potential wind speed at a height of 60 m, accounting for land use. The variants processed with this data show improved agreement to the base model, as shown in the rightmost columns of Fig. 3(d1-d4) and Fig. 4(d1-d2), though the differences for both wind speed and exceedance probability remain significant. Since this study considers a single urban configuration, it remains an open question whether another configuration will yield similar trends and discrepancies. To further quantify the influence of modelled urban features (or lack thereof) in CFD studies, more configurations, different contexts, and varying model sizes should be considered.

5. CONCLUSION

This study compared CFD models of the same location, each set up with different domain sizes and varying number of buildings, to investigate the influence of modelled urban features on a typical pedestrian wind comfort assessment. It is found that typical models, in which building geometries outside of a small assessment region are excluded, significantly overestimate both the average wind speed and the exceedance probability, compared to a model of the same location in

which the entire city district is reconstructed. Part of this difference can be explained by consideration of wind statistics but is mainly due to the omission of (large) objects in the wider surroundings. In cases where no building geometries are added outside the assessment region and the surrounding areas are described purely through roughness parameters, increasing the domain size beyond standard practice has almost negligible effects on the results. For dense urban environments with many high-rise structures, a reconsideration of procedures for wind microclimate assessments may be appropriate. These findings should be justified by comparison with measurements or by examining a wider range of urban configurations and different cities.

ACKNOWLEDGEMENTS

The authors of this paper express their gratitude toward the municipality of Rotterdam who funded part of this research through the 'Kennis en Innovatiefonds'. More specifically we like to thank Simone Tax who was the driving force behind starting this research and who stands side by side with us to disseminate knowledge of wind as a key factor in urban climate to a broad audience.

SUMMARY
Heat waves are growing more frequently and intensely worldwide, with urban areas especially vulnerable due to the urban heat island (UHI) effect. This study evaluated the cooling potential of various green and blue infrastructure configurations within a redevelopment zone in Seoul using ENVI-met simulations. The analysis compared multiple scenarios of park development, incorporating different vegetation types with and without water features. Results demonstrated that plane trees exhibited superior cooling performance to ginkgo and grass coverage. Integrating water bodies with vegetation significantly enhanced cooling effectiveness across all scenarios. These findings provide quantitative evidence for the importance of design and species selection for urban parks to mitigate extreme heat events.

Keywords: Heatwave, ENVI-met, Urban green and blue infrastructure

1. INTRODUCTION

Heat waves have intensified, becoming more frequent and prolonged across the world. For instance, in South Korea, the number of heatwave days in 2023 was 13.9—an increase of 3.6 days from the previous year. Consequently, 2,818 cases of heat-related illnesses were reported, including 32 fatalities (Korea Meteorological Administration, 2023).

The risk of heat waves is more critical in urban areas due to the urban heat island (UHI) effect (Luo et al., 2023; Xin et al., 2024). UHI is the phenomenon in which cities exhibit higher temperatures than surrounding rural areas (Oke et al., 1982). Hong et al., (2019) reported a UHI intensity of 2.5 ± 0.9°C during heatwaves, approximately 0.9°C higher than during non-heatwave periods. Park et al. (2023) analyzed 25-year (1997–2021) observations in Seoul and confirmed that such positive interactions between UHIs and heat waves have become frequent in recent years.

To reduce UHI intensity under heatwave events, urban green and blue infrastructure has emerged as a promising nature-based solution for heat mitigation. Vegetation provides cooling through transpiration and shading, whereas water bodies contribute via evaporation and thermal stratification (Budzik et al., 2025). Numerous studies have investigated the cooling effects of trees

and grasses in existing urban environments. However, there remains a significant research gap in comparing the performance of green and blue infrastructure in newly developed urban parks. To address this, the current study employed Computational Fluid Dynamics (CFD) methodology to quantify the cooling effects of various nature-based solutions. This research aimed to identify optimal combinations of vegetation types and water bodies for maximum cooling effectiveness.

2. METHODOLOGY

2.1. Site description

The study area is a densely populated, low-rise commercial district located in Seoul, South Korea (37.565°N 127.005°E). According to the Köppen-Geiger climate classification system, Seoul experiences a humid continental climate (Dwa), characterized by distinct seasonal variations in temperature and precipitation. The target area comprises 12,096.9m^2 within a larger 111,425m^2 redevelopment zone (refer to Fig. 1). This district has been identified as highly vulnerable to heatwaves based on thermal, demographic, and socioeconomic factors (Kim et al., 2021). Therefore, the area was selected for green space development to improve the thermal environment.

To measure the mitigation of UHI effects during heatwave events, a single-day simulation was performed using meteorological data from August 8, 2023—the hottest day recorded in Seoul that year. In South Korea, a heatwave warning is issued when the daily maximum apparent temperature is forecasted to remain at 33°C or higher for at least two consecutive days. On August 8, the highest temperature of the year was recorded at 35.8°C, and since the daily maximum temperature exceeded 33°C for 12 consecutive days, this period meets the criteria for classification as a heat wave. On this day, the minimum and maximum temperatures were 26.3℃ and 36.4℃, respectively, with relative humidity ranging from 40% to 66%. The daily average wind speed was 2.08 m/s, and the wind direction was 60.97° .

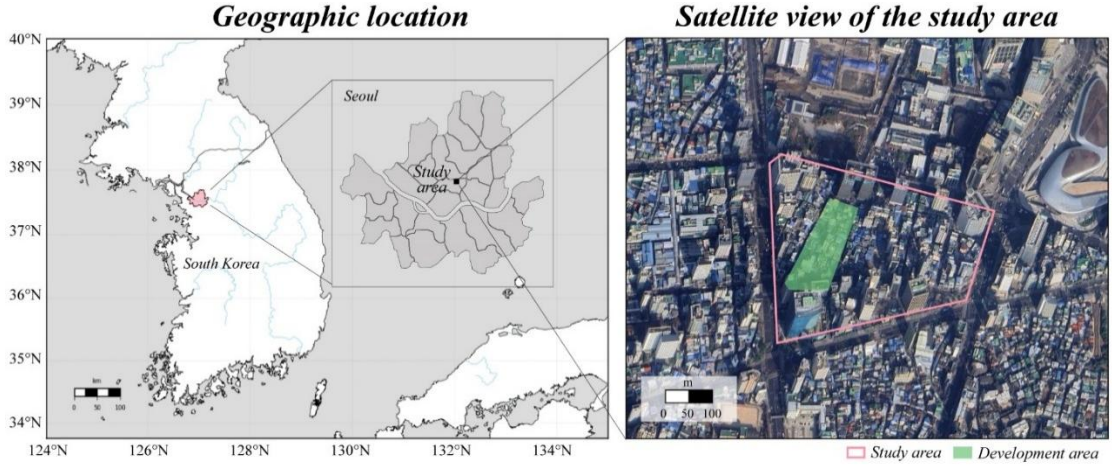

Figure 1. Study site

2.2. ENVI-met model development

A CFD simulation was conducted to evaluate outdoor thermal comfort resulting from the development of green spaces. ENVI-met V5.7.1 was employed as the simulation tool because it specializes in analyzing the cooling effects of vegetation (Liu et al., 2021). Specifically, a three-

dimensional plant tool 'Albero' simulates the physiological activities of plants using $A - g_s$ model, where A represents the photosynthetic rate and g_s denotes stomatal conductance (Bruse, 2004). The model replicates plant strategies involving water use and CO_2 assimilation. The relationship is expressed as in Eq. (1), where C_s and C_i are the CO_2 concentrations at the leaf surface and inside the leaf, respectively. Coefficient 1.6 accounts for the difference in diffusivity between CO_2 and H_2O in the air.

$$g_s = 1.6 \frac{A_n}{C_s - C_i} \quad (1)$$

The 3D model was developed using QGIS 3.40.1. The input data included building geometry surface information and vegetation shape. Detailed input parameters were based on previous research (Kim et al., 2024). The model used 3 m grid sizes in all dimensions, with a simulation domain of 185 × 146 × 25 grid cells and was further refined using the ENVI-met SPACES tool. Initial meteorological data, including air temperature, wind speed, and relative humidity, were obtained from the nearest automatic weather station (AWS). Table 1 details the simulation settings.

Table 1. Detailed settings of ENVI-met simulation

Category	Information
Software	ENVI-met V 5.7.1
Computation domain	555×439×482.2 m (171×135×25 grid cells)
Simulation site	Gwanghui-dong, Seoul, Korea
Simulation period	00:00-23:00 on 8th August, 2023
Meteorology method	Simple Forcing
Meteorological data	Temperature: 26.3℃-36.4℃ Humidity: 40%-66% Wind speed: 2.08 m/s Wind direction: 60.97°

2.3. ENVI-met model validation

The simulation results were validated by comparing the baseline scenario with outdoor sensor data. Environmental data, including temperature, humidity, wind speed, and wind direction, were obtained from Smart Seoul Data of Things (S-DoT) sensors (Bae et al., 2022; Hwang et al., 2023) on August 8, 2023.

To systematically compare the results, a 10 m × 10 m grid was generated in QGIS. Since no S-DoT measurement points were directly within the simulation domain, spatial interpolation was employed in QGIS to create a thermal map with 3 m resolution. Subsequently, ENVI-met results were imported to QGIS. The mean temperature values for each grid cell were extracted using zonal statistics, enabling hourly comparisons over 24 hours.

Statistical analysis of the validation results revealed that the root mean square error (RMSE) varied between 0.26℃ and 1.76℃ (median 1.15℃) (refer to Fig. 2). The mean absolute error (MAE) ranged from 0.17℃ to 1.70℃ (median of 0.92℃). These values align with previous ENVI-met validation studies. For instance, Yang et al. (2021) reported a median RMSE of 1.89°C and 0.86°C. Similarly, Tsoka et al. (2018) found a median RMSE of 1.51°C and a median MAE of 1.34°C.

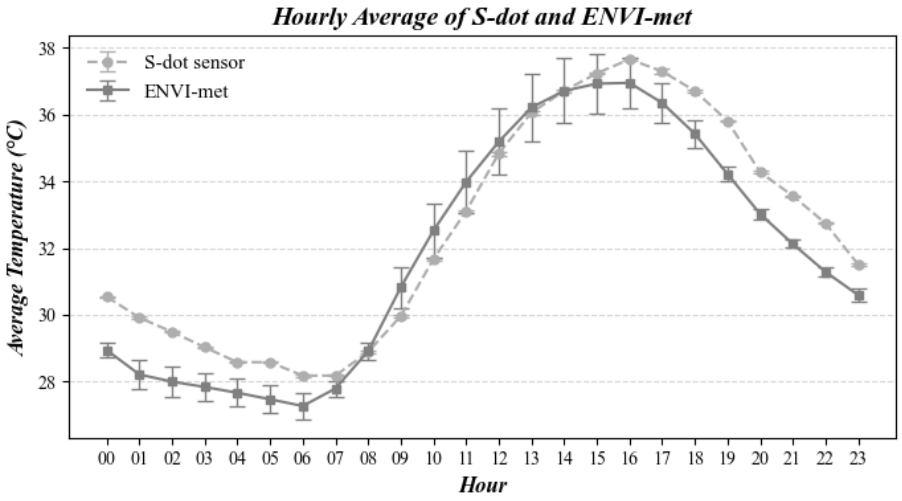

Figure 2. Validation of ENVI-met results against sensor data

2.4. Design strategies for cooling

The green and blue infrastructure development was evaluated through multiple ENVI-met simulation scenarios. A blank scenario was established for the baseline by removing existing structures from the study area. For the development of green and blue space scenarios, 7,974 m² of the target surface was converted to loamy soil to create a park area.

Three vegetation configurations were implemented for green space development: grass, ginkgo with grass, and plane tree with grass. Ginkgo and plane tree species were selected due to their prevalence in Seoul, representing 35% and 16% of urban tree populations, respectively. Table 2 specifies the properties of each vegetation type.

Table 2. Properties of simulated vegetation types

	Grass	Ginkgo	Plane tree
ENVI-met ID	Grass	Ginkgo / Fan Leave Tree (young)	London Plane Tree (young)
Leaf Type	Grass	Deciduous	Deciduous
Height (m)	0.25	8.45	10.55
Width (m)		4.56 × 4.65	5.10 × 5.12
Emissivity of Leaves	0.97	0.96	0.96
LAD	0.3	0.32	0.54

For the development of green space scenarios, grass coverage was implemented uniformly across the loamy soil substrate. In scenarios incorporating trees, 100 planting locations were algorithmically determined using random point generation in QGIS, with a minimum spacing of 6 meters to ensure appropriate canopy development. Previous studies indicated that tree-based green spaces and water features achieve optimal efficiency at approximately 0.30 hectares (Tan et al., 2021). Based on this threshold, water bodies of 3,000 m^2 were incorporated into various scenarios. Consequently, six distinct green and blue infrastructure scenarios (GR, GG, PG, GRW, GGW, PGW) were developed (refer to Fig. 3.)

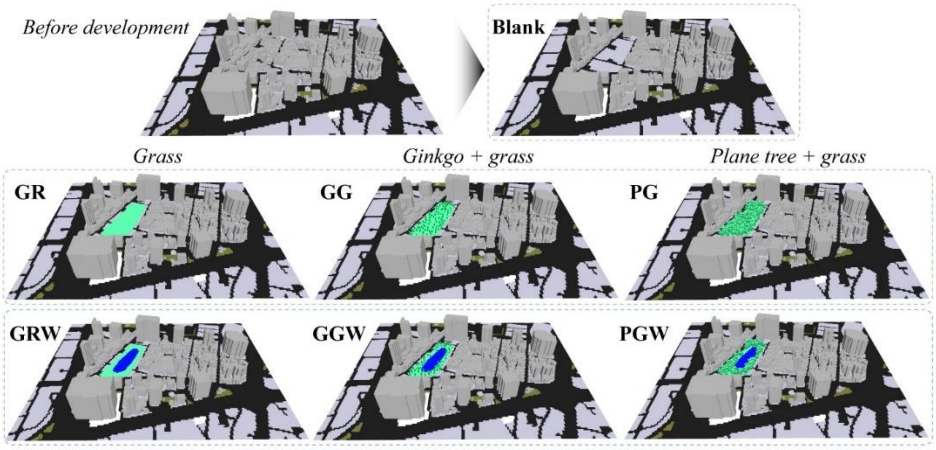

Figure 3. ENVI-met simulation scenarios
(GR(W): grass (and water), GG(W): ginkgo with grass (and water), PG(W): plane tree with grass (and water))

3. RESULTS AND DISCUSSION

The ENVI-met simulation results were pre-processed using the methodology from the validation study to derive the average temperature for each grid cell. To quantify the cooling performance of different scenarios, temperature differences relative to the blank scenario were calculated. These differences were then aggregated and multiplied by the grid area to determine the cumulated cooling effect (in °C×m^2). This analysis was conducted at hourly intervals from 6:00 to 21:00 hours (refer to Fig. 4).

Analysis revealed distinct patterns in cooling effectiveness across scenarios. The grass-only scenario (GR) consistently demonstrated the lowest cumulated cooling effect throughout the observation period, while the plane tree with grass and water body (PGW) exhibited the highest cooling performance. When comparing vegetation types, plane trees showed superior cooling than ginkgo. Generally, the partial replacement of vegetated areas with water bodies enhanced the overall cooling effect of all vegetation configurations. These findings support past studies claiming that water bodies exhibit greater cooling efficacy compared to vegetated areas (Mitra et al., 2024).

While air temperature reached a maximum between 15:00 and 16:00 during the simulation day, the cooling efficiency exhibited a notable decline from 12:00 to 15:00 across all scenarios. This was followed by a temporary recovery in cooling effectiveness until 17:00, after which cooling diminished in correlation with declining ambient temperatures. This temporal pattern can be attributed to the physiological response of stomatal resistance to temperature stress. Particularly, when average air temperatures peaked at 37°C at 15:00, the ENVI-met tree model simulated an increase in stomatal resistance, resulting in reduced transpiration rates and consequently diminished cooling capacity. Recent studies have also highlighted this limitation in vegetation-based cooling strategies under extreme temperature conditions (Gao et al., 2024).

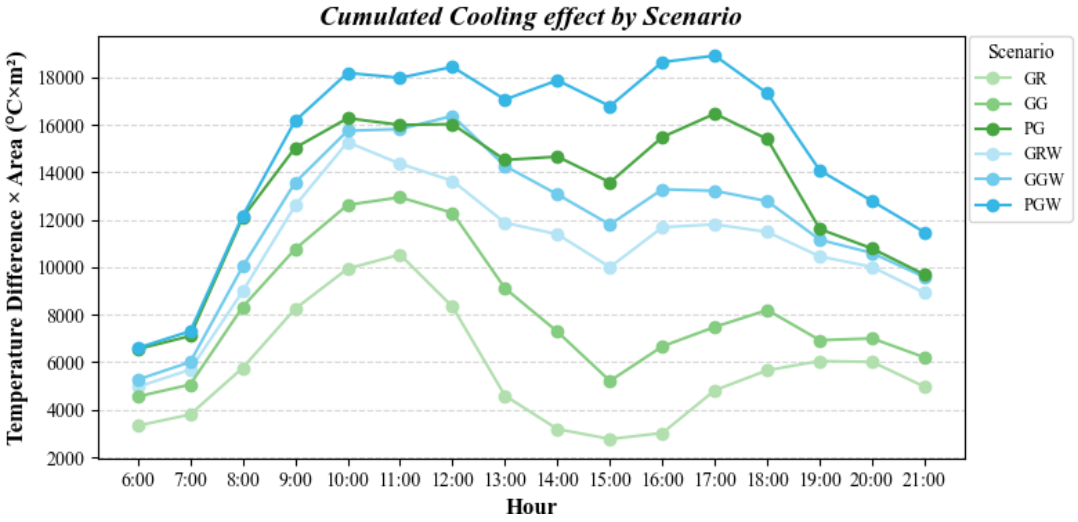

Figure 4. Hourly cumulated cooling effect by scenario

The spatial distribution of cooling effects was visualized at four temporal points (09:00, 12:00, 15:00, and 18:00), revealing distinct patterns across different scenarios (refer to Fig. 5). The grass-only scenario (GR) yielded relatively modest cooling effects. Contrarily, scenarios incorporating ginkgo (GG) and plane tree (PG) demonstrated progressively more intense and spatially extensive cooling patterns. Notably, in scenarios with water bodies, areas designated for water displayed concentrated cooling effects. These spatial patterns indicate the formation of localized "cool islands" by implementing integrated green and blue infrastructure.

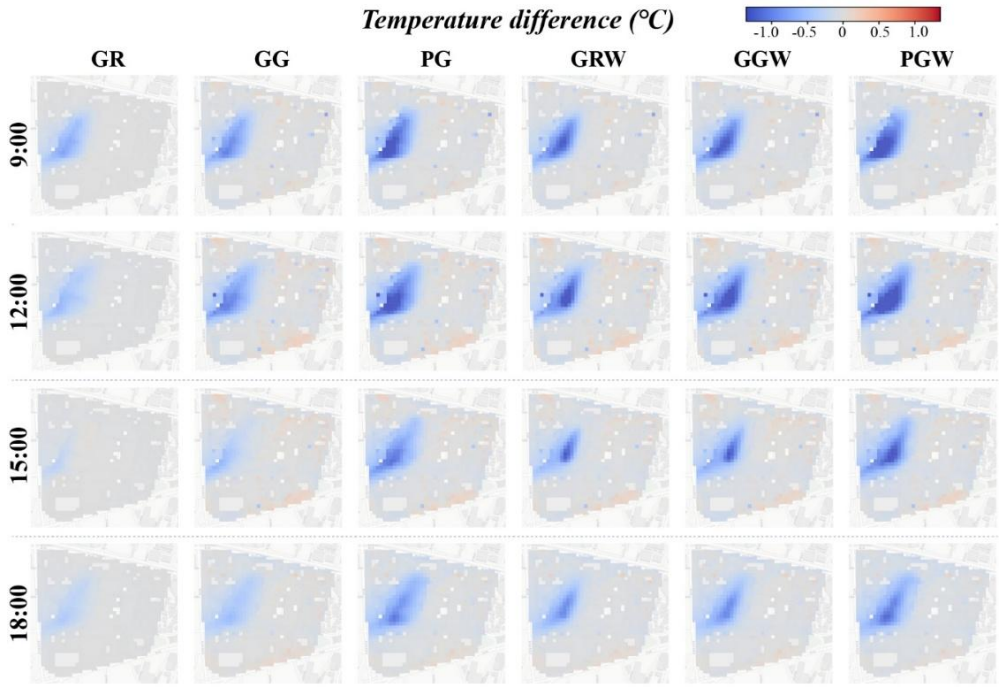

Figure 5. Visualization of cooling effect by scenario during daytime

The observed variations in cooling effectiveness among different vegetation types can be attributed to biophysical parameters. Previous research consistently demonstrates that trees outperform grass in improving the thermal environment (Koc et al., 2018). This superior cooling effect arises from two mechanisms: interception of incoming solar radiation and evaporative cooling through transpiration. The Leaf Area Index (LAI), defined as the total one-sided leaf area per unit ground area (Gao et al., 2023), has been identified as the dominant physical property influencing thermal comfort in urban vegetation (Zhang et al., 2018). In the developed tree scenarios, the plane tree has a high LAI of 5.70 compared to ginkgo's 2.70. The higher LAI values correspond to denser canopies that intercept and absorb a large proportion of incoming solar radiation. Moreover, the higher LAI values provide increased leaf surface area for transpiration, enhancing their potential for evaporative cooling of the environment.

4. CONCLUSION

This study employed ENVI-met simulations to evaluate multiple green and blue infrastructure scenarios in an urban redevelopment area. Implementing approximately 8,000m² of green space contributed to significant improvements in daytime thermal conditions. Among the vegetation configurations analyzed, the plane tree with grass presented superior cooling performance. Furthermore, the integration of a water patch into the vegetation enhanced the cooling effects, suggesting that blue-green infrastructure solutions may be more effective than vegetation-alone strategies during extreme heat events.

This study provides valuable insights into urban climate research and planning. First, it provides a framework to evaluate thermal environment for planned green spaces rather than existing vegetation. Second, the comparative analysis can help policymakers or decision makers to assess various vegetation types and water body configurations based on cooling effectiveness. Specifically, planners can use the results to decide whether to incorporate water bodies into green infrastructure, considering several factors, such as resource availability, budget, and desired uses of the space. As a result, this evidence-based approach is expected to support more strategic, targeted, and cost-effective urban design solutions to mitigate extreme heat.

However, some limitations of the study should be noted. For example, a limited number of tree species were analyzed, even though cooling efficacy varies with tree characteristics, such as crown architecture, stem morphology, and phenology (Li et al., 2024). Future research could benefit from incorporating a broader range of species and conducting more comprehensive parametric analysis. Additionally, integrating advanced methodological approaches, such as the combined CFD-machine learning framework could enhance the robust parametric investigations (Ahn et al., 2024). Finally, incorporating field measurements and advanced remote sensing data from UAVs and drones could provide more robust validation of cooling mechanisms associated with trees and water features.

SUMMARY
Urban wind conditions and greenhouse gas dispersion dynamics in downtown Montréal are simulated using computational fluid dynamics. The numerical models are initialized and validated using data from a large-scale measurement campaign conducted on February 21, 2024. Different numerical solvers are tested to assess their impact on the simulated dynamics. In addition, a cylindrical domain with a rotated inlet and outlet is used to reproduce the observed shift in wind direction with height. When properly initialized, the simulations show good agreement with the observed profiles of wind speed and direction. The model is also able to properly reproduce turbulent dispersion of downtown emissions of carbon dioxide and methane. The distributions and vertical profiles of these greenhouse gases are compared with in-situ measurements and satellite data, and regions with unique dispersion phenomena are investigated.

Keywords: computational fluid dynamics, urban wind flow, greenhouse gas dispersion, measurement campaign.

1. INTRODUCTION

The emission of greenhouse gases (GHGs) into the atmosphere drastically affects the Earth's climate. Emissions from the burning of fossil fuel for energy production, vehicle exhausts, and other anthropogenic sources of GHGs have contributed to an extreme warming trend globally, with the decade from 2014 to 2023 being the warmest ever recorded (NOAA National Centers for Environmental Information, 2024). As temperatures continue to rise, more disastrous effects will begin to be felt across the world (Herring et al., 2018). Additional byproducts of fossil fuel usage include particulate matter, ozone, and other forms of air pollution, which are directly harmful to human health and are attributed to 3.61 million excess deaths per year (Lelieveld et al., 2019). The majority of GHGs and pollutants are emitted in urban areas (UN-Habitat, 2024), where over half of the world's population resides (Ritchie et al. 2024). The negative impacts of these emissions are magnified in these densely populated areas, necessitating thorough study of

the interaction between complex, urban built environments and the dispersion of GHGs and air pollution. Precise knowledge of the spatial and temporal variability of GHGs is also crucial for evaluating their effects on climate. Moreover, satellites measuring atmospheric concentrations of GHGs are able to quantify emissions through source inversion techniques but require their two-dimensional distribution (Jacob et al. 2016). Measure of their distribution is complicated by the morphology of city buildings, leading to strongly local dispersion characteristics. Study of these characteristics is paramount to improving the sustainability of cities and developing strategies to mitigate climate change.

Traditionally, study of air quality in cities has been conducted using in-situ measurements as well as wind tunnel testing. More recently, computational fluid dynamics (CFD) has emerged as a promising way to simulate urban wind flow and dispersion characteristics. The method by which CFD works is to apply simplifications to the Navier-Stokes equations for fluid flow, decreasing the computational expense to solve them and allowing for the investigation of more complex phenomena. Large eddy simulations (LES) provide time dependent solutions and resolve the larger scales of turbulence, while Reynolds-averaged Navier-Stoke (RANS) simulations solve only for steady-state flow and parameterize all scales of turbulence. CFD is uniquely advantaged in its ability to provide GHG concentrations at every location within an area of study, especially important in urban environments. It also provides full control over meteorological conditions and allows for the simulation and investigation of events before they occur. Previous studies have focused primarily on near-field dispersion phenomena, especially in regard to traffic emissions (Tominaga & Stathopoulos 2013; Zhong et al. 2016). Some literature exists simulating the dispersion of GHGs in urban environments, such as Toja-Silva (2017), which investigated the dispersion phenomena from an urban power plant and analyzed the influence of turbulent Schmidt number. The study presented here uses CFD in conjunction with an extensive field measurement campaign to simulate and investigate the distribution of GHGs in the downtown region of Montréal, Canada, for the day of February 21, 2024.

2. METHODOLOGY

Incompressible and compressible steady-state RANS simulations with the standard k-ε turbulence model were carried out using the open-source CFD software OpenFOAM to investigate the urban flow and the dispersion of GHGs across the city. This study also presents the results of an extensive measurement campaign conducted in Greater Montréal, Quebec, Canada, on the day of February 21, 2024, and coordinated in part with these simulations. The campaign's goal was to provide direct measurements of the spatiotemporal variability of GHGs emitted in Montréal, in particular carbon dioxide (CO_2) and methane (CH_4), as these are frequently emitted in cities. Data was taken across the morning and afternoon, both inside the city and off the island of Montréal, allowing for analysis of the differences across the day and to single out the contribution of urban emissions. Wind conditions inside the city were measured using a Halo Photonics StreamLine XR Doppler lidar, which provides vertical profiles of wind velocity. This instrument was positioned downtown on the roof of McGill University's Burnside Hall (45.5047°N, 73.5751°W), atop which was also a Picarro GasScouter for measuring the concentrations of CO_2 and CH_4. To capture the vertical distribution of these GHGs, drone flights were used, measuring the concentrations from 0–120 m above ground level (AGL). The simulated concentrations of GHGs at these locations are then compared directly to these

downtown measurements. Outside of the city, upper air soundings were launched from McGill University's Gault Nature Reserve, 40 km east of Montréal. The Earth Observation System laboratory at the nature reserve was also capable of measuring pertinent meteorological properties as well as concentrations of CO_2. Finally, two flight campaigns were conducted by the National Research Council Canada using its Convair 580 aircraft to record atmospheric properties over Montréal and its surrounding areas. These aircraft flights flew between Ottawa International Airport and the Montréal Metropolitan Airport, passing over the city and making multiple missed approaches while measuring variables such as temperature, wind velocity, and concentration of CO_2 and CH_4.

One aspect revealed by these measurements is a significant difference in the surface level and upper level wind directions. Aircraft measurements from a missed approach at Montréal Metropolitan Airport show northeast flow near the ground and southerly flow aloft, characteristic of veering winds. The Gault radiosonde measurements again show northeast flow near the surface with a west-southwest component higher up. Downtown, the lidar recorded a southeasterly wind shifting to the southwest within the first kilometer. The slight disagreement in surface level wind direction between the measurement sources makes the appropriate selection of inlet wind conditions challenging. However, it is the shift in wind direction with height which presents an even more significant challenge in terms of simulating the actual wind conditions. Traditionally, computational domains model wind direction as a fixed constant with height across a single inlet. With the dispersion and distribution of GHGs depending greatly on the prevailing wind direction, it is vital to be able to reproduce any differences in wind direction across height. Therefore, it was necessary to design the computational domain to facilitate multiple inlet directions, accomplished using a 36-sided cylinder. The cylinder faces were then split horizontally at different heights to correspond with the vertical changes in wind direction. In each resulting vertical section, individual faces were then defined as either inlet, side, or outlet to create a domain in which these faces rotate with height to take into account the shift in wind direction with height (Fig. 1a). Both the aircraft and radiosonde measurements also reveal the presence of a strong low-level jet. As such, the classical logarithmic wind speed profile would not be a suitable boundary condition, and instead, the inlet wind speed was taken directly from the sounding and aircraft data. Both sources of wind speed and direction were tested to assess which led to the best agreement with downstream measurements. For the compressible simulations, temperature and pressure profiles measured by the radiosonde were also used for initialization.

To model GHG emissions within the city, three separate sources were used. According to McGill University's Facilities Management and Ancillary Services, the university's power plant accounts for over 90% of its downtown emissions and burned an estimated 55,900 m^3 of natural gas on February 21, 2024. Emissions rates of CO_2 and CH_4 were calculated according to the National Inventory Report 1990–2022: Greenhouse Gas Sources and Sinks in Canada Annex 6 emission factors (Environment and Climate Change Canada, 2024). Additionally, the city of Montréal releases data on annual natural gas consumption of government buildings which are over 2000 m^2, four of which are included in the domain (Ville de Montréal 2021). The final source considered was emissions resulting from downtown vehicle traffic. Rates of traffic and vehicle type were then estimated from data from the city of Montréal, with different emission factors being used for each category of vehicle. Modified versions of the solvers including

turbulent diffusion were run to simulate the dispersion of the emitted GHGs after the converged wind field was found. In these simulations, the turbulent Schmidt number was set to 0.6, as this was found to most accurately reproduce turbulent dispersion in downtown Montréal (Dyer-Hawes et al., 2024).

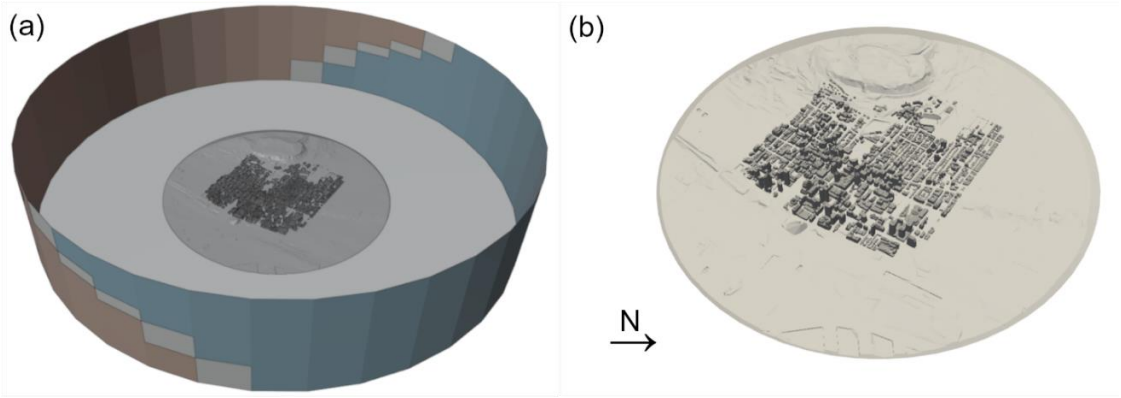

Figure 1. (a) Computational domain highlighting rotating inlet (red) and outlet (blue). (b) Enlarged view of inside of domain with explicitly modelled downtown buildings and topography.

3. RESULTS

Simulations testing the wind speed initialized with either the sounding or aircraft measurements were first conducted. It was found that the sounding wind speed provided the most accurate wind profile as compared to the lidar. These boundary conditions were therefore used for the compressible solver. The comparison between these three simulations and the lidar wind profile is shown in Fig. 2a. Moderate improvements in the prediction of wind speeds are found with the compressible solver. The sounding wind speed profile was also used to test the influence of the wind direction profile used, again comparing between the sounding and aircraft measured wind direction. Here too the sounding measurements provided the best agreement with the lidar measurements (Fig. 2a), and as such the wind speed and direction from the upper air sounding are used to initialize the compressible solver and simulations including GHG dispersion. Turbulence characteristics such as turbulence intensity are also analyzed across the models.

In analyzing the dispersion of GHGs, an initial test was run using the converged incompressible wind field and only including the transport of the background concentrations of CO_2 and CH_4 as measured by the aircraft. No emission sources inside the city were included, resulting in a CO_2 concentration of 403.3 ppm at the location of the downtown Picarro GasScouter. This instrument recorded an average CO_2 concentration of 475.0 ± 5.51 ppm at the time simulated, demonstrating a large discrepancy when emission sources are not modeled. With the downtown emission sources included in the dispersion simulation, the predicted concentration of CO_2 increases to 478.8 ppm, a close match to the observed value. This points to the urban emission sources modeled contributing significantly to local concentrations of GHGs near the GasScouter. With the compressible solver, the predicted concentration decreases to only 426.4 ppm. It is likely that the stable atmospheric conditions and temperature inversion on this day supress the upwards transport of traffic emissions in the compressible simulation. The predicted concentration distributions of CO_2 within the domain are shown in Fig. 3, which suggests that both the

compressible and incompressible solver predict similar distributions of CO_2. Close to streets, the contribution from traffic emissions is greatest. The power plant also significantly affects concentrations in the surrounding areas. Interesting gradients are also noted around the mountain of Mount Royal, suggesting even more local effects in this region. Future measurement campaigns could investigate this phenomenon to better identify the strength of these gradients. Further analysis into the distributions of GHGs can help in the placement of future GHG monitoring stations to properly assess representative concentrations.

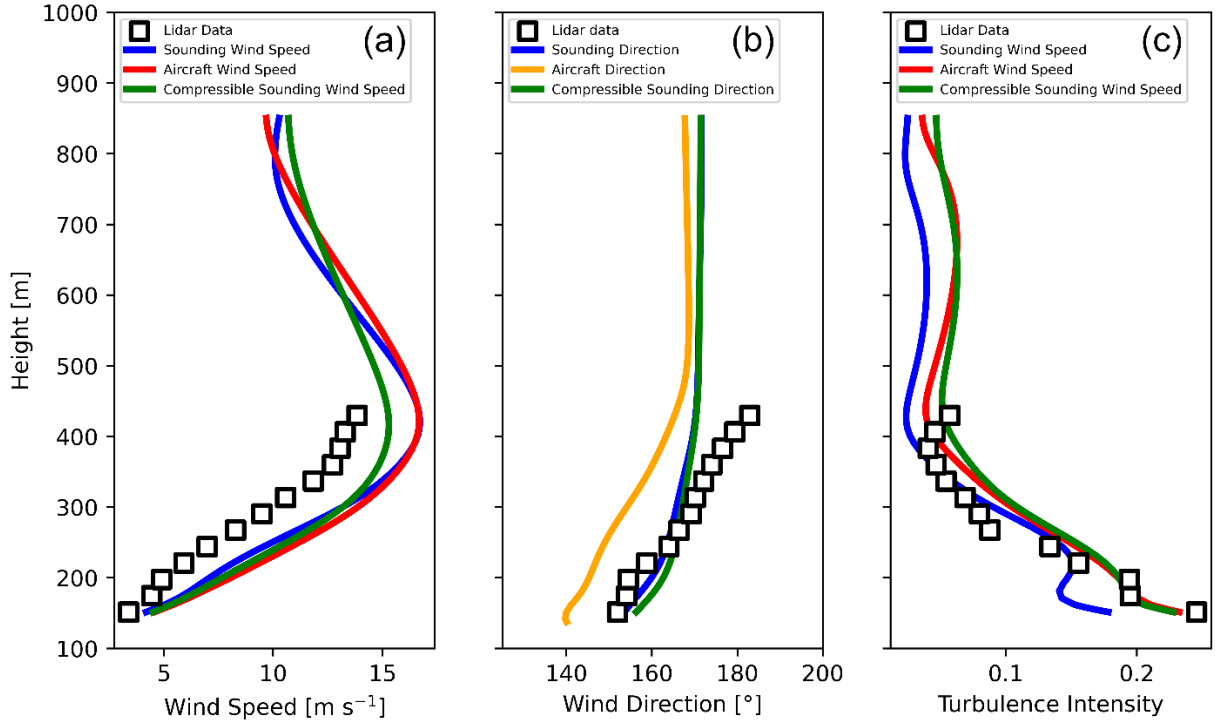

Figure 2. Predicted (a) wind speed, (b) direction, and (c) turbulence intensity by different model configurations compared with 20-min averaged lidar measured wind speed.

The simulated profiles of GHG concentrations are also compared with drone measurements up to a height of 120 m AGL (Fig. 4). While in the case of CO_2, the models properly predict a decrease in concentration with height, disagreement exists between the observed and simulated profiles. The discrepancy points to missing emission sources in the model near the location of the drone measurements. This model underestimation is even more present for CH_4 (Fig. 4b), and this is likely due to the omission of the primary sources of urban CH_4 emissions of natural gas distribution and storage and landfills (Zazzeri et al. 2015; Xueref-Remy et al. 2020). Finally, the results of the dispersion simulations are used as a comparison with satellite measurements of column-averaged CO_2 from the OCO-2 Satellite. This provides a way of validating both the CFD model and satellite measurements, as well as providing the two-dimensional distribution of GHGs needed for satellite source inversion techniques. Additional discussion of the vertical profile of CO_2 at various locations in the city and computational domain are also presented.

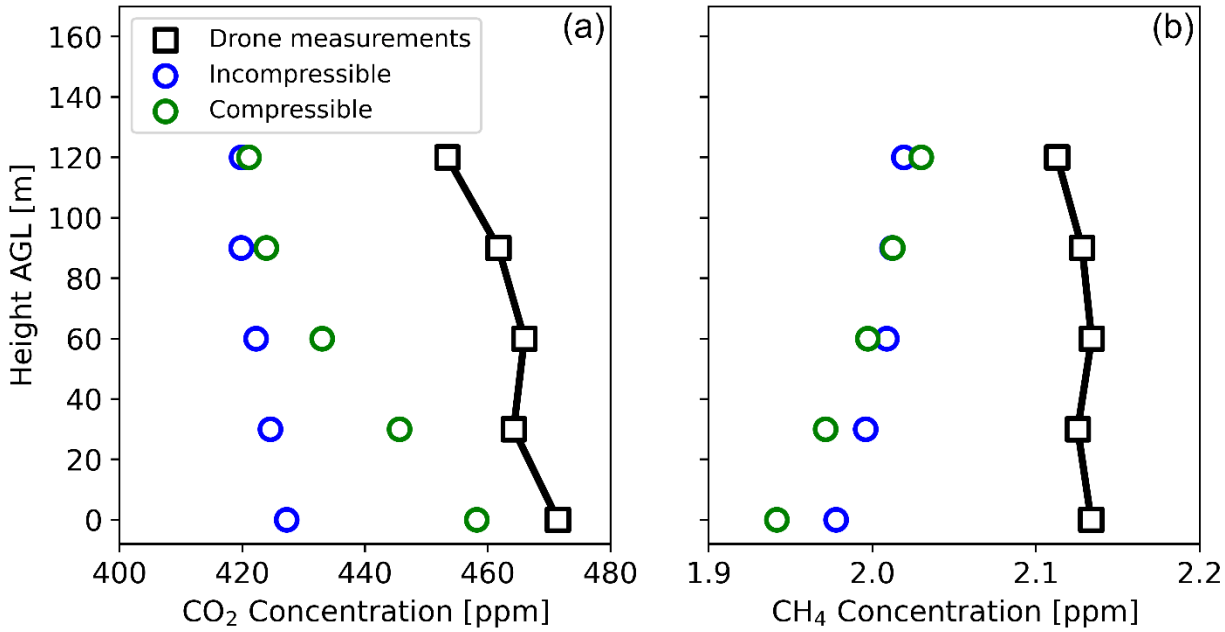

Figure 4. Comparison of model predictions and drone measurements of (a) CO_2 concentration and (b) CH_4 concentration.

4. CONCLUSIONS

This study, by combining computational fluid dynamics with a robust measurement campaign, has demonstrated the ability for numerical simulations to provide estimations of greenhouse gas (GHG) concentrations in complex urban environments such as Montréal. It also puts forward a novel way of designing computational domains to account for shifts in wind direction with height. With this adjustment, the numerical model using both compressible and incompressible Reynolds-average Navier-Stokes simulations accurately reproduced the complex wind conditions present in Montréal on the morning of February 21, 2024. The large variety of measurement campaign data sources allowed for the testing of multiple initial boundary conditions to assess their agreement with the wind velocity profile measured inside the domain by a Doppler lidar. The dispersion of carbon dioxide and methane emitted from buildings and traffic was also simulated, specifically accounting for turbulent diffusion. The resulting distributions were then analyzed investigating local dispersion characteristics in the urban environment. The predicted concentrations were validated against rooftop measurements in the center of downtown, drone measurements, and satellite data. With more emission sources included, future work could investigate the effect of different atmospheric stability conditions, as well as transient dispersion dynamics with large eddy simulations. Additionally, some areas with potential air quality issues were identified using the models. Due to health concerns around exposure to vehicle emissions and their relative importance in urban GHG concentrations, future studies could look to perform more detailed simulations of traffic dispersion dynamics in this downtown region.

SUMMARY
Urban air pollution, primarily caused by vehicular emissions, poses significant public health risks in densely populated cities. This research study investigates the relationship between urban morphology and vehicular pollutant dispersion in four Italian cities: Lecce, Bari, Milan, and Rome. Employing the high-resolution ADMS-Roads dispersion model integrated with urban morphological data, the study analyses pollutant concentrations of NO_2 and PM_{10} across different urban layouts. The results demonstrate how urban configurations influence pollutant dispersion, with compact urban forms exacerbating pollutant accumulation. Findings emphasise the urgent need for sustainable mobility policies and urban planning that mitigate pollution in high-density environments.

Keywords: urban air pollution, urban morphology, AMD-Roads, NO_2 and PM_{10} dispersion patterns.

1. INTRODUCTION

Urban air pollution poses a significant health risk in European cities, where citizens remain exposed to concentrations exceeding the WHO recommendations (Pascal et al., 2013). The spatial structure of urban areas, known as urban morphology, plays a crucial role in shaping pollutant dispersion. In particular, street canyons can act as traps for pollutants, leading to concentrations that exceed ambient levels due to restricted natural airflow (Vardoulakis et al., 2003).

While there has been extensive research on the relationship between urban morphology and pollutant dispersion in Northern European and Asian cities, there is a notable scarcity of studies focusing on Mediterranean urban areas. This gap is significant, as Southern European cities typically feature dense urban forms and experience warmer, drier climates. Combined with seasonal meteorological variability, these factors can uniquely influence pollution dispersion, making the Mediterranean region particularly vulnerable to air pollution (Lelieveld et al., 2002). Addressing this gap is essential, given the escalating concerns about air pollution in Mediterranean cities. It is vital to understand how urban morphology influences pollutant dispersion in these regions so that effective urban planning and environmental health policies can be developed,

considering their specific climatic and structural characteristics.

The present study aims to bridge this knowledge gap by providing a comprehensive analysis of pollutant dispersion using the dispersion model ADMS-Roads (www.cerc.co.uk), across varied urban forms in four Italian cities: Lecce, Bari, Milan, and Rome. A preliminary analysis was presented in Metrangolo et al. (2024). A key objective of this research is to integrate high-resolution dispersion modelling with urban morphological data to develop vehicular pollutant dispersion scenarios - focusing on NO_2 and PM_{10} - that can serve as a foundation for policymakers and urban planners in designing air pollution mitigation strategies for high-density urban environments.

2. METHODOLOGY

2.1. Study areas

The present study focuses on four Italian cities selected for their geographical and morphological diversity: Lecce, Bari, Milan, and Rome. Lecce has a compact historic centre with radial urban growth, while Bari, a coastal city, features both orthogonal grids and irregular layouts. Milan represents a densely populated metropolitan area with a radial and compact configuration, whereas Rome, characterized by a fragmented radial layout, includes extensive green spaces. Fig. 1 shows the geographical locations of the four cities, while Fig. 2 shows the study area configurations in each city.

Fig. 1 Aerial view of Italy with the locations of the four cities investigated in this work.

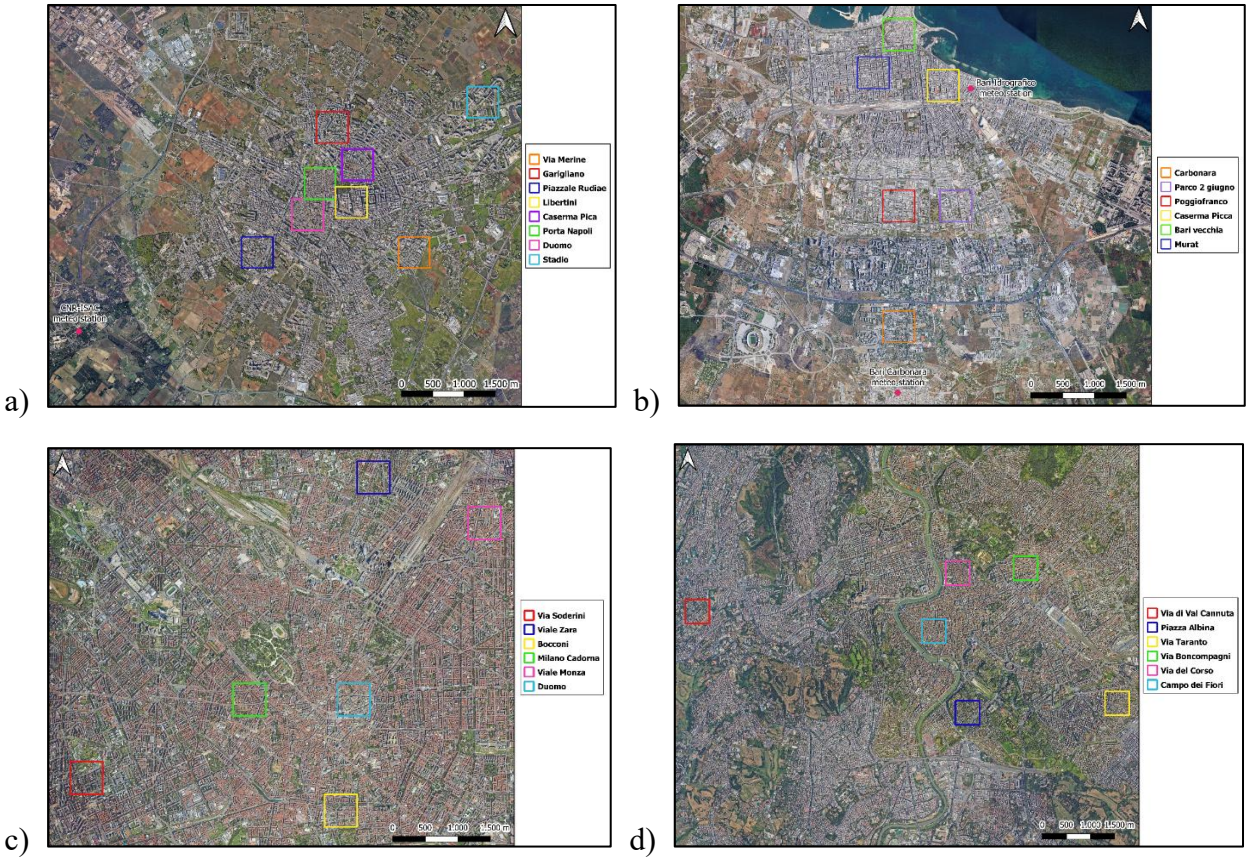

Fig. 2 Aerial view of a) the eight study areas in Lecce (the red point indicates the position of meteorological stations), b) the six study areas in Bari (including the positions of meteorological stations), c) the six study areas in Milan, and d) the six study areas in Rome.

2.2. Selection and characterization of the study areas using QGIS

The selection process of the study areas emphasised quantifiable morphological parameters, including the building plan area fraction (λ_p), the aspect ratio of street canyons (AR) and the mean building height (H). These parameters were computed in QGIS using a 0.1 × 0.1 km grid. Mean morphological values were used to compare urban areas within a consistent range of λ_p values. Four distinct morphological categories were considered: sparse canopy (low λ_p), intermediate canopy ($\lambda_p \approx 0.25$), compact canopy ($\lambda_p \approx 0.40$) and very compact canopy (high λ_p) (Buccolieri et al., 2010).

Initially, eight study sites were examined in Lecce, but this number was reduced to six in Bari, Milan, and Rome for validation purposes. The QGIS plugin "UMEP" was then used to calculate roughness length (z_0) for each grid cell, following the method outlined by Macdonald et al. (1998). The roughness values were integrated into ADMS-Roads to account for the effects of complex terrain.

2.3. Processing of meteorological parameters

Hourly meteorological data - including wind speed, wind direction, air temperature, relative humidity, precipitation and solar radiation - were collected for the period 2019 - 2021. As no

meteorological stations were located directly within the study areas, data from a single station were applied to all sites within each city. The collected data were processed in MATLAB to generate meteorological inputs for ADMS-Roads, which was used to simulate various emission scenarios. Four typical seasons were defined, each representing a three-month period within the 2019 - 2021 timeframe: autumn (September - November), winter (December - February), spring (March - May), and summer (June - August). Hourly averages were calculated for wind speed, air temperature, relative humidity, and solar radiation, while wind direction was determined based on prevailing patterns. These processed data were then used to generate four hourly meteorological files, which were entered into ADMS-Roads. The software's internal meteorological pre-processor further refined these inputs to enhance the characterization of local meteorology and atmospheric turbulence - both critical for accurately simulating pollutant dispersion.

In ADMS-Roads, the vertical wind profile is computed based on a flat-terrain assumption, using the Monin-Obukhov similarity theory within a spatially homogeneous boundary layer. The model allows for specification of different z_0 for the meteorological input site and for each modelled urban area. These z_0 values influence the wind and turbulence profiles, which are adjusted accordingly by the model. Although no complex terrain or building-resolved flow was simulated the change in surface roughness between the meteorological site and the urban modelling areas is accounted for internally by ADMS-Roads to better represent urban wind conditions. This allows for a realistic approximation of how urban morphology affects the local wind profile and, consequently, the dispersion of pollutants.

The mean wind speed, its standard deviation and the prevailing wind direction for the summer season in each city are summarised in Table 1 and graphically shown in Fig. 3.

Table 1. Average wind speed, σ wind speed and mode of wind direction for Lecce, Bari, Milan and Rome, for the "summer season".

City	Average wind speed (m/s)	σ wind speed	Mode of the wind direction
Lecce	2.0	1.1	350
Bari	3.5	1.2	321
Milan	1.3	0.6	121
Rome	2.3	1.3	174

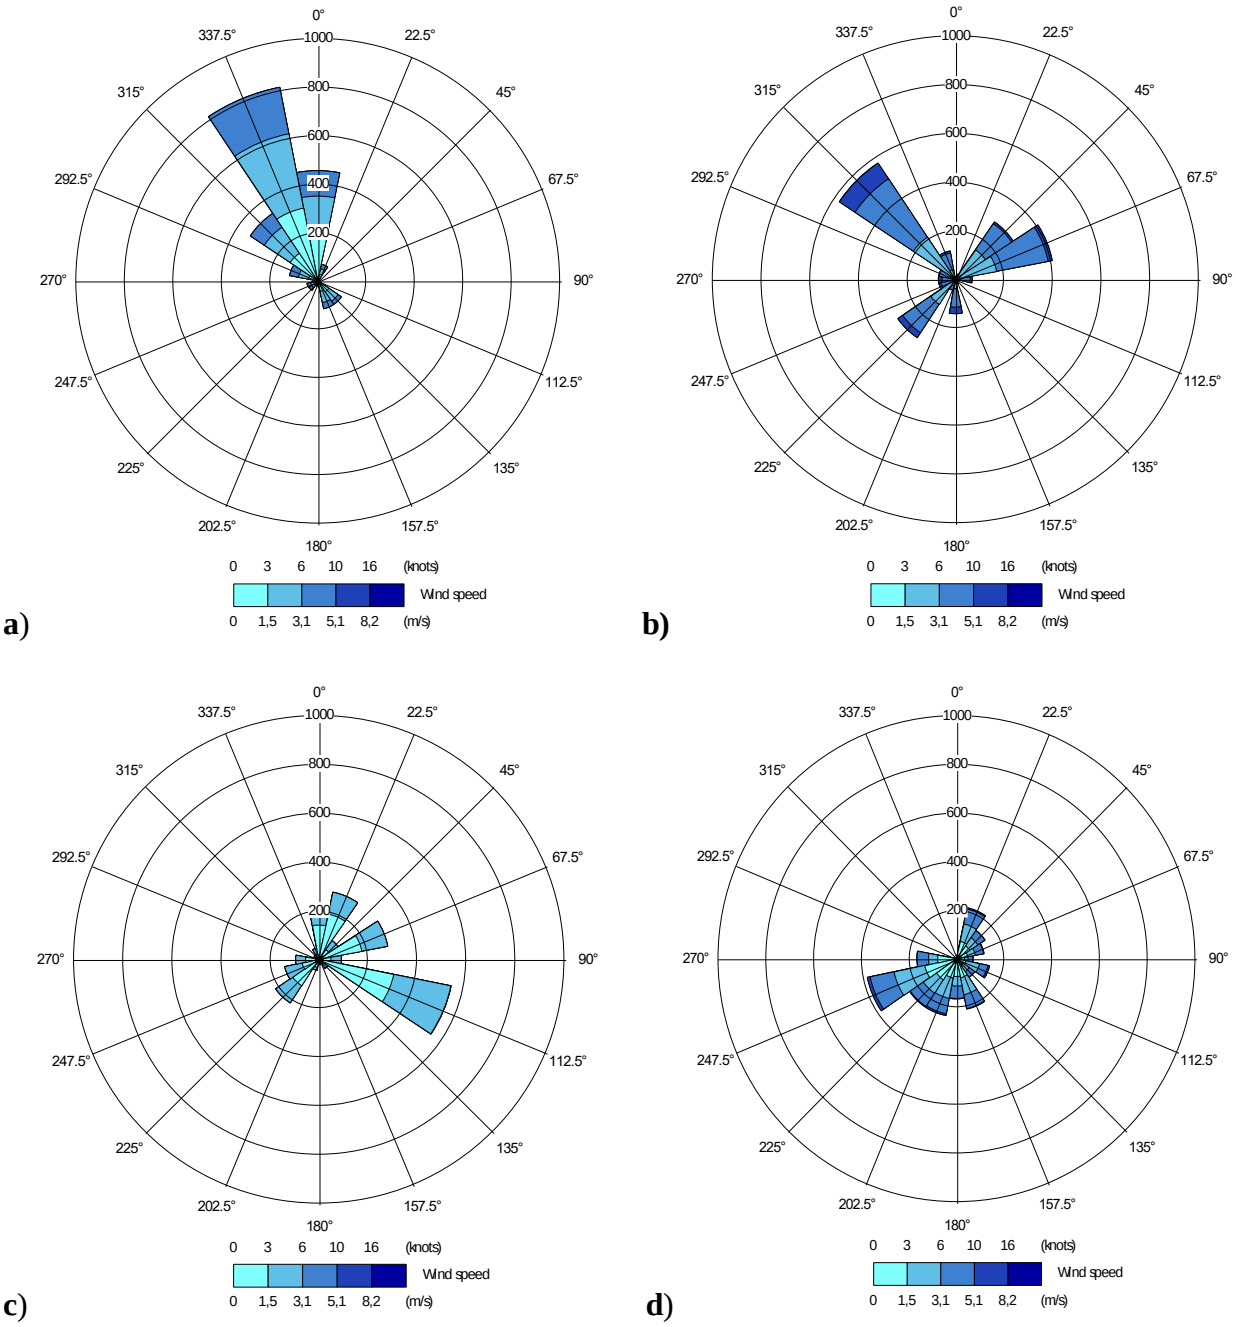

Fig. 3 Wind roses for the "summer season" for the cities of a) Lecce, b) Bari, c) Milan and d) Rome.

2.4. Road geometries and emission modelling

In ADMS-Roads, road geometries were digitised using QGIS, with key parameters such as road width, length and average road canyon height calculated and assigned to each modelled road segment. These parameters ensured an accurate representation of the road network, forming the basis for pollutant dispersion modelling. Additionally, numerical values were assigned to each road source, specifying vehicle types (light duty vehicles), vehicle counts, and average hourly speeds. A standardized capacity of 23,250 light vehicles per study area was assumed, travelling at an average speed of 30 km/h. These values, derived from an estimated daily average of 8,000

vehicles per road based on typical traffic patterns, were applied consistently across all study areas. Vehicle distribution among roads within each area was informed by traffic data from Google Traffic, with adjustments made for variations in traffic volumes across different times of the day and week. The "3DayDiurnal scheme," provided by ADMS-Roads, was used to capture the temporal dynamics of traffic emissions, reflecting increased emissions during weekdays and standard working hours. This methodological approach ensured a more nuanced representation of transport emissions in the model.

The internal ADMS-Roads dataset, designated 'UK EFT v9.0 (2VC)', was used to estimate road transport emissions, with 2022 set as the emission year and 'England (urban)' as the road type. The 2022 emission dataset was chosen to incorporate the most recent emission factors available in the software, aligning with the study's primary focus on the role of urban morphology in pollutant dispersion rather than on precise pollutant concentrations for specific years. The modelling accounted for road canyons and traffic-induced turbulence. The road canyon module, based on the Danish Operational Street Pollution Model (OSPM, Hertel and Berkowicz, 1990), provided an advanced framework for representing complex urban road geometries and their influence on pollutant dispersion. The consistent use of the 'UK EFT v9.0 (2VC)' dataset and the 'England (urban)' road type across all study areas facilitated robust comparisons of how urban morphology affects pollutant dispersion patterns.

The model outputs included pollutant concentrations for two primary vehicle emissions: the hourly average concentration of NO_2 ($\mu g/m^3$) and the daily average concentration of PM_{10} ($\mu g/m^3$). To capture detailed variations in pollutant distribution, each study area was divided into a 31x31 "source-oriented" grid. Additional grid points were strategically placed near road sources to enhance the representation of concentration profiles, ensuring a comprehensive analysis of both spatial and temporal variations in pollutant levels.

3. RESULTS & DISCUSSION

Although street aspect ratio and orientation are known to influence local-scale pollutant dispersion, in this study our aim is to explore broader correlations between overall urban morphology, expressed through the planar building density (λ_p) and simulated pollutant concentrations. The effect of individual street canyons is still accounted for in ADMS-Roads through the explicit input of canyon height and width for each road source, while the dispersion outside canyon zones is parameterized using the area's z_0. Therefore, the aspect ratio is indirectly considered within the modelling framework, even if not directly discussed in the results. Table 2 and Fig. 4 present the ground-level NO_2 and PM_{10} concentrations calculated during the summer months in the study areas of Lecce, Bari, Milan and Rome. Since emissions were homogenized across all study areas to allow for consistent comparison (see subsection 2.4), the results reveal clear distinctions influenced by variations in urban morphology (λ_p) and meteorological conditions.

Pollutants levels vary significantly between cities. Lecce exhibits moderate NO_2 and PM_{10} concentrations, with a decline at high λ_p values. This phenomenon is likely due to a combination of favourable meteorological conditions and specific urban configurations that promote enhanced dispersion of pollutants. Bari, benefiting from the highest average wind speeds among the four cities, shows a clear relationship between urban compactness and pollutant levels. The "Carbonara" area, with a greater proportion of open spaces, displays significantly lower concentrations, whereas the denser "Murat" area experiences higher levels due to pollutant

trapping. Milan records the highest NO_2 and PM_{10} concentrations, particularly in areas with low and intermediate λ_p values, likely due to its dense urban fabric and stagnant atmospheric conditions. In contrast, Rome exhibits a more consistent trend, with slightly lower concentrations in less compact areas, aligning with the presence of extensive open green spaces that facilitate pollutant dispersion.

Table 2. Average NO_2 and PM_{10} concentrations per study area for the city of Lecce, Bari, Milan and Rome, for the summer season, sorted by increasing λ_p value.

Lecce			
Study area	λ_p	NO_2	PM_{10}
Stadio	11.9	20.6	5.3

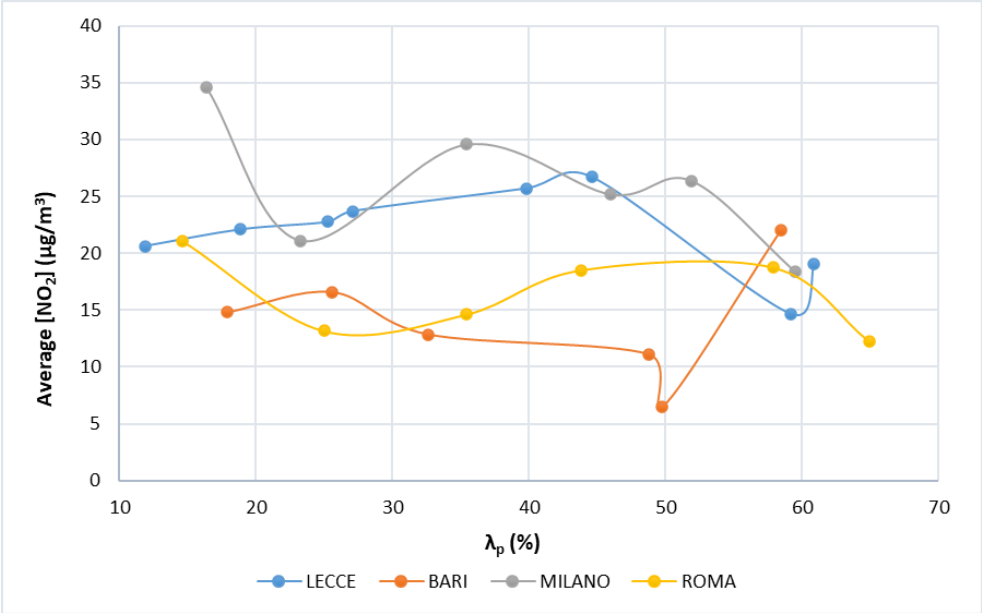

Fig. 4 Graph of the trend in hourly NO_2 concentrations for the "summer season" (averaged over the three years of simulation) for the cities of Lecce Bari, Milan and Rome vs. the spatially averaged λ_p of each study area.

As shown in Fig. 5, contour plots of the average NO_2 concentrations during the summer season are provided for the "Garigliano" area in Lecce, the "Parco 2 Giugno" area in Bari, the "Viale Zara" area in Milan and the "Piazza Albina" area in Rome. These plots generated using ADMS-Roads and refined in QGIS, focus on areas with intermediate λ_p values (around 25%), allowing for a meaningful comparison. As mentioned in subsections 2.3 and 2.4, ADMS-Roads model does not explicitly represent buildings in the domain; instead, it uses a parameterization approach based on z_0 to characterize the influence of urban morphology on dispersion. Consequently, pollutant concentration maps refer to concentrations calculated at ground-level and do not account for building volumes or rooftop height. The presence of pollutant values in correspondence with rooftops does not indicate actual rooftop exposure but reflects the ground-level concentrations projected over the entire map area. For street canyons, the model applies a specific parameterization to capture canyon effects within user-defined canyon zones, while outside these zones, dispersion is modelled based on open terrain characteristics. The plots indicate that pollutant dispersion is strongly influenced by wind direction, with NO_2 spreading predominantly in the direction opposite to the prevailing wind. In Lecce and Bari, this results in a broader dispersion area south of the road source, whereas in Milan and Rome, the dispersion extends further to the north or northwest. Additionally, the contour plots in Fig. 5 highlight that the highest NO_2 concentrations - also applicable to PM_{10} - are primarily found at road intersections, where vehicular flows from multiple directions converge. High concentrations are also observed along roads with heavy traffic volumes and in areas with pronounced street canyons, which further restrict pollutant dispersion.

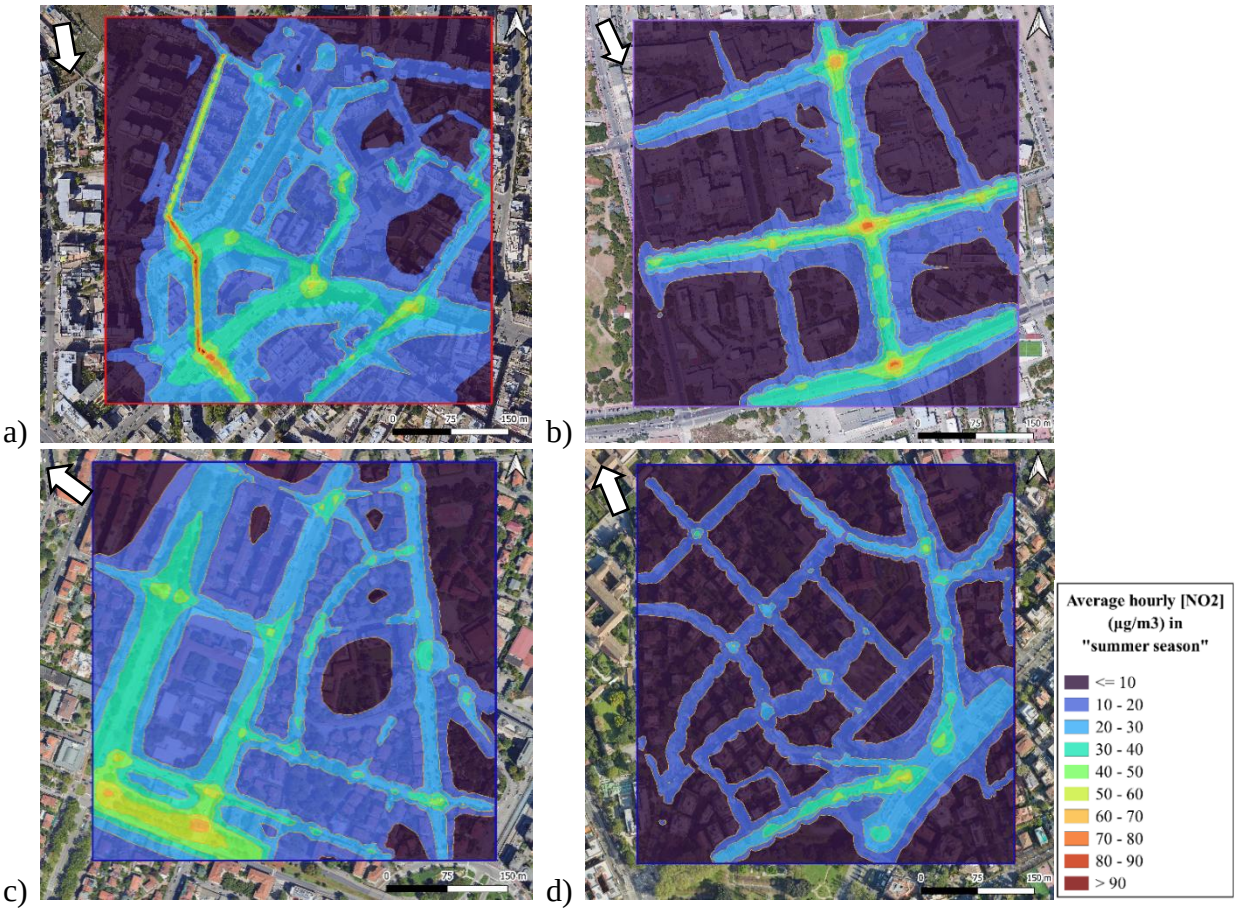

Fig. 5 Contour plot of the 3-year mean values of NO_2 concentration in "summer season" for (a) the "Garigliano" area in Lecce, (b) the "Parco 2 Giugno" area in Bari, (c) the "Viale Zara" area in Milan and (d) the "Piazza Albina" area in Rome. The white arrow on the left serves as an indicator of the wind direction mode.

4. CONCLUSIONS

This study provides quantitative evidence on how urban form influences the dispersion of traffic-related pollutants across four Italian cities with varying morphological and meteorological characteristics. We find that more compact areas (λ_p > 40%) are generally associated with higher pollutant concentrations. However, our results also show that high density does not universally correspond to poor air quality. In Lecce and Rome, some of the most compact areas exhibit lower concentrations than expected, likely due to favourable wind exposure or more ventilated street canyons. In Bari, the contrast is more pronounced: zones with λ_p > 50% show up to 70% higher NO_2 levels than surrounding areas, highlighting how local morphology can amplify pollutant accumulation. These insights demonstrate that morphology alone is not a sufficient predictor; rather, its interaction with local meteorology and emission sources determines the spatial distribution of air pollution. Future developments will focus on integrating more accurate emissions inventories and on validating model predictions with in-situ sensor data. This will strengthen the application of this method in supporting evidence-based urban and environmental policies.. Future research will focus on refining model inputs with more detailed data and integrating sensor measurements to improve accuracy, thus enabling a deeper understanding of urban air pollution dynamics and supporting targeted interventions within the PNRR National Centre for Sustainable Mobility (CN MOST) project. The objective is to develop possible future

pollutant dispersion scenarios, thereby furnishing policy makers and urban planners with useful information to implement effective pollution mitigation strategies. The research will be expanded to other urban areas and incorporate real-time data.

SUMMARY
Sustainable design and green construction practices are effective solutions to provide comfortable thermal conditions for occupants while decreasing the seasonal heating/cooling demand in buildings. Trombe walls (TWs) are building components that can be used to regulate indoor thermal environment. Utilising TWs as a passive heating and cooling method can help in providing desirable indoor comfort conditions while reducing the reliance on mechanical systems. This study evaluates the indoor thermal conditions in a model room with a TW system. This is done by analysing air temperature and velocity distribution under the defined heat flux values on a TW (200, 250, 300, and 350 W/m²) in both summer and winter conditions typical of Irish weather. Using the grid convergence index (GCI) method to optimize the computational fluid dynamics (CFD) model, the study examines how these heat flux values affect the room conditions in relation to thermal comfort standards.

Keywords: Trombe wall; Dwellings; Building performance; Indoor thermal comfort.

1. INTRODUCTION

Trombe walls (TWs) have become a popular passive solar heating system [1-3]. TWs can influence indoor temperature by utilising solar energy and thermal mass [5]. They are composed of a glass layer placed in front of a south-facing wall (for northern hemisphere) composed of a high thermal mass material, such as concrete or adobe [6]. Sunlight passing through the glass during the day heats the wall's surface and allows the TW to absorb thermal energy. The heat is conducted through the TW's structure and slowly released to the indoor environment, providing required indoor thermal conditions [7]. Natural convection and forced convection systems are the two primary varieties of TWs [8]. Natural convection TWs rely on warm air's buoyancy to flow through vents at the top and bottom of the TW structure. TWs with forced convection use fans or other mechanical systems to improve airflow, which can boost the heat transfer efficiency [8]. TWs have been utilised in a variety of settings and structures, including commercial and residential buildings [9]. However, using computational fluid dynamics (CFD) to optimise the design and performance of TWs is essential [10]. CFD models can assist designers in fine-tuning a variety of parameters, including vent size and location, TW thickness and glazing qualities, and simulating airflow and heat transfer within and around the TW [11].

Previous research comprehensively examined the impacts of mesh types and refinement methodology utilising the grid convergence index (GCI) [12] to ensure accurate and reliable results. Baker et al. [13] used the GCI approach to assess how the mesh resolution affected the accuracy of numerical results, i.e. indoor air velocities. Lee et al. [14] developed a method to determine the most suitable mesh for CFD simulations by reducing grid independence tests, focusing on optimal grid resolution, and validating the approach through case studies using GCI method. Hajdukiewicz et al. [15] utilised the GCI method in a 3D CFD model of an internal environment of a room. The GCI values were compared with the accuracy of physical

measurements in a demonstration building and a suitable mesh, as a compromise between the level of uncertainty and computational cost, was selected for further analysis.
The research presented here aims to investigate indoor conditions inside a model room by numerically assessing the effect, of varying heat flux values applied to a TW, on the indoor air temperatures and velocities.

2. METHODOLOGY

2.1. Model Description and boundary conditions

This research utilised a CFD (ANSYS Fluent [16]) model of a room with a natural convection TW system. Different heat flux values were applied on the TW surface, under the summer and winter conditions in Galway, Ireland, to evaluate their impact on indoor air temperature and velocity. The dimensions of the room and some boundary conditions were adopted from a previously published study [17]. The geometry of the investigated room is presented in Figure 1, with room dimensions of 3 m × 4 m × 4 m and the TW 2.4 m high and 0.3 m thicks, with a 0.3 m air gap between the TW and glazing. There were an inlet and outlet defined in the glazing (Figure 1, both 0.1 m wide) to enhance the airflow through the room.

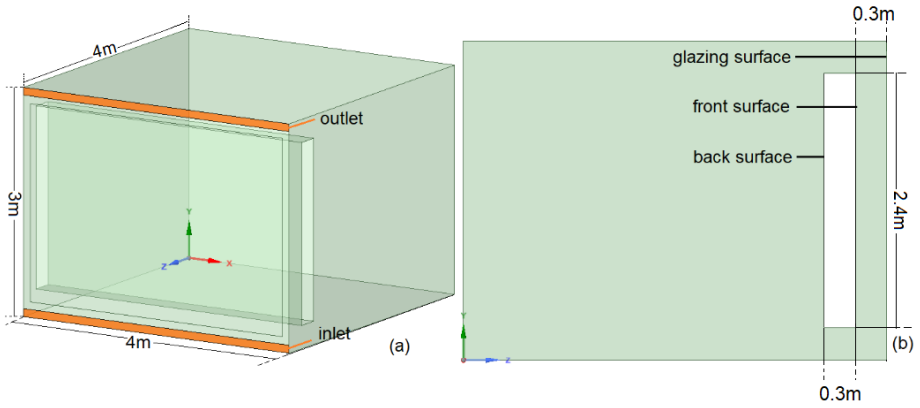

Figure 1. (a) Room geometry with inlet and outlet locations. (b) Cross-sectional view showing the glazing surface, TW front surface, and TW back surface.

Table 1 presents the boundary conditions for the CFD model. Four different heat flux values, including 200, 250, 300 and 350 W/m^2, were applied on the TW front surface to evaluate their impact on the thermal and flow behaviour inside the room. A fixed temperature was assigned to the TW back surface to simulate thermal behaviour. The heat flux values were based on typical solar heat flux values for Galway. The mean outdoor temperatures were assumed as 15.9 $^{\circ}$C for summer conditions (as the average measured [18] air temperature in Galway in August 2020), and 6.3 $^{\circ}$C for winter conditions (as the average measured [18] air temperature in Galway in December 2020). Ideal gas with fixed thermophysical properties was selected as a working fluid in the CFD model. The standard k-ε RNG turbulence model was used. The simulation did not employ a radiation model.

Table 1. Boundary conditions.

Element	Floor	Roof	Glazing surface	Glazing surface	Front surface	Back surface	Other walls	Inlet (summer)	Inlet (winter)	Outlet (summer & winter)
Parameters	T= 15°C	T=25°C & HTC= 90 W/m^2	T=15.9 °C (summer)	T=6.3 °C (winter)	HF: 200-350* W/m^2	T=25°C & HTC= 90 W/m^2	Adiabatic	V=0.1 m/s & Air T=15.9°C (T_{in})	V=0.1 m/s & Air T=6.3°C (T_{out})	1 atm gauge pressure (101,325 Pa)

**: from the surface of TW to the air cavity*

T: Temperature (°C), HF: heat flux (W/m^2), HTC: heat transfer coefficient (W/m^{2}K), V: Air velocity (m/s)

2.2. Grid convergence index method (GCI)

The Richardson Extrapolation approach [19], which requires consistency and uniformity in the mesh refinement, is an error estimator based on merging the discrete solution of two systematically refined meshes. Numerical errors are introduced through the discretisation procedure. Discretisation errors can be quantified with the GCI method. Figure 2 shows the main steps in the GCI method.

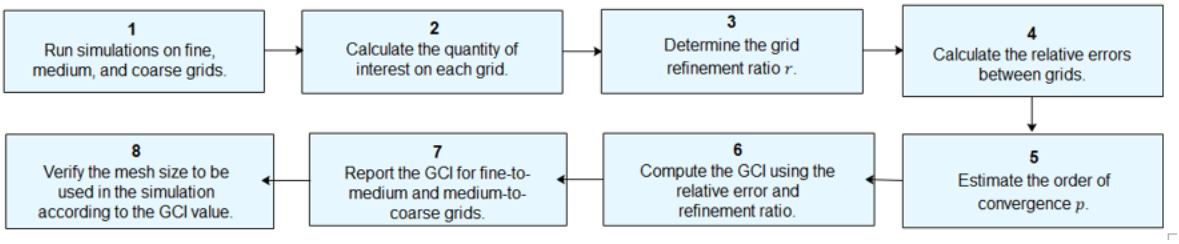

Figure 2. GCI calculation steps

Following the Richardson's extrapolation, the GCI was computed using the following equation [16]:

$$GCI = F_s \frac{\varepsilon}{r^p - 1} \quad (1)$$

Where, ε is the relative error of two grid conditions in the simulation, p is the order of convergence and F_s is the safety factor. When comparing three or more grids, F_s is calculated using a value of 1.25 [12].

2.3. Model Verification

The grid verification was carried out for the model with a heat flux value of 200 W/m^2, where the results of indoor air temperatures were analysed Table 2 presents the number of mesh elements and the grid refinement ratio (r) for those meshes. Using Richardson Extrapolation [19], r values greater than 1.3 (r_{32}=1.35, r_{21}=1.34) were achieved, meeting the recommended criteria [20].

Table 2. Grid parameters for three different mesh sizes.

	Coarse $\boldsymbol{\Delta_3}$	Medium $\boldsymbol{\Delta_2}$	Fine $\boldsymbol{\Delta_1}$	grid refinement ratio ($\boldsymbol{r}$)	
Number of elements	259770	638024	1531189	Coarse- Medium (r_{32})	Medium-Fine (r_{21})
Size of mesh elements	50 mm	20 mm	10 mm	1.35	1.34

The GCI was utilised to perform quantitative grid verification under conditions where monotonic convergence was observed. Table 3 shows the grid convergence error for the computed indoor air temperature on the assigned horizontal planes at head (1.7 m above the floor) and ankle (0.1 m above the floor) levels. The average convergence value (p= 2.3) was applied. The GCI values reduced with grid refinement, demonstrating improved accuracy, with the lowest error observed for the medium-fine grid comparisons (i.e. GCI = 1.5% at head level).

Table 3. Grid convergence error for indoor air temperatures.

	Grid No	Relative Error ($\boldsymbol{\varepsilon}$)	Average convergence value ($\boldsymbol{p}$)	GCI (%)
Head Level	Coarse-medium	0.026	2.3	*3.3*
Head Level	Medium-fine	0.011		*1.5*
Ankle Level	Coarse-medium	0.027		*3.5*
Ankle Level	Medium-fine	0.016		*2.1*

The ASME V&V 20 standard [21] suggests a GCI value below 5% for high-precision simulations, and some researchers even aim for values as low as 1-2%, depending on the study's sensitivity and accuracy requirements [22]. In this research, at the head and ankle levels, the air temperature results showed a GCI error of 1.5% and 2.1%, respectively, between the medium and fine meshes. The medium mesh ($\boldsymbol{\Delta_2}$= 638024) was selected for further calculations, with errors in the lower range of 1-2%, ensuring higher accuracy and reasonable computational resources. The closer to zero the GCI value is, the lower the discretisation error, but higher the computational resources.

3. RESULTS

In order to evaluate the effect of air cavity warming on indoor thermal conditions, the head (XZ plane I - Y = 1.7 m) and ankle (XZ plane II - Y = 0.1 m) levels of a standing occupant were selected as reference planes to analyse results. The air temperature and velocity profiles were simulated for all heat flux values under the summer and winter conditions. Figure 3 illustrates the air temperature distribution on plane I and plane II, for the heat flux of 250 W/m² for both summer and winter conditions. The head level in summer (Plane I) experienced the highest temperature gradients, likely due to hot air rising and accumulating at the upper levels of the room. The colder regions at the ankle level (Figure 3 b and d) resulted from fresh outdoor air entering the space below the TW and warming up due to interaction with the warm air coming from the air cavity between the glass and TW. Figure 4 shows the air velocity streamlines inside the room. The air entered the room through the inlet (at the bottom of the glazing) at velocity of 0.1 m/s, and after mixing with the stale air inside the room and inside the cavity between the TW and glazing, it exited through the outlet. The outlet was set to atmospheric pressure, assumed to be 1 atm, to ensure a consistent flow boundary condition.

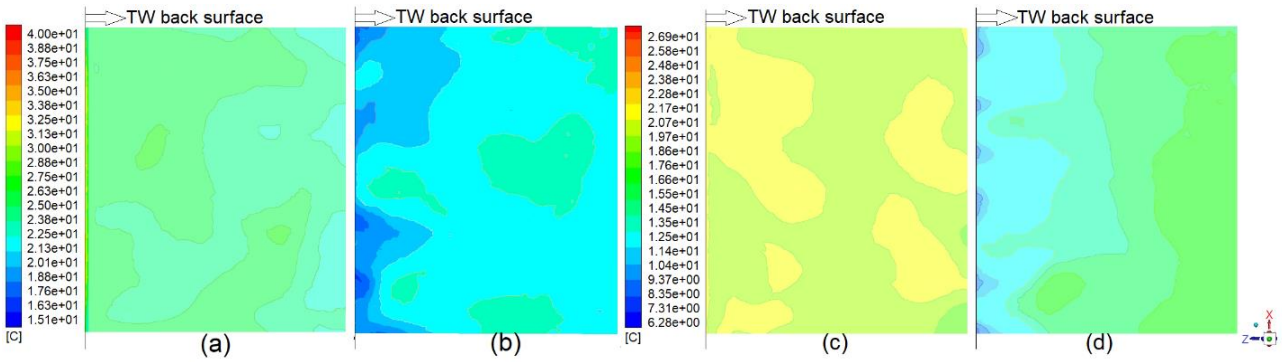

Figure 3. Air temperature distribution for a 250 W/m² heat flux value: (a) plane I (head level) summer, (b) plane II (ankle level) summer, (c) plane I winter, (d) plane II winter.

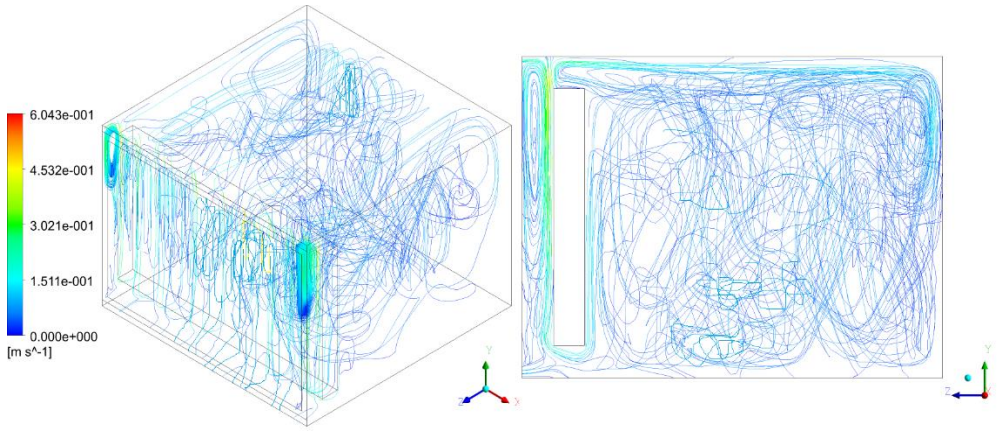

Figure 4. Air velocity distribution inside the room for 250 W/m² heat flux in summer conditions.

Tables 4 and 5 show air temperatures and velocities at the head and ankle levels for all simulated heat fluxes in the summer and winter conditions. At head level (Plane I), the average air temperature increased from 24.17°C to 30.43°C as the heat flux reached from 200 W/m² to 350 W/m². The range of air temperatures across all heat fluxes at head level was between 16.79°C - 32.37°C, showing a consistent rise with increasing heat flux in the summer. In addition, the average air temperature at the ankle level ranged from 20.67°C to 24.34°C, with a lower temperature rise compared to head level due to stronger impact of the inlet air conditions. Table 5 shows the average air temperatures in winter, ranging between 18.21–24.09°C at the head level, and 13.75–17.45°C at the ankle level. Indoor air velocities at head and ankle levels ranged between 0.03 and 0.05 m/s, for both summer and winter.

Table 4. Temperature and velocity results obtained on Plane I and Plane II (summer).

Heat flux (W/m^2)	Head level				Ankle Level			
	Temperature (°C)			Velocity (m/s)	Temperature (°C)			Velocity (m/s)
	Maximum	Minimum	Average	Average	Maximum	Minimum	Average	Average

4. DISCUSSION

There are several standards and guidelines used to assess and ensure thermal comfort in buildings. These standards aim to define and regulate the key environmental factors, such as air temperature, humidity, and air movement, that contribute to occupant's comfort. Among the widely referenced organizations providing such frameworks are the Chartered Institution of Building Services Engineers (CIBSE) [24], the International Organization for Standardization (ISO) [25], and the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) [26], each offering guidelines on different aspects of thermal comfort and environmental performance. Thermal comfort refers to the state in which the building occupants feel neither too hot nor too cold. Table 6 shows the comparison of average room temperature and velocity values with standardized thermal comfort criteria under summer and winter scenarios.

Table 6. Comparison of average indoor air parameters of the room with thermal comfort standards under simulated heat flux scenarios.

Parameter	Thermal comfort bandwidth	HF=200W/m^2	HF=250W/m^2	HF=300W/m^2	HF=350W/m^2
Air Temperature	24-26°C [27], [28]	✓ (S)	✓ (S)	X	X
	25-28°C [29]	✓ (S)	✓ (S)	✓ (S)	X
	24-26°C summer, 25°C winter [30]	✓ (S)	✓ (S)	X	X
	20-23°C in the winter, 22-26°C in the summer [23]	✓ (S)	✓ (S), ✓ (W)	✓ (W)	✓ (W)
Air Velocity	< 0.1 m/s [31]	✓ (S), ✓ (W)	✓ (S), ✓ (W)	✓ (S), ✓ (W)	X
	0.5-1.0 m/s [23]	✓ (S), ✓ (W)	✓ (S), ✓ (W)	✓ (S), ✓ (W)	X

**S: Summer, W: Winter.*

For summer conditions, the average indoor air temperature aligned with the thermal comfort range (22–26°C) at lower heat fluxes (200 W/m² and 250 W/m²). However, at higher heat fluxes (300 W/m² and 350 W/m²), the average air temperature exceeded the comfort thresholds. In winter conditions, the comfortable average air temperatures were met at 250, 300 and 350 W/m², but not achieved at 200 W/m² due to insufficient heating. Air velocity in both seasons remained within acceptable limits (<0.1 m/s) at all heat flux vales. In addition, all scenarios were considered in the previous tables, the average temperatures at ankle level are notably lower compared to head level. This cooler temperature at the lower zone could lead to thermal discomfort, as occupants may experience a cold feet sensation, especially during winter conditions, due to insufficient heat distribution and stratification in the indoor environment. Low temperatures at ankle level may result from the inlet's position, directing fresh air toward the feet and causing discomfort. Adjusting the inlet/outlet configurations could improve heat distribution and enhance thermal comfort. These results suggested that while specific heat flux values could achieve compliance with thermal

comfort standards, the TW system might require further optimisation to reduce vertical temperature stratification and enhance overall performance.

5. CONCLUSION

This study evaluated the indoor thermal and airflow conditions inside a room with a TW system, under varying heat flux conditions in both summer and winter scenarios. The results demonstrated that while specific heat flux values could meet thermal comfort standards for indoor temperature and air velocity, vertical temperature stratification remained a challenge, exceeding recommended limits in some cases. Optimal heat flux values for maintaining comfort conditions were identified as 200 and 250 W/m² in summer and 250, 300 and 350 W/m² in winter with further optimisation and modelling techniques required for decreasing air temperature differences. This study has limitations; it focused on evaluating the indoor environment under the predefined boundary conditions. While the results provided valuable insights, the study did not account for detailed effect of heat transfer through the TW. Future research could explore modelling the TW as a solid structure to include heat conduction through its material and convection between its surfaces and the indoor air. Additionally, the TW could be modelled with integrated phase change materials (PCM) or enhanced with fin geometries to improve heat transfer performance. Such advancements would provide a deeper understanding of the TW system's thermal behavior and its potential applications in diverse building designs. While this study primarily focused on the effect of varying heat flux values on thermal comfort at different vertical levels, it is recognized that the design and placement of inlets and outlets can also significantly influence vertical temperature stratification. A sensitivity analysis on inlet/outlet configuration was not included in the current study but represents an important area for future investigation to better understand airflow dynamics and enhance overall comfort prediction accuracy. Furthermore, incorporating a detailed radiation model in future simulations would allow for a more realistic representation of solar heat transfer, leading to improved prediction of the TW system's thermal response and its impact on indoor comfort conditions.

SUMMARY
Optimizing airflow mixing is critical for improving ventilation, especially in dense-intermittent occupied spaces such as classrooms. However, achieving optimal airflow mixing is challenging due to complex interactions between design parameters. This study explores a promising framework for optimizing airflow mixing in mixed-ventilated classrooms under realistic conditions. Computational Fluid Dynamics (CFD) simulations, combined with Taguchi, ANOVA, and Grey Relational Analysis (GRA), evaluated five parameters: placement and shape of diffusers, air change rate, inlet temperature, and source location. Discrepancies in factor rankings were observed due to variations in response metrics, for instance, source location was identified as both the most influential and least impactful depending on whether CO_2-air mixing or draft risk was prioritized. GRA was used to optimize the overall performance of these factors on airflow mixing and verified then using confirmation CFD runs. These findings provide insights for improving airflow mixing, enhancing air quality, and ensuring occupant comfort in classrooms.

Keywords: Airflow mixing, CFD, Taguchi, GRA.

1. INTRODUCTION

Airflow mixing is critical in building ventilation for improving thermal comfort and indoor air quality (Awbi, 1998). Effective air mixing systems reduce energy consumption and the carbon footprint of heating and cooling. This is particularly important in densely occupied spaces like classrooms, where air quality directly affects students' performance. Over the past fifty years, Computational Fluid Dynamics (CFD) has become a key tool for predicting airflow and ventilation performance in buildings. Providing detailed insights into airflow and pollutant dispersion, CFD enables cost-effective optimization of ventilation systems. It facilitates the evaluation of multiple scenarios, saving time and improving design efficiency. However, CFD is computationally intensive, sensitive to assumptions and mesh quality, and requires specialized expertise. Moreover, the large number of simulation parameters poses a challenge, particularly in parametric studies, where testing all possible cases is often impractical.

Coupling CFD with statistical methods addresses this limitation, showing success in solving problems in the ventilation field and other disciplines. Instead of evaluating all combinations of parameters, a method like Taguchi (Taguchi, 1986) employs orthogonal array techniques to design a simulation matrix with fewer CFD runs, covering the parametric space effectively. This allows

for reliable conclusions without sacrificing simulation outcomes. However, Taguchi's method, suited for single-response optimization, is limited in multi-response problems such as airflow mixing studies. To overcome this, Grey Relational Analysis (GRA) (Julong, 1989) is often integrated with the Taguchi method. Despite these advantages, studies applying Taguchi and GRA methods in building ventilation research often focus on specific applications, limiting generalizability. For instance, Ye et al. (Ye et al., 2021) optimized impinging jet ventilation (IJV) systems, offering insights into airflow and energy efficiency, but excluding other modes such as mixed ventilation. Similarly, Niu et al. (Niu et al., 2022) focused on data center cooling with under-floor air distribution, making their conclusions less relevant to other building types. Yuce et al. (Yuce et al., 2022) applied Taguchi, analysis of variance (ANOVA), and GRA to a two-dimensional benchmark case, but their simplified model lacks the complexity of real-world, three-dimensional environments. Therefore, this research aims to expand the applicability of this approach by testing it in a mixed-ventilated CFD classroom model under realistic conditions, aiming to generalize its use across various scenarios.

2. METHODOLOGY

This research integrates CFD simulations with Taguchi, ANOVA, and GRA methods to optimize five design parameters influencing airflow mixing in classrooms. A validated CFD model was developed with 25 different settings for air terminal layout, air change rates (ACH), inlet temperature (T_{in}), and exhaled CO_2 source location, resulting in 25 simulations based on an orthogonal array (Taguchi method). Four responses were predicted: uniformity index (U_i), zone distribution effectiveness (E_z), draft risk (DR), and temperature difference (ΔT) between head and ankle levels. A mono-assessment using Taguchi and ANOVA evaluated the impact of each factor, while a multi-assessment using Grey Relational Analysis (GRA) consolidated these responses into a single metric, Grey Relational Grade (GRG). Optimal and worst design combinations were identified, and two confirmation simulations validated the multi-response approach. Additionally, the U_i values for these settings are summarized to support the broader application of the Modified Decay Method (Reda et al., 2023), a novel method for measuring air change rates in non-uniformly mixed spaces.

The Taguchi method is a robust tool for identifying the best and worst combinations of factors for a given objective function, offering an efficient and systematic approach to optimizing design performance. By employing an orthogonal array, desired outcomes can be achieved with significantly fewer simulations. In this study, the Taguchi method was applied to design the CFD simulations using the L25 (5^5) orthogonal array, to study the effects of selected factors on airflow mixing at five levels, as summarized in Table 1. The levels and ranges of the factors were chosen after reviewing numerous classroom layouts and HVAC system designs from a relevant study (Reda et al., 2024) for the same building, aligned with recommended design considerations and operating conditions.

Table 1. Five-level factors were examined in the assessment of airflow mixing.

Level	Terminal Layout	Terminal shape	Air change rate [h^{-1}]	Inlet temperature [^oC]	Source location
1	Single	Square	3	12	5
2	Double	Round	6	18	11
3	Triple	Linear	9	24	21
4	Quadruple	Swirl	12	30	31
5	Quintuple	Perforated	15	36	41

The Taguchi method was used to rank factors and identify the best and worst combinations by calculating signal-to-noise ratios (S/N), determining the delta S/N (difference between the maximum and minimum values), and ranking the factors. The factor with the largest delta value is the most influential, while the one with the smallest delta value is the least effective. For U_i and Ez, the "larger-is-better" criterion Eq. (1) was applied to calculate S/N, and for DR and ΔT, the "smaller-is-better" criterion Eq. (2) was used. The ANOVA test quantified the contribution ratio of each factor, with significance accepted below 5%. Meanwhile, GRA was applied for multi-response analysis, converting U_i, E_z, DR, and ΔT into a single GRG. The GRA steps included normalizing each response, calculating the Grey Relational Coefficient (GRC), and determining the GRG based on weights assigned to each response. Various weighting methods, including averaged weight, Principal Component Analysis (PCA) (Qazi et al., 2020), and delta S/N, were tested, but only the averaged weight and PCA methods are presented due to their comparable results. For further details on these methods, readers are referred to previous studies (Ye et al., 2021; Yuce et al., 2022).

$$S/N = -10\,log\left(\frac{1}{n}\sum_{i=1}^{n}\frac{1}{{Y_i}^2}\right) \quad (1)$$

$$S/N = -10\,log\left(\frac{1}{n}\sum_{i=1}^{n}{Y_i}^2\right) \quad (2)$$

where n is the number of simulations and Y_i represents the resulting value for the ith performance characteristics.

A classroom model was developed based on the real dimensions of a classroom from a previous study (Reda et al., 2023). The computational domain included 25 different configurations, as illustrated in Figure 1. The classroom has a floor area of 78 m^2, a height of 3.4 m, and accommodates 40 students and one teacher. Air terminals were positioned on the ceiling for mixed ventilation. ANSYS Fluent software was used for mesh discretization, employing polyhedral meshes for better computational efficiency and accuracy (Chen et al., 2021). A mesh-independency study confirmed the selected resolution was optimal (0.05 m element size and 5,481,036 elements). Mesh quality was assessed using the U_i of CO_2, the root mean square error of CO_2 concentration logs (RMSEL), skewness, and orthogonal quality.

The boundary conditions used were derived from field-collected data in the same classroom (Reda et al., 2023). Supply inlets were defined as mass flow inlets with flow rates ranging from 0.3 to 1.3 kg/s, calculated based on the desired air change rate and diffuser area. The inlet temperature range was set between 12°C and 36°C. The exhaled CO_2 source was modeled as a mass flow inlet, releasing 0.0002 kg/s of air at 34°C with a CO_2 mole fraction of 0.04 (Georgescu et al., 2020). The classroom was maintained at 10% positive pressurization, as indicated by building automation system data. Consequently, the outlet was assigned a mass flow outlet equal to 90% of the inlet flow, with the remaining 10% exiting through the door gap. A no-slip condition was applied to all interior surfaces, and the walls were modeled as adiabatic due to negligible heat transfer compared to occupant heat gains. Seated students and the standing teacher were assumed to generate heat at a rate of 60 W/m^2 across their total body surface area, reflecting sedentary activity levels (ASHRAE, 2023).

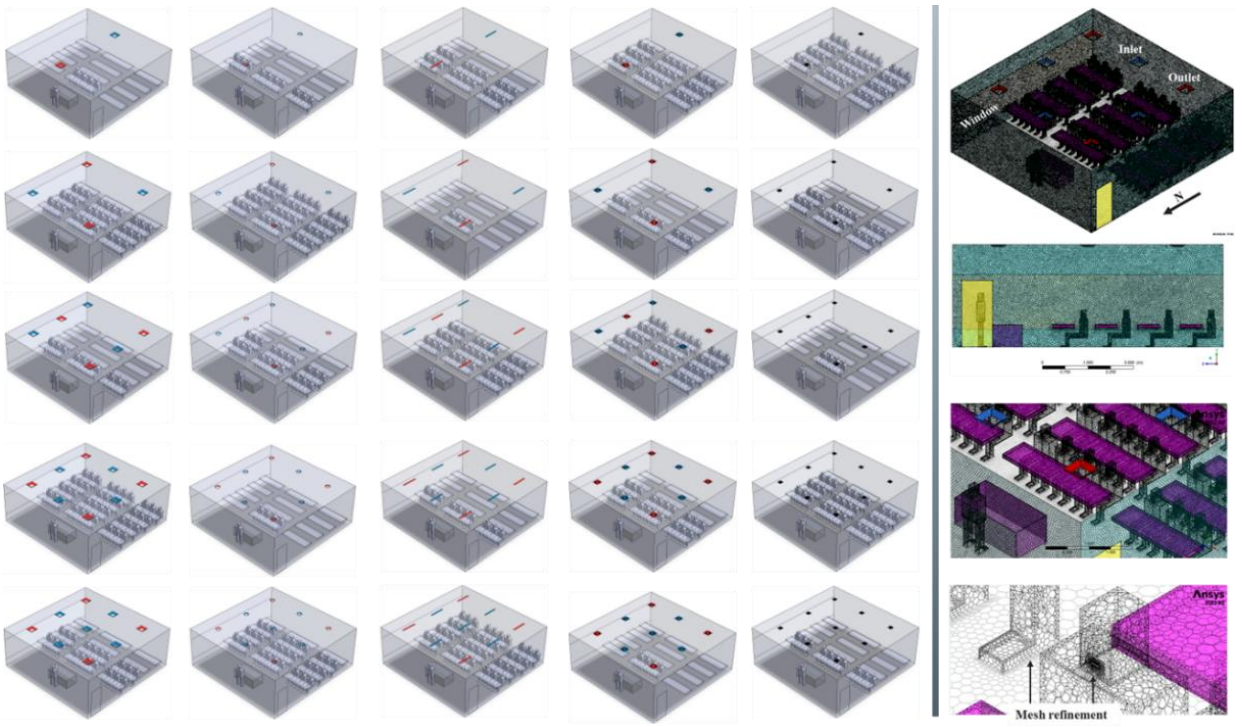

Figure 1. 3D views of the classroom model with air terminal types (square, round, linear, swirl, perforated) in columns and layout configurations (single to quintuple) in rows. Supply diffusers (blue) and return diffusers (red) are shown. The right panel illustrates polyhedral mesh generation for case 16, including refinement details.

Steady-state simulations were conducted governed by conservation equations for mass, momentum, energy, and species transport, with buoyancy effects accounted for by the Boussinesq approximation. The SST k-ω turbulence model (Menter, 1994) was employed with a pressure-based solver of a second-order upwind scheme. Convergence was achieved after 3000 iterations with criteria set to 10^{-4} for most equations and 10^{-6} for energy. The model was validated by comparing predicted CO_2 concentrations with measured data, showing a U_i of 0.74 and 0.76. The mesh with 5.5 million elements was sufficient, and further refinement did not significantly improve accuracy but increased computation time. Discrepancies near the source were attributed to proximity effects. The RMSEL for CO_2 was 12%, with a maximum skewness below 0.85 and a minimum orthogonal quality exceeding 0.1. A fine mesh was applied near occupants to resolve the laminar sublayer effectively.

Airflow mixing was quantified for each simulated case using exhaled-CO_2 tracer gas, employing the U_i (Reda et al., 2023) and E_z (ASHRAE, 2022). Maximizing the U_i and E_z values toward unity indicates a high level of airflow mixing; therefore, the "larger-is-better" criterion was applied in the Taguchi and GRA methods. Additionally, temperature and air velocity fields were analyzed to assess thermal sensation using the DR and ΔT between head and ankle levels. DR should be below 20% to ensure comfort (ASHRAE, 2023), with limitations to temperatures below 34°C and velocities above 0.05 m/s. For cases that included these limitations, DR was set to zero, and the ΔT metric was deemed more representative for assessing discomfort. A maximum ΔT threshold of 3°C between head and ankle levels is recommended (ASHRAE, 2023). The results are presented at the breathing level (1.1m from the floor level).

3. RESULTS AND DISCUSSION

Twenty-five CFD simulations were conducted to investigate the effects of air terminal layout and shape, air change rate, inlet temperature, and source location on airflow mixing at the breathing level (Figure 2). The five-response metrics (U_i, E_z, DR, ΔT, and GRG) along with their corresponding S/N ratios, are summarized in Table 2. This analysis was performed using a mono-assessment and multi-assessment approach. A comparison of these approaches is presented in the final section, along with a summary of the U_i values for all tested cases.

For the U_i (Figure 2.1), the source location emerges as the most influential factor with a p-value of 0.001, while the layout of air terminals has the least impact. The optimal configuration for achieving the highest U_i value is a setup with triple inlets and outlets using swirl diffusers, tested at a 3 h^{-1} ACH, 36°C inlet temperature, and 5-source locations (Tri-Swr-3-36-5). Conversely, the worst case for U_i is Quin-Perf-9-12-41. For the E_z (Figure 2.2), the ACH is the most significant factor with a p-value of 0.03, while the layout of air terminals again has the least impact. The optimal configuration for E_z is Quad-Sq-3-12-31, while the worst case is Quin-Perf-15-36-5. Notably, these optimal and worst scenarios were not part of the conducted simulations (Table 2), highlighting the strength of the Taguchi method in predicting extreme combinations without requiring all possible cases to be modeled.

For the DR (Figure 2.3), the inlet temperature is identified as the most influential factor (p-value = 0.04), while the source location has the least impact. The optimal combination of factors for minimizing DR is Sing-Sq-6-30-41. Conversely, the worst combination is Quin-Ro-15-12-21. For the ΔT (Figure 2.4), the shape of air terminals emerges as the most effective factor (p-value = 0.02), while the layout of air terminals has the least influence. The optimal combination for ΔT is Quin-Perf-15-30-5, while the worst combination is Doub-Sq-3-24-41. Like previous metrics, these optimal and worst combinations were not part of the conducted simulations. These findings were independently analyzed using the "larger-is-better" criterion for U_i and E_z, while DR and ΔT were examined with the "smaller-is-better" criterion. All least influence factors show a p-value exceeding 0.05.

The four latter metrics were analyzed dependently by transforming them into the GRG, applying the "larger-is-better" criterion. The GRA results are presented in Table 2, both with the average weight of responses and using the PCA. Figures 2.5 and 2.6 show the S/N ratios of the GRG based on both methods, respectively. Using the average weight of responses, the source location is identified as the most influential factor (p-value = 0.03), while the layout of air terminals has the least impact. The best and worst combinations are Tri-Sq-15-12-5 and Quad-Swr-3-30-41. Similarly, applying the PCA method confirms that the source location remains the most effective factor (p-value = 0.01), with the layout again being the least effective. The best and worst combinations are comparable with the average method, being Tri-Ro-15-12-5 and Quad-Swr-3-30-41, respectively. It is also observed that the air change rate and inlet temperature interchangeably rank as the second and third most significant factors affecting airflow mixing. None of these combinations were included in the conducted simulations. Verifying the GRG-PCA optimization, Figures 2.7-2.12 present two confirmation cases i.e., the optimal case (Tri-Ro-15-12-5) and the worst case (Quad-Swr-3-30-41). The average values of the U_i, E_z, DR, and ΔT at the breathing level equal 0.97, 0.18, 14%, and 0.3 ^oC for the optimal case, which become 0.53, 0.73, 2%, and 3.8 ^oC for the worse case.

Layout: Sing is single, Doub is double, Trip is triple, Quad is quadruple, and Quint is quintuple.
Shape: Sq is square, Ro is round, Lin is linear, Swr is swirl, and Perf is perforated.
ACH is the air change rate [h^{-1}], T_{in} is the inlet temperature [°C], and source # is the number of locations of exhaled-CO_2 from nostrils. U_i is the uniformity index, S/N is the signal-to-noise ratio [dB], E_z is the zone distribution effectiveness, DR is the draft risk, and ΔT is the temperature difference between head and ankle levels [°C].
GRG is the grey relational grade, Ave is the averaged value of responses, and PCA is the principal components analysis.

The comparison of mono-assessment and multi-assessment approaches reveals significant differences in factor rankings. Source location and air change rate are identified as key factors affecting CO_2-air mixing in the classroom, aligned with prior findings (Niu et al., 2022; Ye et al., 2021; Yuce et al., 2022), highlighting the importance of supply inlet height, velocity, nozzle positioning, and inlet dimensions for optimizing ventilation and comfort. Inlet temperature and air terminal shape also strongly influence draft risk and temperature discomfort, with latter studies confirming their role in thermal comfort and energy efficiency. Discrepancies in factor rankings, such as the varying impact of source location on U_i and DR, reflect context-dependent responses. When using a single metric (GRG) to evaluate overall system performance, four dominant factors source location, air change rate, inlet temperature, and air terminal shape emerge. The diffuser layout shows minimal impact on airflow mixing, explaining its limited focus in past research compared to other factors.

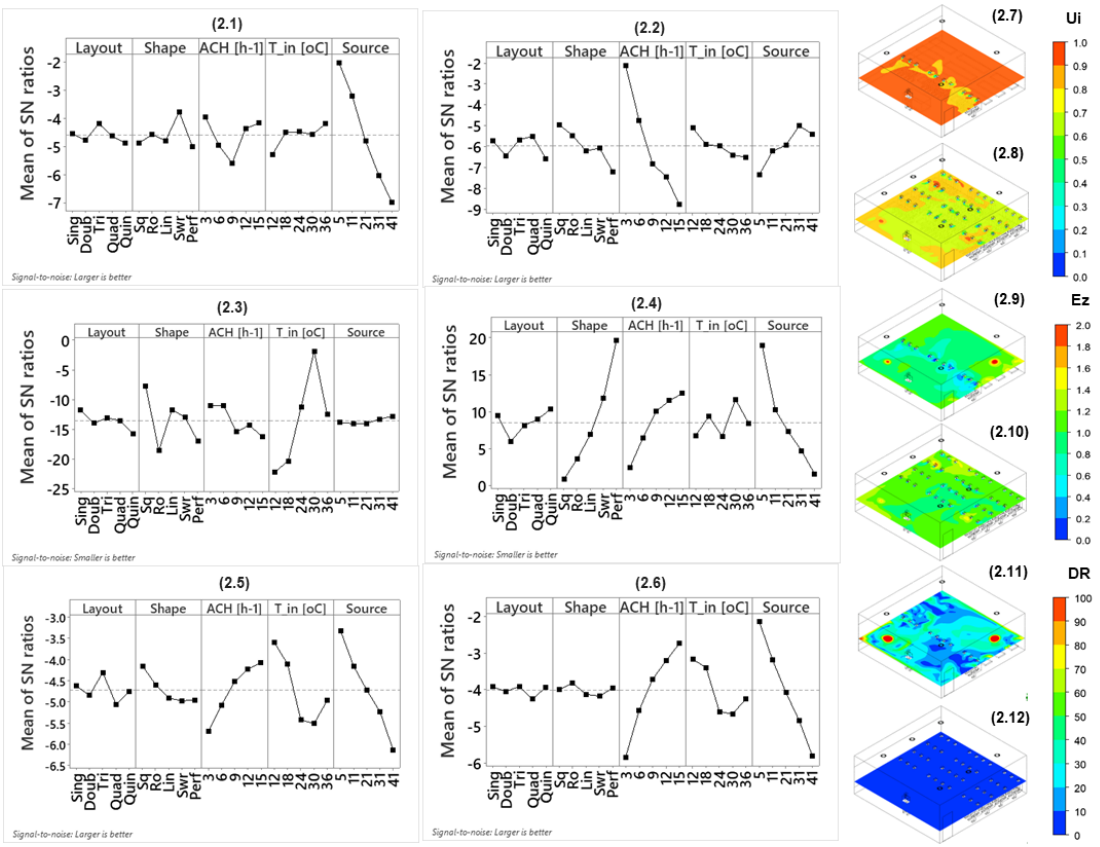

Figure 2. Left: Signal-to-noise (S/N) ratio plots for layout, air terminal shape, ACH, inlet temperature, and source location. Mono assessment: (2.1) Ui, (2.2) Ez, (2.3) DR, (2.4) ΔT. Multi assessment: (2.5) GRG (average weights), (2.6) GRG (PCA). Right: Contour plots for optimal (Tri-Ro-15-12-5) and worst (Quad-Swr-3-30-41) cases, showing Ui (2.7, 2.8), Ez (2.9, 2.10), and DR (2.11, 2.12) at the breathing level.

The previous analysis examines how the studied factors influence airflow mixing in classrooms, quantified using the U_i. Recently, U_i has proven effective in improving the accuracy of the decay method, which tends to underestimate air change rates by 20-25% due to the well-mixed air assumption. Therefore, a modified decay method (Reda et al., 2023) was developed and validated in a real classroom using field testing, wherein the U_i value was experimentally calculated at the breathing level. The U_i values for various mixed ventilation settings tested here can further enhance the applicability of the modified decay method. Across the tested scenarios, the U_i values range from 0.38 to 0.88, with an average of 0.60 ± 0.13, highlighting variability in airflow distribution.

4. CONCLUSIONS

This study tested a systematic framework to optimize airflow mixing in classrooms with mixed ventilation, considering the interactions among design factors in real-world settings. Using CFD simulations combined with the Taguchi method, ANOVA, and Grey Relational Analysis (GRA), five key parameters were analyzed: air terminal layout and shape, air change rate (ACH), inlet temperature, and exhaled CO_2 source placement. The Taguchi and ANOVA methods were initially applied (Mono assessment) to assess the impact of each factor on uniformity index (U_i), zone distribution effectiveness (E_z), draft risk (DR), and temperature difference (ΔT) between head and ankle levels. Followed by a multi-assessment approach using GRA to consolidate these responses into a single metric, Grey Relational Grade (GRG), for a comprehensive evaluation of airflow

mixing. Key findings revealed that source location and ACH significantly affect airflow mixing. The optimal configurations, involving Tri-Sq-15-12-5 and Tri-Ro-15-12-5 setups with triple square and round diffusers, respectively, with an ACH of 15 h^{-1}, an inlet temperature of 12°C, and 5 source locations, achieved high uniformity and distribution effectiveness. In contrast, poor configurations, such as Quad-Swr-3-30-41 and Trip-Swr-3-24-41, with lower ACHs and higher inlet temperatures, led to poor mixing. Discrepancies in rankings between mono-assessment and multi-assessment approaches showed varying impacts depending on the metric, with source location being crucial for U_i but less influential for DR. These results highlight the complex interactions in ventilation design and the need for tailored solutions. Future research should expand simulation sets, incorporate different geometries with dynamic occupancy, and integrate real-world data to enhance model accuracy and adaptability in educational environments.

SUMMARY
Old urban neighbourhoods usually possess diverse morphological patterns while fostering many intellectual and adaptive strategies to cope with heat waves. Shading, an approach of establishing thermally comfortable outdoor environments and a medium of place-making in high-density old urban neighbourhoods, can be traced and learned for climatic adaptive rehabilitation and urban governance. This study takes *Chang'an Neighbourhood* as a case study site, representing a typical traditional and old neighbourhood with high-density morphological characteristics in Wuhan, China. The study adopted Christopher Alexander's *Pattern Language* theory and methodology for field survey to systematically investigate the typical forms of informal shadings to be employed by occupants in the site. It then conducted computational simulations with the ENVI-met platform to test the cooling effect of these soft and micro-scale shading strategies during peak hours in summer daytime. The paper also preliminarily discusses how the informal shading strategies can be applied in old urban neighbourhoods to alleviate urban heat island effects during urban design and planning. Findings of the study provides insights of informality into urban renewal that aim to achieve ecologically resilient and healthy development.

Keywords: Shading forms, Cooling effect, Computational simulations, Urban informality

1. INTRODUCTION

With the increase of global warming and rapid urban transformation, thermal environments in urban spaces are gradually deteriorating in recent years, with increasingly frequent heat wave events posing significant threat to human health and well-being. People urgently need to seek more effective and adaptive approaches to counter such tricky situations, particularly, in cities located within high temperature and humid climate zones. The effects and beneficials of shading in urban outdoor spaces have been widely investigated and demonstrated. Watanabe et al. (2014) conducted an on-site study to examine the performance of shadows of several shading forms. Their test results illustrated that the cooling effect from buildings' shadows outperformed the pergola shadows. Focusing on the impact of shading forms on campus thermal environments, Xiong et al. (2024) carried out field measurements and found that shading could effectively block solar radiation during hot summer days. Specifically, pavilion and awning shadings offered better thermal comfort conditions compared to the shadings by tree canopies. They concluded that distinct spatial morphological elements affected outdoor spaces' micro-climate conditions, with varying shadows exhibiting different levels of cooling effects. Using ladybug tools, Nicholson et al. (2024) tested multiple thermal effects of shadings in urban street spaces and developed a workflow for effective shading design. In addition, Al Tahir et al. (2025)'s experiments further verified the cooling performances of artificial shadings, which were affected by structural and material characteristics.

Buildings, structures, and plants are prevalent sources of shadows in urban built-up areas. In high-density old urban neighbourhoods, residents always improvise soft and adaptive approaches to enable shadings, so as to ameliorate their outdoor living environments, characterized by their ease of construction, and thus highlighting their flexibility and adaptability to diverse spatial patterns. Lin et al. (2010) pointed out that low rate of shadows in outdoor spaces are discomfort for people during hot summer, while outdoor environments with a high rate of shadows are not comfortable for outdoor activities in cold winter. People seek shaded areas to shield themselves from the sun's beams in summer, whereas in winter, they need sufficient sunlight to increase air temperature and illumination of their houses and outdoor spaces. In this regards, informal shading can be adopted to adapt to various local climatic conditions, so as to enhance thermal resistance of outdoor spaces within the neighbourhoods. This study aims to examine the cooling effect of informal shadings in high-density old urban neighbourhoods. Taking Wuhan's *Chang'an Neighbourhood* as a case site, the study adopted Christopher Alexander's *Pattern Language* for field survey to systematically investigate the typical forms of informal shading to be employed by occupants in the site. It then conducts computational simulations with the ENVI-met platform to measure the cooling effects of these soft and micro-scale shading strategies during peak hours of summer daytime. The paper also discusses how the informal shading strategies can be integrated into the processes of urban planning and design to alleviate urban heat islands. Findings of the study provide insights of informality into urban renewal that aim to achieve ecologically resilient and healthy development.

2. MATERIALS AND METHODS

2.1. Case Study Site

Wuhan, which is a metropolis located on the eastern Jianghan Plain in central China, features a subtropical mild monsoon climate characterized by hot-humid and abundant rainfall. The city of Wuhan has a long summer season that starts in early May and lasts until late September, with air temperatures frequently reaching among the range of 37~39 ℃. Meanwhile, there are thousands of lakes and rivers in this city, which significantly contribute to the forming of stuffy and thermally uncomfortable feeling in the summer (Wang et al., 2013).

Old urban neighbourhoods (*lao-jie-qu*), specifically those *Lifen* neighbourhoods within the core area of Wuhan's concessions, still co-exist and co-develop with modern residential areas in the city (Pan, 2023; Xi et al., 2024). The traditional buildings with old masonry structural systems and poor infrastructure have hindered residents' quality of life and social well-being in the contemporary era, particularly, when confronting the threatening of climate change and the shock of radical urban transformations. A field survey by Yuan et al. (2014) have identified that there are several issues of liveability in Wuhan's French Concession, including deteriorating living conditions and environmental qualities, as well as lack of sufficient amenities and aging facilities. The street spaces in these typical old neighbourhoods, including those narrow and heterogeneous alleys, usually serve multiple habitation functions, ranging from playing, chatting, planting, cooking, cleaning, to drying vegetables and fruits, etc. Thus, this study specifically evaluates the impact of informal shading forms on thermal comfort conditions in street spaces of high-density old urban neighbourhoods as residents often adjust their outdoor living spaces by adopting and integrating informal and intellectual shading strategies. The *Chang'an Neighbourhood*, which is a typical *Lifen* neighbourhood situated in the French Concession, was chosen for case study (Fig. 1).

Fig. 1. Location and urban contexts of the case study site (source: drawn by authors based on Baidu Satellite Map)

2.2 Forms of Informal Shading

The theory and methodology of *Pattern Language* was initially established by Christopher Alexander for systematically capturing material, social and humanistic attributes of architectures and spaces in cities (Alexander, 1977). The *Pattern Language* provides a clear logic and working framework for identifying both physical elements and social features that constitute architectural and urban spaces, which can further be utilized to examine their individual roles and interactive functions and thereby facilitating effective place-making in urban planning and design. Two typical types of informal shading forms in *Chang'an Neighbourhood* have been surveyed and analysed in this study, namely, Climbing Plants (Type A) and Canvas Roofs (Type B) (Table 1).

Table 1. Examined forms of informal shading based on *Pattern Language* (source: surveyed by authors)

Type A	**Climbing Plants**		
Hypothesis	Climbing plants can fill up the gaps in leaves and provide soft and biophilic shading in high-density neighbourhoods.		
Problems it tackles	From an environmental standpoint, it enhances the beauty of the surroundings; from an architectural standpoint, it offers sections of shade during the sweltering summer days and lessen the amount of heat radiation that buildings absorb. Its biophilic design well fits with the scorching summers and chilly winters found in cities located in hot and humid climate zones.		
Practical implications	Regular pruning is required, which makes upkeep inconvenient and expensive. With the plants grow and spread, they put more strain on the building roofs and facades, which need to be care about the issue of safety and fire risks.	*Related to other patterns*	- Housing clusters - Small path shape - Entrance transition
Type B	**Canvas Roofs**		
Hypothesis	There are common usage forms of canvas roofs in high-density traditional and old urban neighbourhoods across Chinese cities.		
Problems it tackles	Increase the lifespan of ground items, diversify, and customize the shapes, colours, and materials; lessen the glare issue brought on by the west sun; and lessen the erosion of rain on building components that are more susceptible to damage, such the gate.		
Practical implications	Beyond generation of some safety issues such as structural damage in events of heavy rain or snowfall, when confronting strong wind, canvas roofs can also contribute to noise pollution.	*Related to other patterns*	- Edge of Buildings - Entrance transition - Small path shape

2.2 Data Source and Protocol of Computational Simulations

Computational fluid dynamics (CFD) is an evaluation technique that employs computer algorithms and mathematical models to predict fluid flow behaviors. ENVI-met, a prevailing microclimate numerical modeling software, enables effective simulation of the impact of buildings, vegetation, and surface materials on urban environmental performances, and has been extensively applied to assess the effectiveness of various strategies in mitigation of urban heat islands and enhancement of outdoor thermal comfort conditions. In this study, the meteorological data to be used to set the background climatic and initial environmental conditions for CFD simulations was obtained from the platform of Meteorological Station Data (https://www.ladybug.tools/epwmap/), including the data of dry bulb temperature, relative humidity, wind speed and wind direction, etc. In addition, the modelling base maps were adapted from Google Earth, and information of building heights and spatial geometries of the site were collected from field measurement by employing a laser rangefinder. Meanwhile, this study established 3D models for simulations in ENVI-met V5.7.1, with a modelling area size of 108m×80m×30m and a unit grid size of 4.00m×4.00m×1.00m. Taking 31 July as a peak summer day in Wuhan City, all the simulations were set to run from 08:00 am to 18:00 pm (10 hours, covering the hottest period of 10:00 am~16:00 pm). The observation height was set at a pedestrian level (1.5 meters high). Details of the initial settings for the simulations as well as the 24-hour cycle of the air temperature (Ta) and relative humidity (RH) were shown in Table 2 and Table 3, respectively. Finally, the thermal comfort conditions of the *Original* (Scenario 1: without shadings), *Type A* (Scenario 2: with shadings of climbing plants), and *Type B* (Scenario 3: with shadings of canvas roofs) were simulated and compared.

Table 2. Initial settings of environmental parameters for the CFD simulations

Environmental Parameters	Settings/ Assigned Values	
Location of the tested sites	Wuhan City, China	
Climate type	Subtropical climate	
Model dimension	x-Grids: 27, y-Grids: 20, z-Grids: 20

This study measured air temperature (T_a), mean radiant temperature (MRT), predicted mean vote (PMV), and operative temperature (T_{op}) under different informal shading forms. For each scenario, all the simulated environmental parameters of the nine tested points were averaged for further analysis and comparison (Table 2). The index of T_{op}, which combines both effects of T_a and MRT, was calculated using Eq. 1, where the wind speed (v) was measured at the same height as the observation height of the study (Tymkow et al., 2013). The values of T_{op} (ºC) were calculated based on Eq. 1, while the values of MRT (ºC) and PMV (-3 ~ +3) could be directly computed and outputted by ENVI-met simulations Notably, this study looked at relative values of environmental indices to quantify the extent of change of thermal conditions by comparing informal shading and the original situations, including $\triangle$PMV (Eq. 2) and $\triangle T_{op}$ (Eq. 3).

$$T_{op} = \frac{\mathrm{MRT} + (\mathrm{Ta} \times \sqrt{10v})}{1 + \sqrt{10v}} \qquad \text{(Eq.1)}$$

$$\triangle \mathrm{PMV} = \left| \mathrm{PMV} - \mathrm{PMV}_{original} \right| \quad \text{(Eq.2)} \qquad \triangle T_{op} = \left| T_{op} - T_{op_original} \right| \quad \text{(Eq.3)}$$

3. RESULTS AND DISCUSSION

3.1 Variations and Trends of Cooling Performances

Test results illustrated that the informal shadings Type A and Type B's average values in T_a, MRT, PMV and T_{op} were all lower than the *Original* situation hour by hour during 10:00 am~16:00 pm. Thus, the $\triangle$ PMV and $\triangle T_{op}$ values theoretically reflected the informal shadings' degrees of

amelioration in outdoor thermal comfort conditions. T_a and MRT closely correlates with the angle of solar altitude. Specifically, the three scenarios' T_a and MRT was observed to be above 40°C and 45°C respectively during 13:00 pm~16:00 pm, reflecting extremely hot conditions. The hourly average PMV and T_{op} in Type A and Type B were all lower than the original situation during 13:00 pm~16:00 pm. Among Type A and Type B, their hourly $\triangle$PMV and hourly $\triangle T_{op}$ varied by ranges of 0.24~1.69 and 1.62 °C~9.73°C, respectively. The maximum difference of $\triangle$PMV and $\triangle T_{op}$ among the three scenarios both occurred at 13:00 pm (Fig. 2). These preliminarily reveal that adding informal shading elements could ameliorate outdoor spaces' thermal comfort conditions while maintaining the original building layouts and spatial forms of the old neighbourhoods.

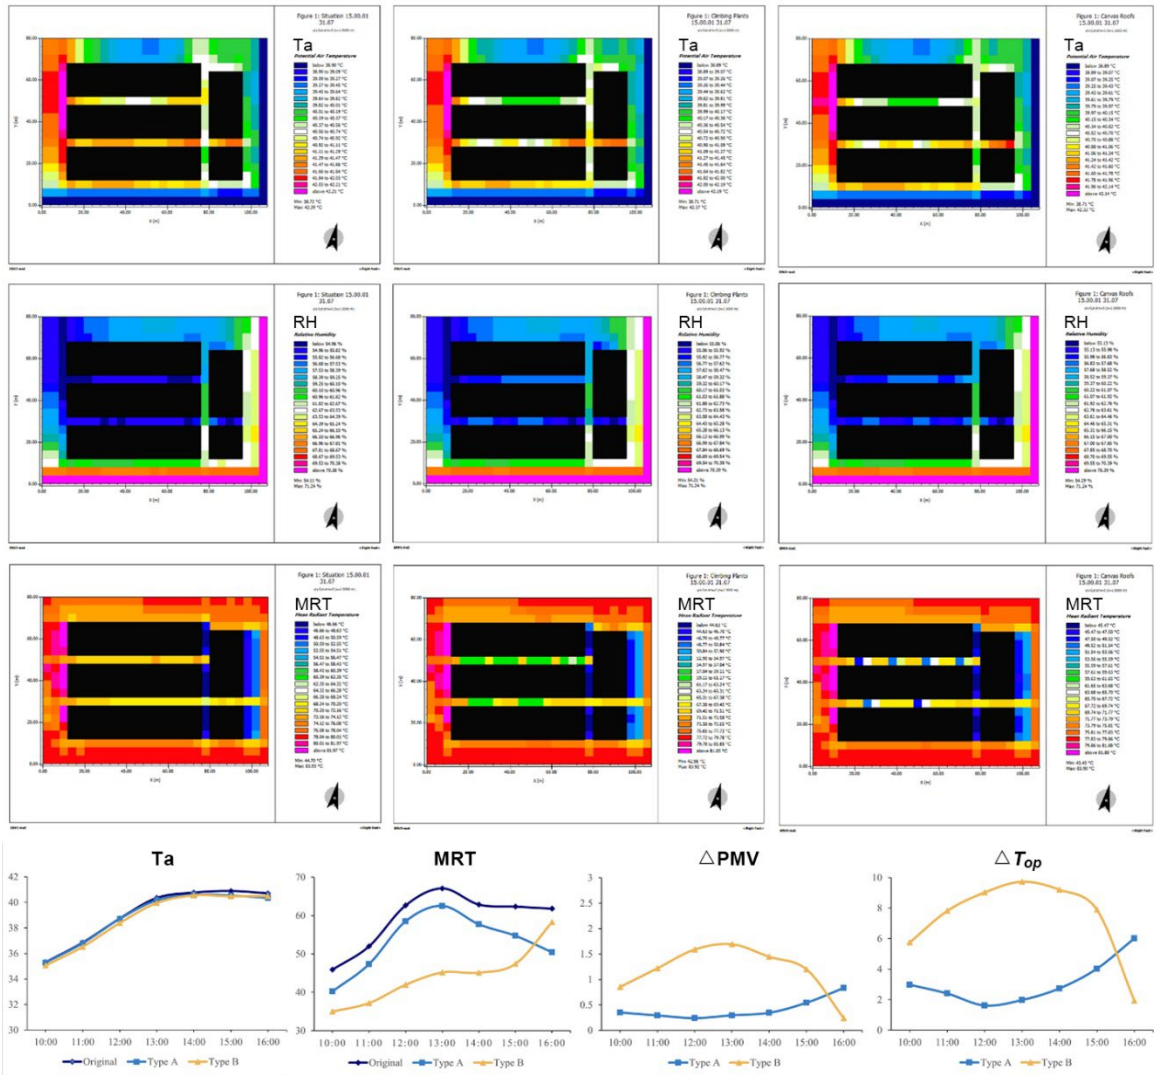

Fig. 2. Results of simulations (Ta, RH, MRT at 15:00 pm, Original, Type A, and Type B, respectively) and change trend of Ta (°C), MRT (°C), $\triangle$PMV and $\triangle T_{op}$ (°C) during peak hours (10:00 am~16:00 pm)

On the other hand, Type B exhibited greater cooling effect than Type A during 10:00 am~15:00 pm. However, the situation reversed during 15:00 pm~16:00 pm. Type B's $\triangle$PMV started to present a decreasing trend at 12:00 pm, and its $\triangle T_{op}$ declined beginning at 13:00 pm as well. In

comparison, both $\triangle$PMV and $\triangle T_{op}$ in Type A experienced decrease during 10:00 am~13:00 pm while went up stably from 13:00 pm to 16:00 pm. This indicates that Type A's cooling effect strengthened hour by hour after the noon. It is worthy noted that the $\triangle$PMV and $\triangle T_{op}$ in Type A was observed to be higher than that in Type B at 16:00 pm, indicating that Type B's cooling effect is degrading hour by hour starting from 16:00 pm (Fig 2). This could be due to the climbing plants' transpiration in Type A. The cooling effect to be generated from transpiration continues to work even though the sun's angle shifts and the level of solar radiation declines in late afternoon.

The thermal environments in alley spaces are greatly influenced by the ratio of shaded areas during daytime. The average T_a and MRT of all tested points in Type B presented an increasing trend starting from 15:00 pm, while MRT in nearby unshaded areas within the site exhibited a decreasing trend (Fig. 2). This resulted from the significant change of shadow areas' locations as the solar altitude angle shifts throughout the day and significantly affects the shading effect in narrow alleys. Notably, considerable difference in spaces with North-South orientation was observed since all tested points in these spaces were blocked by building shadows in the daytime. By contrast, shadow areas in East-West alleys were not fixed, instead, keep gradually changing along with the shifting of solar angle in the sky (Fig. 3). Consequently, the climbing plants in Type A could still absorb heat and energies via transpiration mechanism while reflecting sunlight by the leaves. In summary, this study has captured obvious cooling effects in informal shadings Type A and Type B. Type A exhibited stronger cooling effect after 16:00 pm, while Type B performed better before to that time. These findings also generally consistent with existing studies, e.g., Xiong et al., 2024.

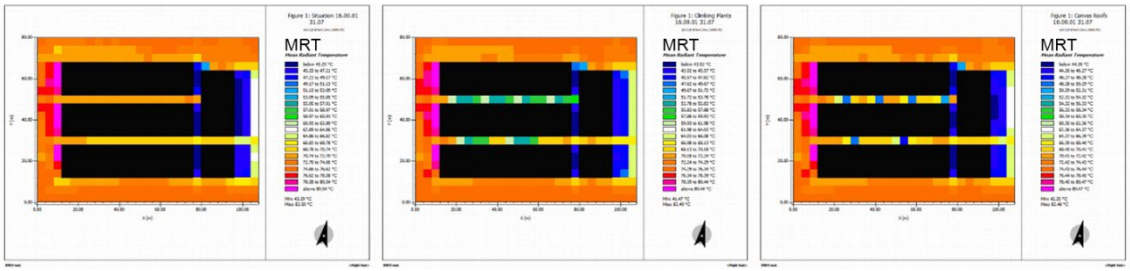

Fig. 3. The MRT (°C) variations at 16:00 pm in scenarios of Original, Type A, and Type B, respectively

3.2 Functions and Roles of Informal Shading in High-density Dwellings

Street spaces, particularly those narrow alleys in high-density old urban neighbourhoods, serve as important "outdoor living rooms", covering regular daily activities, recreation, and transportation functions (Pan, 2023). Shading is crucial for residents during hot summer as it generates shadows for ameliorating outdoor thermal comfort conditions, enabling people to conduct diverse everyday life activities, and as a result, maintaining urban dynamics and developing community social capital (Pan, 2024). High-density old urban neighbourhoods, like *Lifen* in Wuhan, usually possess narrow alleys with high aspect ratio (H/W) and diverse forms of small-scale public spaces. This study has demonstrated that the absence of shadows in compact old urban neighbourhoods can be compensated by introducing informal shading elements and then enable enhancement of outdoor thermal comfort conditions. However, there are much less green areas in high-density old urban neighbourhoods. The informal shading form of Type A (Climbing Plants) could be utilized to supplement the amount of greenery for the neighbourhoods while functioning as efficient way to establishing both thermally and visually comfortable spaces for residents. Meanwhile, growing specific climbing plants (e.g., grapes, loofah, and gourds) can be combined with the purposes of

urban framing and food production. For Type B (Canvas Roofs), by obstructing direct sunlight, it could effectively improve outdoor spaces' thermal environments as well. Additionally, those traditional old neighbourhoods located in central urban areas keep transforming with the city (re)development. Therefore, the added shading elements need to be adaptive to the emerging situations to promote urban resilience. While employing canvas roofs with diverse shapes, hues, and materials could foster soft habitation environments and new neighbourhood cultures.

4. CONCLUSION

This study has examined the cooling effect of two typical informal shading forms in Wuhan's old urban neighbourhood through computational simulations. The results illustrated that these two informal shading forms functioned to enhancing outdoor thermal comfort conditions. Canvas roofs generally presented greater cooling effect than climbing plants before late afternoon. The $\triangle$PMV difference reached the greatest at noon, and canvas roofs exhibited lower $\triangle$PMV than climbing plants in late afternoon. Meanwhile, the changing solar angle had significant impact on the cooling performance of canvas roof. Overall, informal shading, containing multiple daily functions and fostering community place-making, enables residents' continuing outdoor living in old urban neighbourhoods. Since the study was initiated in the autumn of 2024, our field measurement data did not reflect summer conditions in Wuhan. Thus, this pilot study relied on open-source data for CFD simulations. Future study should investigate more detailed spatial characteristics of informal shadings and collect more accurate environmental data for detailed and more efficient simulations.

SUMMARY
Urban heat waves and rising temperatures pose significant threats to human health, leading to increased mortality in many urban areas. Bus commuters, outdoor workers, the elderly, and socially vulnerable populations, including the homeless, are particularly at-risk during heat waves. While outdoor cooling spots can provide relief, existing solutions such as conventional air conditioning and evaporative cooling systems are often expensive or ineffective in humid climates. This study proposes a membrane-assisted radiant cooling system for outdoor applications that directly cools nearby individuals through radiative heat transfer, minimizing convective heat loss to the ambient environment. The thermal performance and human thermal sensation of this cooling hub were analyzed using Computational Fluid Dynamics (CFD) techniques and the CFD-CTM-JOS3 coupling method, considering factors such as solar radiation, asymmetric long-wave radiation, and other environmental conditions. On a typical summer day in Hong Kong, the proposed system's maximum heat extraction rate is 280.5 W/m² at 13:00 hr (air temperature: 31.6°C, relative humidity: 60%) for the street canyon configuration. Individuals under the cooling hub experienced a thermal sensation vote of -1 (indicating slightly cool), while those at the conventional bus stop had a vote of 3.57 (indicating hot). The current design has a radiative heat transfer efficiency of 8%, indicating significant potential for energy savings. Future research will focus on optimizing the structural design to enhance cooling efficiency and maximize this potential.

Keywords: membrane-assisted radiant cooling system, outdoor cooling, human thermal sensation, cooling shelter.

1 RESEARCH BACKGROUND

Urban heat waves and urban heat island effects are pressing issues that need urgent solutions, especially in outdoor environments. The vulnerable populations affected by these heat issues include children, the elderly, and those who spend considerable time outdoors. Many cities are inadequately designed and prepared to handle extreme heat events, resulting in increased heat-related mortality and morbidity rates worldwide (Campbell, Remenyi, White, & Johnston, 2018). Climate injustice directly impacts low-income communities, particularly those who work outdoors or wait for public transport in the scorching sun. Individuals in these situations require not just shelters but also cooling strategies that can protect them from intense heat stress.

Outdoor cooling strategies such as shading, park cooling, induced wind movement through surrounding building designs, green cover, and reflective coatings on road surfaces can help reduce temperatures. However, their effectiveness in improving outdoor comfort during extreme heat

events is often questionable. Techniques like mist cooling and evaporative cooling offer localized cooling options but tend to consume a lot of water and may not be effective in humid climates (Kyogoku & Takebayashi, 2023). In addition to existing urban cooling techniques, providing localized outdoor cooling hubs is an effective way to safeguard people from heat waves. These challenges highlight the need for alternative outdoor cooling solutions.

One such alternative cooling technique is to cool individuals directly, rather than the air. The membrane-assisted radiant cooling technique is a proven method for semi-outdoor and outdoor spaces, as it radiatively cools the occupants (Teitelbaum, Chen, et al., 2019; Yang et al., 2024). The schematic of the membrane-assisted radiant cooling panels in the localised outdoor cooling hub (LOCH) is shown in Figure 1 (Dharmasastha, Zhong, Niu, & Liang, 2024). The concept of membrane-assisted radiant cooling system was proposed by Morse in 1963, and recently revived by Teitelbaum in 2019 ((Morse, 1963; Teitelbaum, Rysanek, et al., 2019). An infrared transparent (IRT) film is used to isolate the radiant panel from the humid ambient environment, and the air gap design between the panel and membrane ensures the lowest convective heat transfer and reduces the risk of condensation. The IRT membrane allows infrared radiation to pass through, enabling the cooling panel to absorb radiation from both human bodies and surrounding heat sources. This makes it suitable for humid outdoor conditions, and experimental studies have demonstrated promising thermal comfort results in semi-outdoor and outdoor settings (Teitelbaum, Chen, et al., 2019; Yang et al., 2024). However, despite these promising results, there is a scarcity of numerical studies investigating the thermal comfort performance of membrane-assisted radiant cooling in outdoor applications, particularly within street canyon environments. This study addresses this gap by developing a numerical model of a LOCH equipped with a membrane-assisted radiant cooling system within a street canyon setting. This model incorporates all relevant outdoor ambient factors and replicates a typical Hong Kong bus stop structure. The heat transfer components of the cooling system in the outdoor is shown in Figure 1b. The system's cooling performance is analyzed for a typical summer day in Hong Kong (July 21st) and compared to a conventional bus stop.

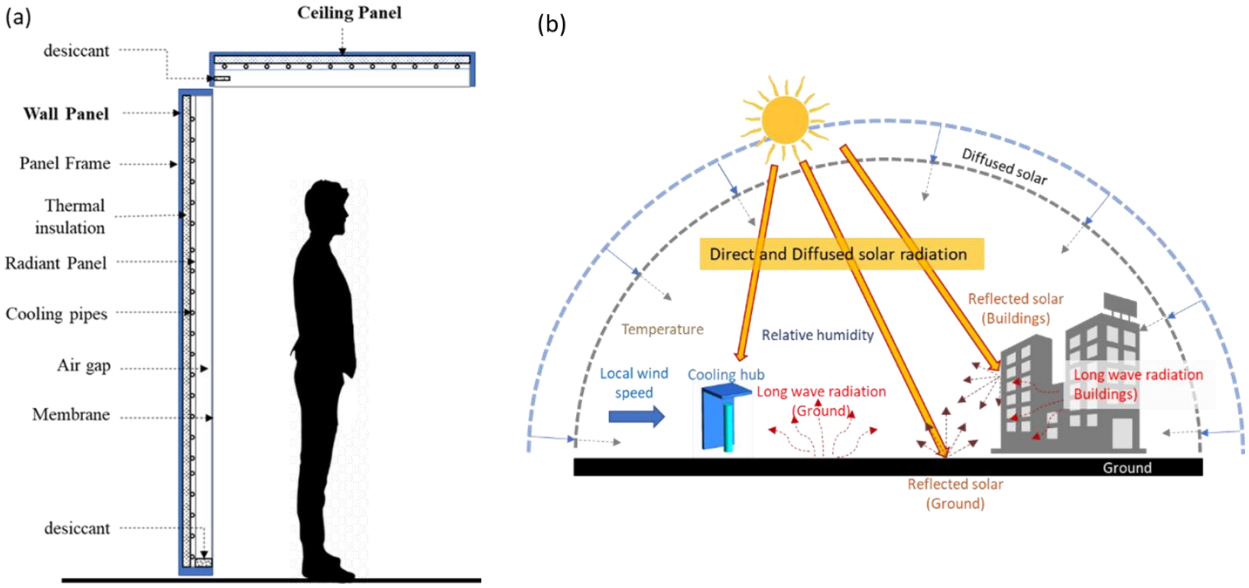

Figure 1 (a) Schematic of LOCH (b) Heat transfer components of the membrane-assisted RCS in the outdoor environment (Roshan, Moghbel, & Attia, 2020)

2 METHODOLOGY

A steady-state 3D CFD model of the localized cooling hub (LOCH) with a standing female computational thermal manikin (CTM) in the outdoor environment has been developed using ANSYS Fluent. The thermal sensation under the cooling hub is assessed by coupling the CFD simulation with the human thermoregulation model (CFD-CTM-JOS3 coupling method), along with the CBE comfort model (K Dharmasastha et al., 2024).

The framework of the methodology utilized in the study is shown in Figure 2. Initially, energy and radiation modelling using Rhino-Grasshopper is employed to simulate the building and ground surface temperatures for the street canyon configurations. Key inputs to this modelling include local weather data, street canyon geometry, and material properties. The resulting ground and building surface temperatures were then used as boundary conditions for the subsequent CFD simulations. Since the one-way coupling method (CFD-CTM-JOS-3 coupling) is suitable for the outdoor environment (K Dharmasastha et al., 2024), the ambient parameters and heat transfer coefficients acquired in the CFD simulation were directly input into the JOS-3 model (Takahashi et al., 2021) to simulate skin temperature. Finally, the obtained skin temperature data will be post-processed for thermal sensation assessment using the updated CBE comfort model (Xie et al., 2018; Xie et al., 2020).

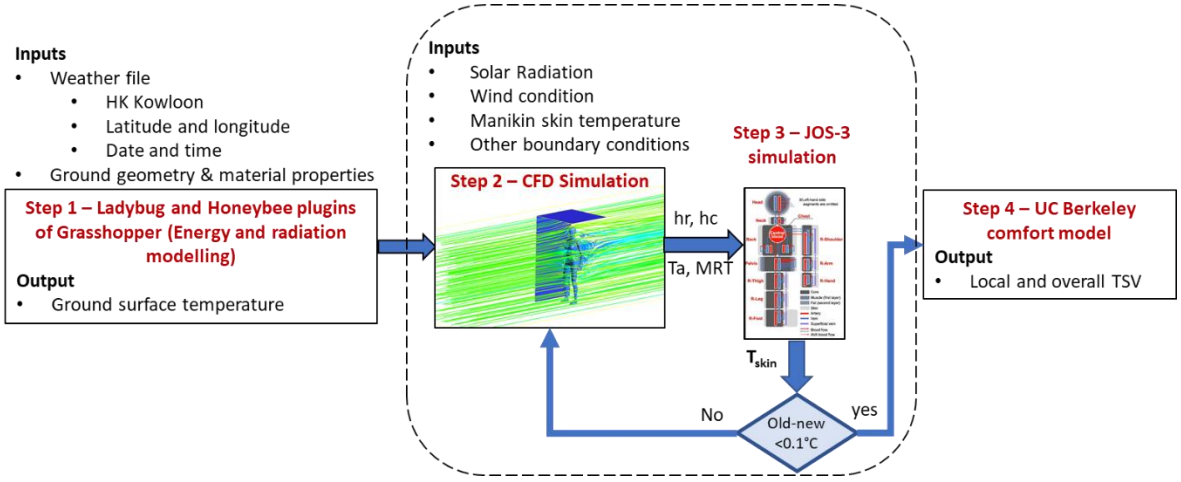

Figure 2 Framework of the methodology to assess the heat extraction rate and thermal sensation

The CFD model was validated against chamber test results, and the coupling method was compared with thermal comfort survey results (Yang et al., 2024). Thermal and comfort performance, in terms of cooling capacity and thermal sensation vote (TSV), were analyzed at 9:00, 11:00, 13:00, and 15:00 on a typical Hong Kong summer day (July 21st).

3 RESULTS AND DISCUSSIONS

3.1 Cooling performance analysis

Figure 3 shows the total heat extraction rate (Q_t), radiative heat flux (Q_r), convective heat flux (Q_c) and solar heat flux (Q_s) handled by the radiant cooling panels at different times of the day. A maximum heat extraction rate of 280.50 W/m² was observed at 13:00 hr. This study utilized a mid-infrared (MIR)-selective membrane, which reflects direct solar radiation. Consequently, even with

direct solar exposure at 9:00 hr, excessive heat extraction load was controlled. Building heights and street widths contribute to shading sidewalks during morning and evening hours. The observed maximum solar heat flux was 21% of the total heat extraction rate. Absorption of direct solar radiation by surrounding surfaces increases their temperature, leading to increased long wave radiative heat loads on the panel. Radiative heat load contributes 56-63% of the total heat extraction rate during the analyzed times. The radiative heat transfer efficiency was estimated for the current design is 8%. This suggests significant energy-saving potential, as the majority of the heat load originates from the surroundings, not occupants. This can be mitigated by shelter designs that maximize the view factor between the panels and occupants while minimizing the view factor between the panels and the surroundings. Alternatively, using a sky-window selective coating or membrane can control radiative heat load within the 8-13µm wavelength band, where human radiation emission is concentrated.

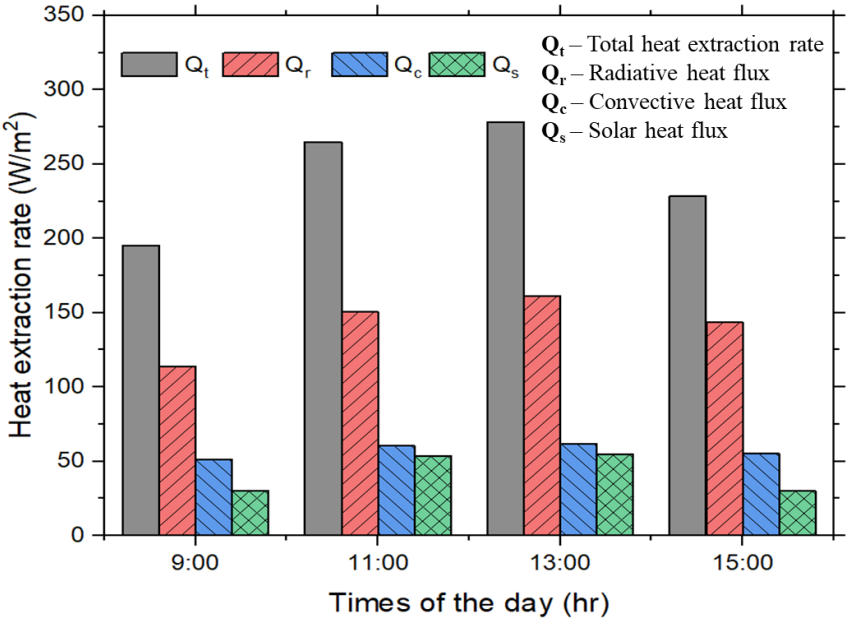

Figure 3 Comparison of heat load components for different times of the day

3.2 Comfort performance analysis

Solar radiation, particularly direct exposure and inhomogeneous exposure, significantly influences thermal sensation. Figure 4 illustrates the solar heat flux contour on the CTM body parts at different times. At 13:00 hr, the entire CTM body is shaded, while at other times, partial exposure to solar radiation creates inhomogeneous thermal condition, influencing local thermal sensation and skin temperature, affecting overall sensation. Figure 5 presents skin temperature and thermal sensation under the LOCH. At 09:00, direct solar radiation on the front of the body creates an uncomfortable and inhomogeneous thermal situation. This localized heating is evident in the predicted skin temperature and local thermal sensation of the chest, rated 3.4 (hot). However, the LOCH cools the back surface, positively influencing overall thermal sensation. Despite the front body's exposure to solar radiation, the strong cool sensation on the back (TSV_back: -1.8) improves the overall thermal sensation (TSV_overall: -1.8). This is because, according to the CBE comfort model, local thermal sensations below -1 on dominant body parts (forehead, chest,

abdomen, back, and pelvis) strongly influence the overall thermal sensation. At 11:00, the lower body (legs, thighs, and feet) is exposed to solar radiation, again creating inhomogeneous exposure and localized discomfort. By 13:00 hr, the entire body is shaded, but local thermal sensation on most body parts (excluding the back) is warmer than at other times. Consequently, the overall thermal sensation is warmer at 13:00 hr (TSV: -0.99, slightly cool) than at other times. Despite peak summer conditions (31.6°C and 60% relative humidity), the LOCH provides a comfortable, slightly cool sensation. At 15:00, the building behind the LOCH provides partial shade, improving local thermal sensation for most body parts compared to 11:00 and 13:00. The overall thermal sensations at 09:00, 11:00, 13:00, and 15:00 are -1.8, -1.3, -0.99, and -0.17, respectively.

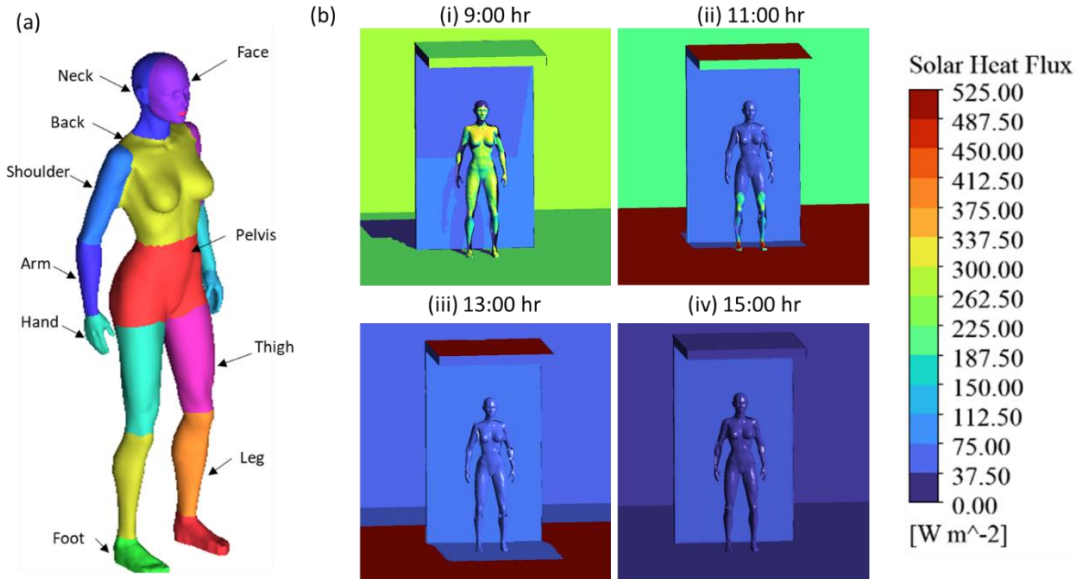

Figure 4 (a) Body parts of CTM (b) Solar heat flux contour of CTM and radiant cooling panel

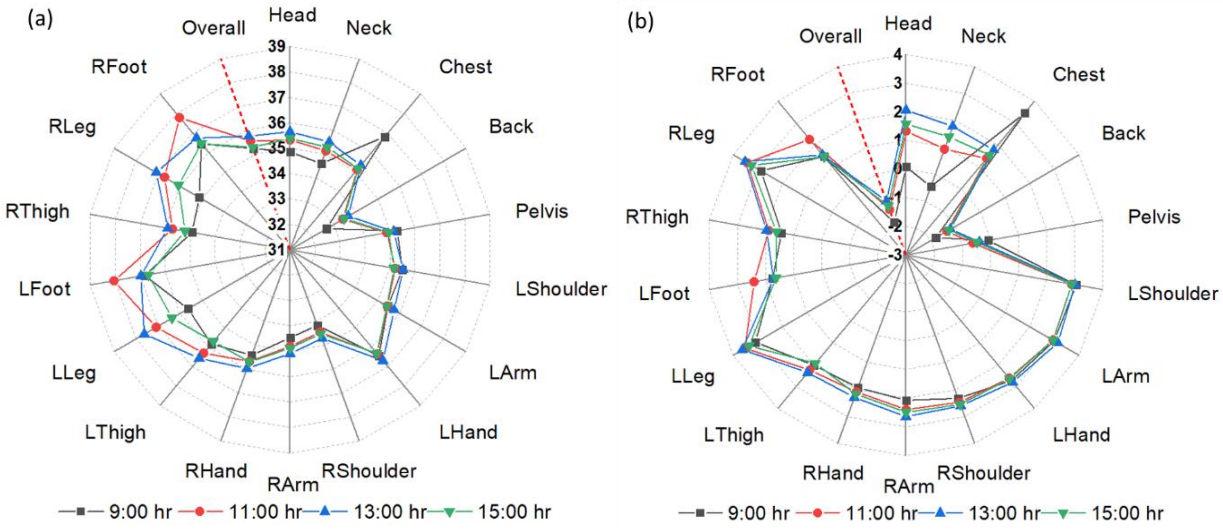

Figure 5 Local and overall (a) skin temperature and (b) thermal sensation in the LOCH

3.3 Comfort performance comparison with conventional bus stop

This section compares and analyzes the comfort performance of the LOCH against a conventional bus stop. Figure 6 shows the skin temperature and TSV comparison at 13:00 hr. A 1.7°C temperature difference is observed between the LOCH and the conventional bus stop on the back surface of the body, while other body parts show differences of less than 0.5°C. The proposed cooling system predominantly influences the back, head, and Neck. Regarding local thermal sensation on the back, a marginal difference exists between the LOCH and the conventional bus stop. This is because the predicted back skin temperature falls within the acceptable range i.e., within the null zone range (Xie et al., 2020). However, the LOCH induces a strong cooling thermal sensation on the back (TSV < -1), in turn, the overall thermal sensation within the LOCH is slightly cool (TSV: -0.99). Small skin temperature differences on the head and neck, i.e., 0.4°C and 0.5°C, respectively, between the conventional bus stop and the LOCH result in significant differences in local TSV i.e., 0.7 and 1.0, respectively. The dominant local discomfort on the head and neck in the conventional bus stop case (TSV of 2.8 and 2.7, respectively) leads to a hot overall TSV of 3.57, compared to a slightly cool -0.99 within the LOCH.

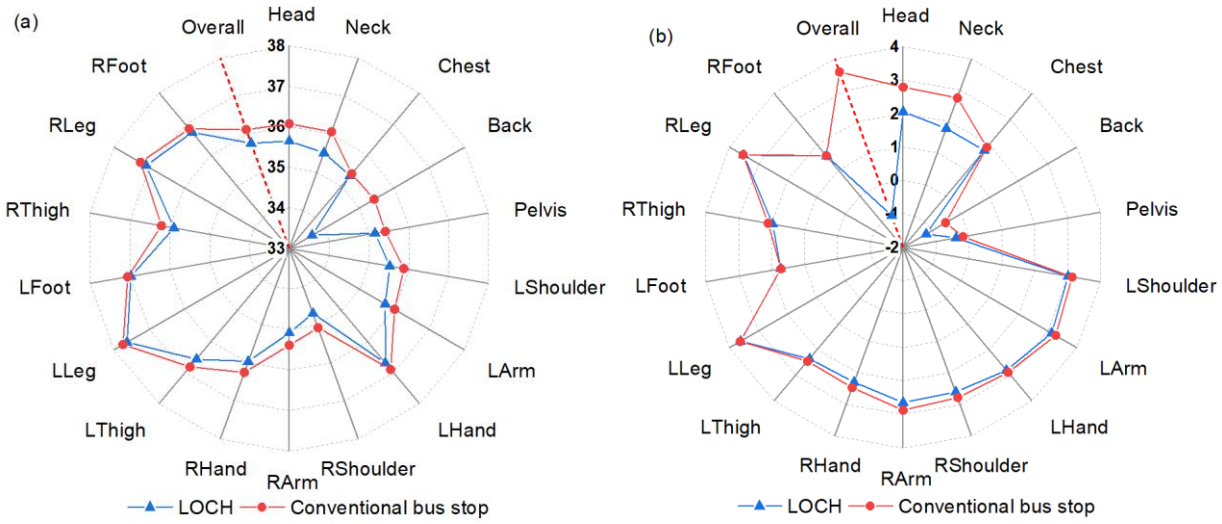

Figure 6 Comparison of (a) skin temperature and (b) TSV between LOCH and conventional bus stop at 13:00 hr

3.4 Discussions

The proposed cooling system design provides a cool thermal sensation during a typical Hong Kong summer day. However, exposed body parts experience hot local thermal sensations. The current prototype accommodates a single person, but a practical design should accommodate 3-5 people. This study is limited to a North-South orientation of street canyon. In this case, occupants may experience sun exposure during either morning or evening, depending on the LOCH's facing direction, especially if the opposite building is not sufficiently tall. In West-East oriented canyons, individuals standing at the edges will be exposed to solar radiation during morning and evening, leading to local discomfort, while those within the cooling hub should experience a comparatively better thermal sensation. Therefore, the primary modification needed is to maximize shading throughout the day. Even with full shade at noon, high diffuse solar radiation can cause occupants to feel warm or hot. The current design's large view factor between occupants and the surroundings increases radiative heat transfer, contributing to discomfort. Modifying the design to maximize the

view factor between occupants and the cooling panel, while minimizing the view factor with the surroundings, can address this issue. This strategy enhances both comfort and energy efficiency.

4. CONCLUSION

This study investigated the thermal and comfort performance of LOCH within a street canyon configuration at various times during a typical Hong Kong summer day. Comfort performance was analyzed using skin temperature and Thermal Sensation Vote (TSV) derived from coupling CFD and the JOS-3 human thermoregulation model along with an updated CBE comfort model. For the panel temperature of 10°C, a maximum heat extraction rate of 280.50 W/m² was observed at 13:00 hr. The radiative heat load contributes 56-63% of total heat extraction rate, and only around 8% of radiative heat transfer is from occupant, and remaining from the surrounding surfaces.

Solar heat flux significantly influences thermal sensation, and the cooling system effectively reduces back skin temperature, improving local and overall thermal sensation. Due to the ineffective structure design of LOCH which is replication of conventional bus stop, during morning and evening hours, solar exposure on certain body parts causes significant local discomfort. At 13:00 hr, while the LOCH design provides shade, diffuse and longwave radiation still contribute to a warmer sensation; however, a slightly cool overall thermal sensation (TSV: -0.99) is achieved even during peak Hong Kong summer conditions (Ta: 31.6°C, RH: 60%). A conventional bus stop failed to provide comfort at 13:00 hr, with occupants experiencing a hot thermal sensation, in contrast to the LOCH's slightly cool sensation. A limitation of this study is the exclusion of clothing insulation in the JOS-3 model, which will be addressed in future work. Further research will also optimize the design to maximize the view factor between occupants and the cooling panel while minimizing it with the surroundings, enhancing both efficiency and comfort. The performance of membrane-assisted radiant cooling in high-temperature locations, design improvements for extreme conditions and mitigating longwave radiation effects, and integration with low-grade energy sources will also be explored.

Bridging the Climate Divide: Oman's Blueprint for Resilient Infrastructure

Abdullah Ansari[1], Khalifa Al-Jabri[2], Mubarak Al-Alawi[2]

[1]Earthquake Monitoring Center, Sultan Qaboos University, Muscat, PC: 123 Al Khoudh, Oman
[2]Department of Civil and Architectural Engineering, Sultan Qaboos University, Muscat, PC: 123 Al Khoudh, Muscat, Oman

SUMMARY
Oman, located in a climatically sensitive region, faces escalating challenges to its infrastructure from climate change impacts, notably extreme temperatures, cyclones, and floods. This study offers a technical evaluation of climate change's direct impacts on critical infrastructure systems in Oman, analyzing the economic and operational disruptions. Recent events, such as cyclones and flooding, have intensified economic losses, severely affecting transportation networks, urban infrastructure, and energy projects. Key infrastructure projects, including coastal developments and major roadways, serve as case studies to underscore the vulnerability of Oman's infrastructure to climatic hazards. The paper systematically reviews adaptation strategies initiated by the government, assessing their effectiveness in reducing infrastructure vulnerability and promoting resilience, especially in high-risk coastal regions. Despite ongoing efforts, significant challenges persist, such as funding limitations, coordination gaps among agencies, and inadequate long-term planning frameworks. The study presents a detailed technical assessment of adaptation measures, highlighting both successful initiatives and areas requiring enhanced focus. The analysis links findings to Vision Oman 2040, emphasizing the alignment between sustainable infrastructure development and climate resilience goals. By offering a comprehensive review of climate impacts and adaptive responses, the study guides policymakers on integrating climate risk assessments into infrastructure projects, encouraging more robust planning mechanisms, and fostering community engagement. This paper contributes to the global dialogue on climate adaptation and resilience, providing valuable insights for other nations with similar environmental vulnerabilities.

Keywords: climate change, infrastructure resilience, cyclones, flooding, sustainable development, vision Oman 2040

1. INTRODUCTION

Oman, located on the southeastern coast of the Arabian Peninsula, is characterized by diverse geographical features, including mountainous regions, deserts, and a long coastline along the Arabian Sea. Its strategic location makes it susceptible to various climate-related hazards, such as cyclones, floods, and extreme temperatures (Mansour et al. 2021). For instance, Cyclone Gonu in 2007 caused damages estimated at over $4 billion, while flash floods in 2010 led to losses exceeding $1 billion. Such events highlight the urgent need for effective climate change adaptation strategies to safeguard Oman's infrastructure and economy (Fritz et al. 2010). In the last decade, Oman, alongside its neighboring countries in the Gulf Cooperation Council (GCC), has faced numerous climate challenges, as illustrated in the table below (CAA 2020).

The present study focuses on the impact of climate change on infrastructure projects in Oman, examining the specific hazards posed by cyclones, floods, and rising temperatures. It aims to assess the resilience of current infrastructure and explore adaptation strategies that align with national development goals. Vision Oman 2040 (2021) emphasizes the importance of sustainable development and resilience in the face of climate challenges. By addressing climate vulnerabilities and promoting sustainable practices, the present study aligns with Vision Oman 2040 (2021)

objectives of fostering a robust and adaptive economy while ensuring the safety and welfare of its citizens.

2. IMPACT OF CLIMATE CHANGE ON INFRASTRUCTURE

2.1. Cyclones and Floods

Cyclones and floods have severely impacted Oman's infrastructure, particularly in coastal and low-lying regions. Both types of events have caused extensive damage to roads, bridges, and other critical infrastructure, leading to significant disruptions and economic losses. Table ` highlights key infrastructure projects affected by cyclones and major flood events.

Table 1. Notable climate events, economic impacts, and vulnerabilities in GCC countries (Waha et al. 2017).

Country	Notable Climate Events (Last 10 Years)	Economic Impact	Climate Vulnerabilities
Oman	Cyclone Mekunu (2018), Cyclone Shaheen (2021), floods in 2010, 2022 and 2024	$5 billion	Coastal erosion, flooding, heatwaves
Qatar	Extreme heat events (2015, 2019), flash floods (2018)	$600 million	Heat stress, water scarcity
UAE	Extreme heatwaves (2017, 2020), heavy rains and flooding (2021)	$800 million	Coastal flooding, water scarcity
Saudi Arabia	Dust storms, extreme heatwaves (2016-2022), flooding in Jeddah (2020)	$2 billion	Heat stress, desertification, flooding
Bahrain	Extreme heat events, flooding (2017), rising sea levels	$400 million	Coastal flooding, water scarcity

These events highlight the vulnerabilities in Oman's infrastructure, especially in flood-prone areas (Al Rasbi 2019). Cyclones and floods have had profound effects on transportation routes, drainage systems, and accessibility, emphasizing the necessity for improved resilience measures in the design and management of infrastructure. Figure. 1 shows the impact of climate events on the infrastructure and urbans areas in Oman.

2.2. Extreme Temperatures

Rising temperatures are another pressing challenge, affecting the longevity and functionality of Oman's infrastructure. Table 2 shows key projects impacted by prolonged periods of extreme heat:

Table 2. Thermal impacts on infrastructure projects highlighting maintenance challenges (Coll 2015).

Project	Year(s)	Impact
Sultan Qaboos Grand Mosque Complex	Ongoing (since 2015)	Thermal expansion has caused cracks in stone surfaces and pavement damage, requiring regular maintenance.
Muscat International Airport	Ongoing (since 2010)	Extreme heat has accelerated runway surface degradation, increasing resurfacing needs.
Oil and Gas Pipelines in Desert	Ongoing	Prolonged high temperatures have caused material fatigue, raising the risk of leaks and increasing cooling demands at pumping stations.

These impacts highlight the need for adaptive strategies, such as the use of heat-resistant materials, to mitigate long-term damage and operational disruptions in key sectors like aviation and energy.

(a) Infrastructure

(b) Urban Areas

Figure 1. The impact of climate events on the infrastructure and urbans areas in Oman.

3. VULNERABILITY AND RISK MANAGEMENT

Vulnerability and risk assessments are vital for understanding the susceptibility of infrastructure to climate-induced risks. These assessments inform the design and implementation of resilience measures across various sectors, including transportation, urban development, and energy infrastructure in Oman.

3.1 Transportation Infrastructure Vulnerability

Oman's transportation networks face significant risks from extreme weather, particularly cyclones and floods. Table 3 is summarizing the vulnerability of critical transportation infrastructure to climate change-related events. It shows how critical transportation projects such as the Batinah Coastal Road and Al Sharqiyah Expressway are exposed to various climate-related risks. Upgrading drainage capacity and constructing protective barriers are some of the key adaptation strategies identified.

3.2 Urban Development

Urban areas in Oman, particularly Muscat and Salalah, are at high risk of flooding. The vulnerability of key urban infrastructure projects and proposed adaptation measures as shown in Table 4. Table 4 shows that urban flood management is critical in cities like Muscat and Salalah. Adaptation strategies involve enhancing drainage systems and integrating green infrastructure solutions to reduce the impact of future floods.

Table 3. Transportation infrastructure projects with climate risks, impacts, and adaptation measures (Al-Awadhi et al. 2019; Ansari et al. 2024).

Project Name	Infrastructure Type	Climate Risk	Impact	Proposed Adaptation
Batinah Coastal Road	Coastal Highway	Cyclones, Storm Surges	Road blockages, structural damage	Upgrade drainage systems, build flood barriers
Al Sharqiyah Expressway	Inland Highway	Flash Floods	Road washouts, erosion	Enhance drainage capacity, adjust elevation of vulnerable sections
Al-Sharqiyah Expressway Tunnel-2 (AST2)	Tunnel	Flooding, Seismic Events	Tunnel closure, water ingress, collapse	Reinforce lining, improve drainage systems

Table 4. Urban development projects with climate risks, impacts, and adaptation measures (Al Shueili 2015).

Project Name	Infrastructure Type	Climate Risk	Impact	Proposed Adaptation
Muscat Urban Infrastructure	Muscat	Flash Floods, Cyclones	Submerged roads, damage to buildings	Upgrade drainage systems, build retention basins
Salalah Flood Mitigation Project	Salalah	Intense Rainfall, Floods	Road closures, residential area flooding	Expand drainage channels, construct retention ponds

4. CLIMATE RESILIENT INFRASTRUCTURE

Adaptation strategies are crucial for mitigating the impacts of climate change on oman's infrastructure. This section delves into specific projects and the adaptation measures implemented to enhance resilience, focusing on transportation networks, urban development, and energy infrastructure. Below is a detailed explanation of the ongoing and planned adaptation strategies, supported by actual project details presented in Table 5.

4.1 Transportation Sector Adaptation

Oman’s transportation network, particularly coastal highways and tunnels, is highly susceptible to extreme weather events like cyclones, flooding, and high temperatures. To address these vulnerabilities, key projects have been designed or upgraded to withstand climate-related hazards.

In the transportation sector, projects like the Batinah Coastal Road and Al-Sharqiyah Expressway Tunnel-2 highlight key adaptation strategies such as road elevation, slope stabilization, and advanced drainage systems. The Bausher-Al Amerat Tunnel, once completed, will replace a frequently flooded mountain road, providing a more resilient transport link between Muscat and Al Amerat cities.

4.2 Urban Development Adaptation (NCSI 2023)

Urban areas in Oman, particularly Muscat and Salalah, are prone to flooding during heavy rainfall and cyclones. To mitigate these risks, urban development projects (Table 6) have focused on

enhancing flood management through the construction of stormwater drainage systems, retention basins, and the integration of green infrastructure solutions.

Table 5. Current status of transportation infrastructure projects (TMST 2023).

Project Name	Location	Climate Risk	Adaptation Strategy	Project Status
Batinah Coastal Road	Northern Oman	Cyclones, Storm Surges	Elevated road sections, drainage upgrades, flood barriers	Ongoing (Phase 2 construction)
Al-Sharqiyah Expressway	Eastern Oman	Flash Floods	Advanced drainage systems, slope stabilization	Completed (2023)
Al-Sharqiyah Expressway Tunnel-2	Al-Sharqiyah Region	Flooding, Landslides, Seismic Risks	Lining reinforcement, enhanced drainage, flood-resistant design	Ongoing (expected completion 2025)
Bausher-Al Amerat Tunnel Project	Muscat	Heavy Rain, Flash Floods	Tunnel construction to replace vulnerable mountain road	Planned (proposal stage)

Table 6. Current status of urban development projects.

Project Name	City	Climate Risk	Adaptation Strategy	Project Status
Muscat Drainage Improvement Plan	Muscat	Flash Floods, Cyclones	Expansion of drainage systems, retention basins, green spaces, protection dams	Planned (to begin in 2024)
Salalah Flood Mitigation Project	Salalah	Intense Rainfall, Cyclones	Upgraded drainage channels, flood retention ponds, protection dams	Completed (2022)
Duqm Smart City Project	Duqm	Rising Sea Levels, Storm Surges	Coastal flood defenses, permeable pavements, green infrastructure	Ongoing (Phase 1 completion in 2025)
Sohar Industrial City Flood Management	Sohar	Flash Floods	Industrial drainage systems, flood-resistant design	Planned (early stages)

In Muscat and Salalah, urban drainage improvement projects and flood mitigation efforts have been prioritized, with Muscat planning to expand its stormwater drainage systems. The Duqm Smart City project, a major urban development, integrates climate-resilient infrastructure with coastal defenses and green infrastructure. Figure 2 shows, as an example, the flood route of Wadi Al-Khoudh in Muscat and the proposed flood mitigation's solution.

Figure 2. The flood's route of Wadi Al-Khoudh in Muscat and the proposed route

4.3 Water Management and Agriculture Adaptation

Oman's water management and agricultural sectors are increasingly affected by reduced rainfall, flash floods, and rising temperatures. Various projects have been initiated to improve water security, including desalination plants and modern irrigation techniques to adapt to changing climate conditions. Table 7 presents the current status of water management and agriculture related projects

Table 7. Current status of water management and agriculture related projects **(**Shammas 2007; Muscat Municipality 2024).

Project Name	Location	Climate Risk	Adaptation Strategy	Project Status
Barka Desalination Plant Expansion	Barka	Drought, Water Scarcity	Increased desalination capacity, water storage infrastructure	Ongoing (Phase 3)
Wadi Dayqah Dam Irrigation Project	Al Sharqiyah Region	Drought, Flash Floods	Efficient irrigation systems, water storage management	Completed (2021)
Nizwa Aquifer Recharge Project	Nizwa	Water Scarcity, Overuse	Managed aquifer recharge, sustainable water extraction	Planned (design stage)

In the water management sector, the Barka Desalination Plant and the Nizwa Aquifer Recharge Project are two key projects aimed at securing water resources for Oman’s growing population. Modern irrigation techniques such as drip irrigation and rainwater harvesting are being implemented to enhance the resilience of the agricultural sector.

5. CHALLENGES IN IMPLEMENTATION

5.1 Technical expertise and capacity building

Oman faces challenges related to the technical expertise required for designing and implementing climate-resilient infrastructure (MOF 2024). Although international collaboration is helping bridge this gap, the local workforce may still lack the specialized knowledge necessary to design solutions for complex climate scenarios, particularly for large-scale projects like tunnels and coastal defenses (Shammas 2007; McBean and Rodgers 2010). To enhance scientific robustness, integrate quantitative analyses such as cost-benefit assessments, climate vulnerability indices, or scenario modeling to evaluate the long-term effectiveness and feasibility of adaptation strategies across diverse climatic contexts.

5.2 Public and community engagement

Engaging the public and local communities is critical for the success of adaptation projects. However, in Oman, public awareness of climate risks and the benefits of climate-resilient infrastructure is still developing (Hafidh et al. 2017; UNDP 2020). In regions of Oman, particularly coastal areas such as Qurayyat, community involvement in climate-resilient design has been effective, as local feedback has influenced flood mitigation strategies. Nevertheless, challenges like a lack of technical knowledge and minimal engagement in rural interior regions obstruct wider implementation, highlighting the necessity for comprehensive education and outreach initiatives. Without adequate community participation, especially in urban planning or water management projects, adaptation efforts may face resistance or fail to address local needs

effectively. Adaptation strategies need to include engineering standards like raised road embankments capable of enduring flooding that occurs once every century, sturdy concrete culverts for efficient drainage, and roofing systems that resist high winds in accordance with cyclonic load criteria. These measures are informed by revised construction regulations specific to local geoclimatic hazards. Table 8 summarizes examples of challenges in climate change adaptation projects in Oman, focusing on project success rates and economic aspects:

Table 8. Project challenges and economic impact (Vision Oman 2040 (2021))

Project Name	Key Challenges	Project Success Rate	Economic Aspects
Al-Sharqiyah Expressway Tunnel-2	Delays due to inter-ministerial approvals	Moderate	Increased costs due to delays; potential for improved trade and transport efficiency once completed.
Duqm Smart City Project	Limited local technical expertise	Moderate	High initial investment required; potential for long-term economic benefits through sustainable urban development.
Muscat Drainage Improvement Plan	Public resistance and lack of community engagement	Moderate	Project funding impacted by community opposition; successful implementation could reduce economic losses from flooding.

6. CONCLUSIONS

The pressing challenges posed by climate change necessitate immediate and coordinated responses to safeguard infrastructure in Oman. This research underscores the profound vulnerabilities inherent in Oman's geographical location, making it susceptible to a range of climate hazards, including cyclones, floods, and extreme temperatures. Significant events, such as Cyclone Mekunu and Cyclone Shaheen, have not only inflicted substantial economic losses but have also disrupted essential services and infrastructure, underscoring the urgent need for effective adaptation strategies. The findings illustrate that while some infrastructure projects, such as the Al-Sharqiyah Expressway Tunnel-2 and the Batinah Coastal Road, have begun to incorporate resilience measures, many others remain at risk due to inadequate planning and resource allocation. The paper highlights the necessity for innovative approaches that integrate climate adaptation into all stages of project development, ensuring that infrastructure can withstand the increasing frequency and intensity of climate events.

A comprehensive perspective on the sustainability of Oman’s climate-resilient infrastructure design stresses the importance of incorporating adaptive strategies like raised roadways, strong drainage systems, and structures designed to withstand cyclones. These measures, in harmony with green technologies and local risk evaluations, guarantee longevity, reduce maintenance expenses, and enhance the objectives of Vision Oman 2040 for sustainable urban progress. Moreover, the alignment of these adaptation strategies with Vision Oman 2040 presents a unique opportunity to promote sustainable development while enhancing national resilience. Emphasizing the importance of collaboration among government, private sector, and communities will be crucial for developing effective policies and investment strategies that prioritize climate resilience.

Natural ventilation effects on a residential building sensible and latent energy loads in Toronto

Amir A. Aliabadi[1]

[1] *School of Engineering, University of Guelph, Guelph, Ontario, Canada, aaliabad@uoguelph.ca*

ABSTRACT

Natural Ventilation (NV) is a passive approach to reduce the building energy demand in suitable climate zones. However, most studies considering NV models or experiments only focus on the sensible load (cooling) reduction of buildings, while they do not investigate the implications of NV in latent load (humidification and dehumidification) changes in buildings. This study uses an urban physics model, the Vertical City Weather Generator (VCWG v1.4.7) software, to address this research gap. Simulations are executed for the climate of Toronto (zone 5) in 2020 to analyze the NV potential for single-detached two-story residential homes. A rule-based controller is implemented to make decisions on opening/closing windows based on indoor/outdoor temperatures, humidities, and sensible cooling/heating loads, while targeting temperature and humidity setpoints. The base case building of interest exhibits features (envelop thermal resistance, infiltration rate, ventilation rate, glazing ratio, and solar heat gain coefficient) according to common codes and standards in the region. Some sensitivity tests are performed to understand the effects of building envelop infiltration and thermal resistance in the performance of the NV system. Additional cases exhibit air tight buildings, high insulation buildings, and air tight/high insulation buildings associated with the Passive House standard. Using NV, annual energy savings around ~ 10 kW-hr m^{-2} are possible for combined sensible and latent loads. The implications of latent load, envelop infiltration, and envelop thermal resistance are discussed.

Keywords: building energy modeling, natural ventilation, sensible and latent loads.

INTRODUCTION

To moderate the impact of buildings on climate change [9], Natural Ventilation (NV) is a suitable technique to lower the sensible cooling demand of buildings in favorable climates. However, most typically, NV is only analyzed by considering the sensible cooling demand of buildings, while ignoring the implications on the latent demand. For instance, by opening windows, the sensible cooling demand of a building may be reduced, but air that is either too moist or too dry can enter the building and increase the latent demand, i.e. by dehumidification or humidification demands, respectively [7, 8, 16, 15]. In this study, an urban physics model is used to consider the implications of both sensible and latent demands when using NV for the climate of Toronto. Simulations are conducted for a full year in 2020. A rule-based controller is developed and implemented to decide when windows shall be opened to enhance NV ventilation based on environmental and building performance variables.

METHODS

Model Description

The Vertical City Weather Generator (VCWG v1.4.7) is a microscale and multiphysics urban physics model that predicts the urban environmental and building performance variables. As shown in Figure 1, it integrates various submodels to account for exchanges of momentum, heat, humidity, and water through soil, urban surfaces, and the atmosphere. The modelling paradigms employed are the Resistance Capacitance (RC) thermal network, Navier-Stokes transport in the vertical direction, Monin-Obukhov Similarity Theory (MOST), and lump energy modeling [1]. Full descriptions of the model are provided in prior literature [4, 10, 11, 2, 15, 14]. VCWG is forced with weather data generated by another software titled the Vatic Weather File Generator (VWFG v1.0.0), which uses the ERA5 dataset from the European Centre for Medium-Range Weather Forecasts (ECMWF) and prepares data in the EnergyPlus Weather (EPW) file format at hourly resolution [3]. The rule-based controller for NV is discussed in our previous study [15]. Briefly, NV is considered under cooling mode. If $T_{\text{out}} < T_{\text{in}}$ & $T_{\text{set}} < T_{\text{in}}$ [K] then a specific humidity condition is checked to trigger NV. For this condition either of the following criteria must be met: $q_{\text{in}} > q_{\text{set}}$ & $q_{\text{out}} < q_{\text{in}}$ or $q_{\text{in}} < q_{\text{set}}$ & $q_{\text{out}} > q_{\text{in}}$ [kgv kga^{-1}]. To trigger NV, windows are opened and a new air exchange rate is calculated due to ventilation, infiltration, and NV.

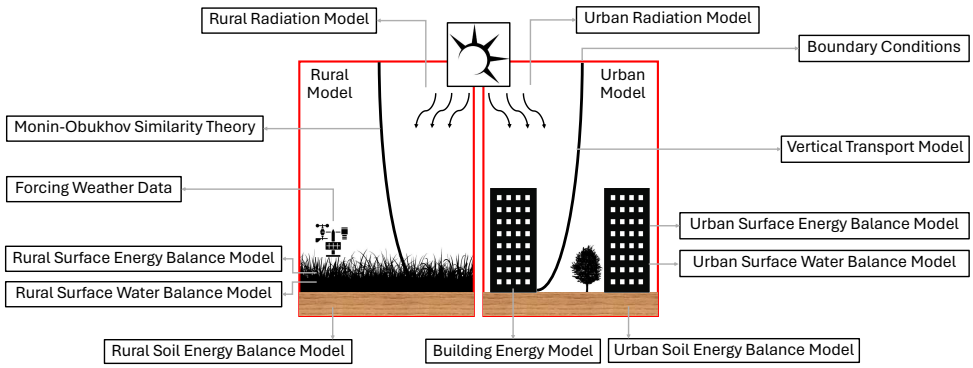

Figure 1. Schematic of the Vertical City Weather Generator (VCWG v1.4.7).

Simulation Cases

Two sets of simulations are conducted with and without NV. Four buildings are considered according to Table 1. The base building is associated with relevant codes and standards [12, 6, 5]. The air tight or high insulation buildings exhibit a low infiltration rate or a high envelop thermal resistance. The Passive House building exhibits both a low infiltration rate and a high envelop thermal resistance [13]. It is primarily intended to conduct the simulations for the year 2020, although some months (February, March, April) have been substituded in prior years (2018 and 2019), for which the forcing weather data have not been reliable in 2020.

Building Energy Loads

NV is formulated in the context of the building sensible and latent load calculation. The sensible load, $\pm[Q_{\text{vent}} + Q_{\text{inf}} + Q_{\text{int}} + Q_{\text{mass}} + Q_{\text{wall}} + Q_{\text{ceil}} + Q_{\text{win}} + Q_{\text{tran}}]$, involves ventilation load Q_{vent}, infiltration load Q_{inf}, internal heat from occupants and equipment Q_{int}, heat from the building's mass Q_{mass}, heat from walls Q_{wall}, heat from ceilings Q_{ceil}, heat conduction through windows

Table 1. Building features for Toronto (zone 5) based on codes and standards.

Parameter	Base	Air Tight	High Insulation	Passive House
Roof Resistance [m^2 K W^{-1}]	6.41	6.41	11.5	11.5
Wall Resistance [m^2 K W^{-1}]	3.6	3.6	7.0	7.0
Window U-value [W m^{-2} K^{-1}]	1.9	1.9	1.9	1.9
Infiltration Rate [ACH]	3.0	0.6	3.0	0.6
Ventilation Rate [L s^{-1} m^{-2}]	0.3	0.3	0.3	0.3
Glazing Ratio [-]	0.4	0.4	0.4	0.4
Solar Heat Gain Coefficient [-]	0.4	0.4	0.4	0.4

Q_{win}, and radiant heat passing through windows Q_{tran} [W]. In this formulation, the positive sign (+) will be used to calcaulte the sensible cooling demand, and the negative sign (−) will be used to calculate the sensible heating demand. Except for Q_{int}, which is scheduled in VCWG, the other terms are parameterized using the heat balance method:

$$
\begin{aligned}
Q_{\text{vent}} &= V_{\text{vent}} \rho_a c_{pa} (T_{\text{out}} - T_{\text{set}}) \\
Q_{\text{inf}} &= V_{\text{inf}} \rho_a c_{pa} (T_{\text{out}} - T_{\text{set}}) \\
Q_{\text{mass}} &= A_{\text{bui}} h_m (T_{\text{mass}} - T_{\text{set}}) \\
Q_{\text{wall}} &= A_{\text{wall}} h_w (T_{\text{wall}} - T_{\text{set}}) \\
Q_{\text{ceil}} &= A_{\text{bui}} h_c (T_{\text{ceil}} - T_{\text{set}}) \\
Q_{\text{win}} &= A_{\text{win}} U_w (T_{\text{out}} - T_{\text{set}}) \\
Q_{\text{tran}} &= A_{\text{win}} S \times SHGC,
\end{aligned}
\tag{1}
$$

where V_{vent} and V_{inf} [m^3 s^{-1}] are ventilation and infiltration air flow rates, ρ_a [kg m^{-3}] is density of air, c_{pa} [J kg^{-1} $^\circ C^{-1}$] is heat capacity of air, A_{bui} [m^2] is building footprint area, T_{mass}, T_{wall}, T_{ceil}, T_{set}, and T_{out} [$^\circ$C] are mass, wall, ceiling, set-point, and outdoor temperatures, A_{bui}, A_{wall}, and A_{win} [m^2] are building footprint, wall, and window areas, h_m, h_w, and h_c [W m^{-2} $^\circ C^{-1}$] are convective heat transfer coefficients, U_w [W m^{-2} $^\circ C^{-1}$] is the window U-value, S [W m^{-2}] is the shortwave radiation flux through the window, and $SHGC$ [-] is the solar heat gain coefficient for the window. The sensible load is met by the building's sensible cooling/heating equipment. The latent load, $\pm[Q_{\text{latvent}} + Q_{\text{latinf}} + Q_{\text{latint}}]$, involves latent heat from ventilation Q_{latvent}, latent heat from infiltration Q_{latinf}, and latent heat from internal heat from occupants and equipment Q_{latint} [W]. In this formulation, the positive sign (+) will be used to calcaulte the dehumidification demand, and the negative sign (−) will be used to calculate the humidification demand. These loads are met by the building's humidification/dehumidification equipment. Except for Q_{latint}, which is scheduled in VCWG as a fraction of sensible heat from occupants and equipment Q_{int}, the other terms are parameterized using the humidity balance method:

$$
\begin{aligned}
Q_{\text{latvent}} &= V_{\text{vent}} \rho_a L_v (q_{\text{out}} - q_{\text{set}}) \\
Q_{\text{latinf}} &= V_{\text{inf}} \rho_a L_v (q_{\text{out}} - q_{\text{set}}),
\end{aligned}
$$

where L_v [J kg_v^{-1}] is latent heat of vaporization for water, and q_{out} and q_{set} [kgv kga^{-1}] are outdoor and set-point specific humidities, respectively. When NV is deployed, the model enhances the infiltration rate V_{inf} [m^3 s^{-1}] and thus captures the physics properly. In this version of VCWG,

latent load is only computed if the building is cooled or heated, regardless of building sensible (cooling or heating) demands. The cooling is triggered when the sensible cooling load is positive and canyon air temperature is greater than 288 K. The heating is triggered when the sensible heating load is positive and canyon air temperature is less than 288 K. The buildings are arranged in rows with a separation of 30 m maintained in each horizontal direction (x and y). Temperature, specific humidity, and wind (the x and y components) data within the urban roughness sub-layer were extracted along the vertical direction (z) from VCWG. The buildings are low-rise residential units designed with dimensions of 13.8 m $\times$ 13.8 m $\times$ 6 m. Each story features two windows on each side, with an equivalent area of 26.4 m^2 per facade. The NV system model assumes a single equivalent window on each building side and is based on the ASHRAE Fundamentals handbook. The calculation of the NV system air flow rate is performed by $Q_{NV} = CAU$, where Q_{NV} [m^3 s^{-1}] is flow rate, $C = 0.5$ [-] is a coefficient describing the effectiveness of windows (it can be assumed to be 0.5 to 0.6 for normal winds and 0.25 to 0.35 for diagonal winds), A [m^2] is the free area of inlet openings, and U [m s^{-1}] is the wind speed normal to the facade. Once Q_{NV} is known, it can be added to the base infiltration rate V_{inf} [m^3 s^{-1}] in the VCWG model.

Diagnostic Equations for Indoor Temperature and Specific Humidity

Following the sign conventions discussed above, the heat balance equation can be rewritten in the following form, which separates terms including or excluding the unknown indoor temperature

$$\underbrace{\text{Cooling Load} - \text{Heating Load} - Q_{\text{tran}} - Q_{\text{int}}}_{Q} = Q_{\text{vent}} + Q_{\text{inf}} + Q_{\text{mass}} + Q_{\text{wall}} + Q_{\text{ceil}} + Q_{\text{win}} \tag{2}$$

$$\begin{aligned} Q = {} & \underbrace{V_{\text{vent}}\rho_a c_{pa} T_{\text{out}} + V_{\text{inf}}\rho_a c_{pa} T_{\text{out}} + A_{\text{bui}} h_m T_{\text{mass}} + A_{\text{wall}} h_w T_{\text{wall}} + A_{\text{bui}} h_c T_{\text{ceil}} + A_{\text{win}} U_w T_{\text{out}}}_{H1} \\ & - [\underbrace{V_{\text{vent}}\rho_a c_{pa} + V_{\text{inf}}\rho_a c_{pa} + A_{\text{bui}} h_m + A_{\text{wall}} h_w + A_{\text{bui}} h_c + A_{\text{win}} U_w}_{H2}] T_{\text{in}} \end{aligned} \tag{3}$$

Likewise the specific humidity balance equation can be rewritten as the following form, which separates terms including or excluding the unknown indoor specific humidity

$$\underbrace{\text{Dehumidification Load} - \text{Humidification Load} - Q_{\text{latint}}}_{QL} = Q_{\text{latvent}} + Q_{\text{latinf}} \tag{4}$$

$$QL = \underbrace{V_{\text{vent}}\rho_a L_v q_{\text{out}} + V_{\text{inf}}\rho_a L_v q_{\text{out}}}_{HL1} - \underbrace{[V_{\text{vent}}\rho_a L_v + V_{\text{inf}}\rho_a L_v]}_{HL2} q_{\text{in}} \tag{5}$$

In VCWG v1.4.7, the resulting two equations $T_{\text{in}} = (H1 - Q)/H2$ and $q_{\text{in}} = (HL1 - QL)/HL2$ are re-evaluated in each timestep to give the indoor temperature and specific humidity.

Waste Heat Rejection into the Urban Environment

Under cooling mode, we assume that both sensible cooling and dehumidification demands are met by a refrigeration cycle with a known Coefficient Of Performance (COP). Using the first law of thermodynamics, the waste heat rejected to the environment will be given by,

$$\text{Waste Heat} = (\text{Sensible Demand} + \text{Dehumidification Demand}) \left(1 + \frac{1}{COP}\right). \tag{6}$$

Under heating mode, we assume that both sensible heating and humidification demands are met by a furnace with a known thermal efficiency (η). Using the first law of thermodynamics, the waste heat rejected to the environment will be given by,

$$\text{Waste Heat} = (\text{Sensible Demand} + \text{Humidification Demand}) \left(\frac{1}{\eta} - 1 \right). \quad (7)$$

What if the building has a humidification demand under cooling mode, or dehumidification demand under heating mode? In this case, latent demand is properly logged, but its associated waste heat is not considered by the model. In another word, the waste heat for latent demand in our model is formulated for dry climates under heating mode and humid climates under cooling mode.

RESULTS AND DISCUSSION

Figure 2 shows the monthly energy demands for the base and Passive House cases with and without using NV. Compared to the base case, the Passive House exhibits lower heating, dehumidification, and humidification demands, but it exhibits greater cooling demand. Under cooling mode, the energy savings using NV is greater for the Passive House than the base case. However, NV causes greater dehumidification demand for the Passive House compared to the change in dehumidification demand for the base case. Reasons for these findings are justified in our previous study [15]. Figure 3 shows the hourly results for temperatures, specific humidities, sensible energy demands, latent energy demands, and window state for the greater part of the month of May. This month, in shoulder season, is suitable to assess the effectiveness of NV because the building can be under sensible cooling, sensible heating, or neither. The indoor temperature is maintained strictly between the cooling set point (297.05 K) and heating set point (291.15 K). On the other hand, although mostly maintained within the corresponding cooling relative humidity (60 %) and heating relative humidity (40 %), the specific humidity can deviate outside this range. This is due to the fact that humidification and dehumidification only occur when there is sensible cooling or heating. When there is no sensible cooling or heating, the indoor specific humidity approaches that of the outdoor specific humidity. The window state time series show that windows are only opened when indoor/outdoor temperature and specific humidities are favorable for NV. For example, for the last third of the month (>600 hr), the windows actively open when the building has sensible cooling demand and indoor/outdoor temperature and specific humidity meet the conditions of the NV controller. Table 2 shows the annual energy savings by using NV. Since the rule-based control algorithm primarily attempts to save the sensible energy demand, we can note that the greatest energy saving is associated with the sensible cooling demand. Under heating mode, the indoor and outdoor conditions are seldom met for NV, so no savings are possible for the sensible heating demand. The saving in sensible cooling demand is notably more for air tight buildings. Further, increasing thermal insulation of the building envelop does not impact the building energy loads as far as NV is concerned. It can be seen that NV implicates the latent loads, but since the control is designed to operate windows considering indoor and outdoor humidities, the changes in latent loads are an order of magnitude less than those of the sensible cooling loads as a result of triggering NV.

CONCLUSIONS

Our study shows that consideration of both sensible and latent energy demands are possible when using Natural Ventilation (NV). Using the simulations for Toronto in 2020, we find that up to 10

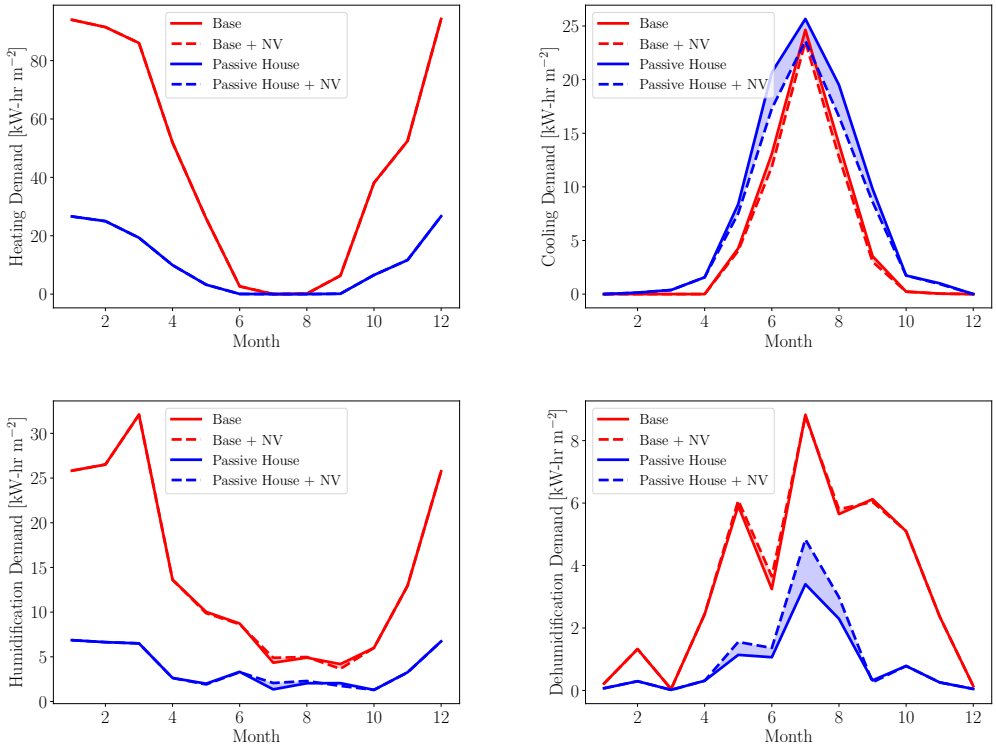

Figure 2. Monthly building energy demands for the base and Passive House cases; the difference between employing no Natural Ventilation (NV) and employing NV is shown with shaded color.

Table 2. Annual energy savings (+) and losses (−) due to using Natural Ventilation (NV).

Building Energy Demand	Base	Air Tight	High Insulation	Passive House
Sensible Heating [kW-hr m^{-2}]	−0.10	−0.08	−0.11	−0.07
Sensible Cooling [kW-hr m^{-2}]	+4.28	+10.86	+4.13	+10.51
Dehumidification [kW-hr m^{-2}]	−0.59	−0.90	−1.8	−2.78
Humidification [kW-hr m^{-2}]	+0.12	−0.68	+0.33	−0.51

kW-hr m^{-2} of sensible cooling energy can be saved per year by employing NV, with implications on latent demand being less than one order of magnitude compared to the sensible cooling demand. We also find that the effectiveness of NV is most sensitive to the building's air tightness, as opposed to the envelop's thermal resistance. Air tight buildings exhibit greater potential for energy savings using NV. Our findings suggest that NV has a potential to reduce building energy loads under cooling conditions. These simulation findings are yet to be corroborated by field experiments.

SUMMARY
The low-carbon renewal of traditional buildings is crucial for achieving global climate targets. However, current evaluation standards fail to adequately address the characteristics and preservation needs of traditional buildings, leading to ineffective guidance for their sustainable renewal. This study focuses on the applicability of China's current standard "Assessment standard for green building" GB/T50378-2019 in the low-carbon retrofit of bungalow courtyards in the Old City of Beijing through the methods including field surveys, expert ratings, and analytic hierarchy process(AHP). Ultimately, 13 mandatory control indicators such as the use of underground space and adjustable sun shading are removed, and 4 flexible scoring indicators are added, including the inheritance of courtyard spatial patterns, coordination of facade styles, prolongation and utilization of brick-wood structures, and enhancement of functional suitability. The new evaluation index system conforms to the low-carbon renewal of bungalow courtyards in the Old City of Beijing which includes six aspects: durability, comfort, environment, energy, management, and value sustainability, with 47 scoring indicators are assigned weights.

Keywords: bungalow courtyards, evaluation system, low-carbon renewal

1. INTRODUCTION

In response to global climate change, carbon and emission reduction have emerged as significant international concerns in recent years(Zhang et al., 2021).The China Construction Carbon Emissions Report shows that in 2020 the total carbon emissions from the entire construction process constituted 50.9% of the national carbon emissions. Green retrofitting of existing buildings is a crucial approach to reducing these emissions(Villalba et al., 2024), particularly for historic buildings, which often have low energy efficiency and significant potential for low-carbon renovation(Arumägi & Kalamees, 2014; Qian et al., 2024).The green renovation of traditional buildings not only needs to follow the requirements of environmental comfort and energy saving, but also the heritage conservation(Gremmelspacher et al., 2021).However, there is a conflict between the need to conserve historical features and the carbon reduction measures typically applied to new construction(Franco & Mauri, 2024; Serrano et al., 2022).Currently, China’s Building Evaluation Standard for Green Retrofit of Existing Buildings does not adequately address the unique characteristics and preservation requirements of traditional buildings, rendering it ineffective for guiding their sustainable renovation.

The bungalow courtyards in Beijing represent one of the important typologies Chinese traditional dwellings. The old city of Beijing contains nearly 7 million square metres of brick-and-wood

structured bungalow courtyards, which offer substantial potential for low-carbon renovation. Therefore, it is necessary to develop a green building evaluation system that is more suitable for the renovation of traditional courtyards in Beijing by modifying the indicators and adjusting the weights.

2. LITERATURE REVIEW

2.1. Existing evaluation for green retrofit of existing buildings worldwide

Several countries have developed evaluation systems for the green renovation of existing buildings, such as BREEAM, LEED, DGNB, and CASBEE(Ferrari et al., 2022). The evaluation systems adjust indicators and their weights to suit the characteristics of retrofitting. For example, BREEAM Domestic Refurbishment, a standard for residential renovations, removing those like “ecology” and “runoff,” which are relevant only to new builds. DGNB, meanwhile, assigns zero weighting to site quality, as it cannot be determined in renovation projects.

A comparison of green renovation evaluation systems for existing buildings across countries shows that resource conservation is a core focus. China’s 2021 Green Renovation Standard covers six areas: safety and durability, health and comfort, convenience, resource conservation, environmental livability, and innovation. "Resource conservation" is assigned a maximum score of 200 points, while the others each have a maximum of 100 points. Some systems include qualitative requirements for heritage-protected traditional buildings. For example, BREEAM allows special consideration for historically or architecturally significant buildings if energy efficiency measures would compromise their appearance. DGNB evaluates functionality and aesthetic quality, focusing on enhancing adaptability while preserving original form. For heritage buildings, DGNB suggests qualitative assessment methods. China’s system aligns poorly with traditional building renovations, with only 2.9% of the total score related to cultural value. Scholars propose adjusting indicators and emphasising those reflecting cultural value(Zuo & Gao, 2017).

2.2. Research on evaluation for green retrofit of existing buildings

Current research focuses on green renovation evaluation systems tailored to different climate characteristics or building types. Some studies have developed systems specifically for industrial or public building renovations(Guo et al., 2022). Historical buildings, particularly traditional residential buildings, have attracted considerable scholarly attention(Fiore et al., 2020; Gravagnuolo et al., 2020; Martínez-Molina et al., 2016). While energy consumption and conservation are primary criteria in the renovation of historical buildings, other factors, such as sustainability, economic considerations and cultural value are also important(Webb, 2017). Roberti et al. used the Analytic Hierarchy Process (AHP) to assess the relative importance of various building components in visual, spatial and physical terms based on expert ratings(Roberti et al., 2017). Additionally, some studies have adjusted indicator weights based on climate characteristics(Ma et al., 2021), such as Ma et al.’s modification of indicator weightings for residential buildings in cold regions(Cao et al., 2024). Furthermore, some research has enhanced green building evaluation systems from a lifecycle perspective, emphasising low-carbon energy conservation in renovations throughout a building's entire life-cycle(Song et al., 2024).

The adjustment of evaluation system weights includes both objective and subjective weighting methods, such as the grey comprehensive evaluation method, fuzzy comprehensive evaluation method, data envelopment analysis (DEA) method, artificial neural network (ANN) method, and

the TOPSIS method(Villalba et al., 2024). The Analytic Hierarchy Process (AHP), proposed by Saaty, is one of the most widely used subjective weighting methods(Saaty, 1980).AHP simulates human reasoning in the decision-making process to handle uncertainty, making it suitable for determining the weights of qualitative indicators that are difficult to quantify(Lallam et al., 2023). AHP has been successfully applied by many scholars in decision-making for weight adjustments(Abadi & Moore, 2022; Mayhoub et al., 2021).

2.3. Low-carbon retrofit of bungalow courtyards

Research shows that the uniqueness of green renovation for traditional buildings lies in their physical characteristics and preservation principles(Webb, 2017). The physical characteristics of Beijing's traditional courtyard houses include: 1) courtyard layout with limited space; 2) brick-wooden structure with pitched roof; 3) small proportion of exterior windows; 4)wooden doors and tiled roofs, leading to poor airtightness. Regarding preservation principles, the retrofitting of traditional courtyards must adhere to the Technical Guidelines for the Protection and Repair of the Old City of Beijing (2019), which impose stringent controls on the structure, proportions, scale, colour, materials, and detailing. Certain green renovation measures, such as external wall insulation, shading devices, and renewable energy systems, may impact the traditional façade. As a result, the green renovation of courtyard houses within the core functional area of the capital is constrained by façade protection regulations.

3. METHOD

3.1. Construction of evaluation index system

The construction of the indicator system is based on the current Green Building Evaluation Standard for Existing Buildings, incorporating multi-objective decision-making on energy consumption, thermal comfort, and the preservation of traditional architectural façades. This process ensures the systematic and comprehensive nature of the system by determining the reduction and adjustment of indicators. Through field research and the Delphi method(Fathullah et al., 2023), interviews were conducted with 10 industry experts, followed by feedback processing, expert consultation, and further rounds of opinion solicitation. This iterative process was repeated twice to analyse the compatibility of various items with the courtyard houses in the core functional area of the capital. Based on the existing evaluation system, the new set of indicators will be adjusted to address the material spatial characteristics and cultural significance of existing residential building renovations and the traditional courtyard houses in the core functional area of the capital.

3.2. Determination of the weight of evaluation index

To ensure the objectivity of the weight construction process, this study will employ expert scoring and the Analytic Hierarchy Process (AHP) to establish a weighting system for the new set of indicators. The construction of the evaluation system involves six experts with extensive experience in the green building industry, who will assess the appropriateness and significance of each indicator in the context of renovation projects for this type of building. The experts include three practitioners involved in building projects and three academic researchers. Scoring results from the professionals will be collected through a survey questionnaire, followed by the creation of a judgement matrix and consistency testing of the matrix.

4. RESULT

4.1. Evaluation index system

After adjustment, the system consists of 6 top-level indicators, 13 middle-level indicators, and 47 bottom-level indicators, as shown in Fig.1. The goal layer includes safety and durability, health and comfort, convenience, resource conservation, environmental livability, and value sustainability. In alignment with the characteristics of the old city courtyard houses, the original additional item "Enhancement and Innovation" has been specified as "Value Sustainability," as shown in the table. Compared to the current Green Building Evaluation Standard, the green evaluation system for the courtyard houses in the core functional area of the capital has undergone two types of changes: deletions and additions.

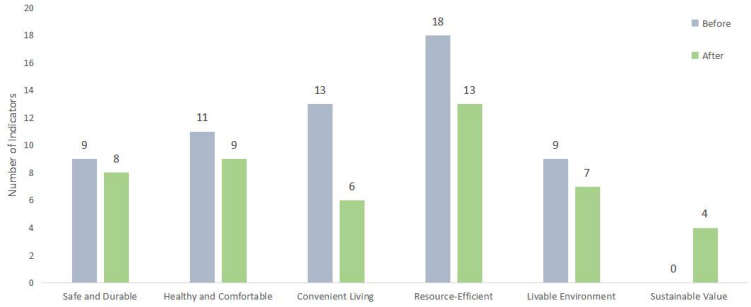

Figure 1. Comparison of the number of indicators before and after adjustment.

A total of 17 indicators have been removed from the system. The exclusion of these indicators is based on an analysis of their compatibility with the renovation process of courtyard houses. The 17 removed indicators primarily fall into two categories: 1) scoring items that cannot be achieved due to the inherent characteristics of courtyard houses, such as sunlight exposure and evacuation distance; and 2) scoring items that do not apply to the scale of courtyard house renovations, such as those related to underground spaces and community-scale issues. The reasons for the removal of each indicator are outlined in Table 1.

Table 1. Deleted indicators and reasons.

top-level indicators	bottom-level indicators	Deleted reasons
A Safety and Durability	Pedestrian and Vehicle Separation	More than 50% of the roads are between 3-5 meters, making it difficult for most roads to meet pedestrian and vehicle separation requirements.
B Health and Comfort	Water Storage Facilities	Water storage facilities are required for buildings over six stories that require secondary water supply; however, most courtyard houses in the old city are single-story and do not need water storage facilities.
	Sunshade Facilities	Traditional bungalow courtyards in Beijing, situated in a severe cold climate zone, have small windows for winter insulation, with protruding eaves providing natural shading. Installing external sunshades would compromise architectural style protection.
C Safety and Convenience	Public Transport Accessibility	Not applicable for existing building renovations where site selection cannot be changed.
	Urban Public Space Walkability	
	Provision of Public Services	Not suitable for courtyard renovation projects with limited space.
	Fitness Area Setup	
	Energy Monitoring	Courtyard houses are multi-family residences with complex ownership issues, making it difficult to install monitoring equipment due to property rights conflicts.
	Air Quality Monitoring	
	Property Management and Implementation	Traditional courtyards do not have property management.

D Resource Efficiency	Land Conservation	Courtyard renovations do not involve land changes.
	Underground Space Development	Traditional blocks do not allow underground development.
	Parking	Courtyard renovations do not involve parking issues.
	Outdoor Scenic Water Bodies	Courtyard spaces are limited and do not have scenic water bodies.
	Use of Non-traditional Water Sources	Courtyard updates cannot renovate water sources; this indicator only applies to concentrated renovations or new construction projects.
E Environmentally Livable	Protection of Site Natural Ecology	This evaluation criterion is for large-scale new construction or reconstruction projects; courtyard renovations do not involve damaging site ecology.
	Site Noise	Renovations of flat courtyard houses do not affect site noise environment.

A total of four new indicators have been added to the indicator layer. In response to the unique challenge of cultural heritage preservation in the renovation of Beijing's traditional bungalow courtyard,a new goal layer, "Value Sustainability," has been introduced.This layer incorporates both cultural heritage and building renovation aspects, including four indicators: preservation of courtyard spatial layout, façade harmony, extended lifespan of brick-wooden structures, and enhancement of functional suitability. From a life-cycle perspective, the retrofitting addresses the needs of green low-carbon and sustainable development by reusing structure and materials, while updating the functionality to meet modern requirements.

4.2. Weight of the evaluation index

The determination of weights is based on a judgment matrix derived from the Analytic Hierarchy Process, using the modified Saaty's 1–9 scale to obtain the ratings of six experts for the indicator weights, followed by consistency testing. Taking the first expert as an example, the judgment matrix for the goal layer is shown in Table 2. The final weights for each level of the indicators are derived by aggregating the experience-based weight sequences provided by the six experts.

Table 2. Empirical judgment matrix for the weight of the criteria layer index of the first expert.

	Safe and Durable	Healthy and Comfortable	Convenient Living	Resource-Efficient	Livable Environment	Sustainable Value	Weight
Safe and Durable	1	1	2	1/2	1	1/2	0.134
Healthy and Comfortable	1	1	2	1/2	1	1/2	0.134
Convenient Living	1/2	1/2	1	1/4	1	1/4	0.077
Resource-Efficient	2	2	4	1	2	1	0.267
Livable Environment	1	1	1	1/2	1	1/2	0.121
Sustainable Value	2	2	4	1	2	1	0.267

λ max=6.0546，CR=0.0087

Table 3. Empirical judgment values of top-level index weight by experts.

Top-level indicators	**Experts**					
	1	2	3	4	5	6
Safe and Durable	0.152	0.211	0.111	0.195	0.056	0.250
Healthy and Comfortable	0.174	0.158	0.148	0.171	0.111	0.139
Convenient Living	0.130	0.105	0.111	0.171	0.056	0.111
Resource-Efficient	0.196	0.211	0.074	0.073	0.500	0.194
Livable Environment	0.152	0.158	0.259	0.171	0.167	0.111
Sustainable Value	0.196	0.158	0.296	0.220	0.111	0.194

5. DISCUSSION

Compared to the initial weights, the weights of the Top-level indicators "Resource Conservation", "Convenient Living" and "Health and Comfort" have relatively decreased, while the remaining indicators have seen an increase, as shown in Table 4. Notably, the weight of "Value Sustainability" has risen by 14.5%. Given the cultural significance of courtyard houses in the core functional area of the capital, the importance of value continuity and façade preservation is extremely high, resulting in a substantial increase in its weight in the green evaluation. "Resource Conservation" still holds the highest weight, while the reduction in the weight of "Convenient Living" is primarily due to the smaller number of indicators in this category after the reconfiguration. During the expert scoring process, the influence of the reduced number of indicators led to a corresponding decrease in its weight.

After removing indicators that are not applicable to the bungalow courtyard in the core functional area of the capital, over 70% of the indicators in the system have seen an increase in their weight. This adjustment provides more effective guidance for the selection of strategies in the renovation projects. A few indicators have experienced a decrease in weight, mainly those that are of lower importance or difficult to implement in the context of courtyard house renovations, such as "Safety Protection Design," which is relatively less critical for courtyard houses, and "Renewable Energy," which conflicts with façade preservation(López & Frontini, 2014).

Table 4. Initial and adjusted weights of the bottom-level indicators.

top-level indicators	Initial Weight	Adjusted Weight	bottom-level indicators	Initial Weight	Adjusted Weight
A Safety and Durability	0.157	0.159	Enhanced Earthquake Resistance	1.4%	2.7%
			Safety Protection Design	2.1%	1.8%
			Safety Protection Products	1.4%	1.9%
			Pavement Anti-Slip Measures	1.4%	2.3%
			Improved Flexibility	2.6%	1.7%
			Durability of Components and Parts	1.4%	1.9%
			Durability of Structural Materials	1.4%	2.0%
			Durability of Finishing Materials	1.3%	1.7%
B Healthy and Comfortable	0.157	0.143	Air Pollutant Concentration	1.7%	1.6%
			Healthy Interior Decoration Materials	1.1%	1.7%
			Water Quality Requirements	1.1%	1.6%
			Drainage facility signage	1.1%	1.5%
			Indoor Noise Control	1.1%	1.0%
			Room Sound Insulation	1.4%	1.3%
			Natural Daylighting	1.7%	1.4%
			Thermal and Humid Environment	1.1%	2.2%
			Natural Ventilation	1.1%	2.0%
C Safety and Convenience	0.157	0.105	Age-Inclusive Accessibility	1.1%	2.2%
			Water Usage Monitoring	1.0%	1.7%
			Intelligent Service System	1.3%	1.9%
			Average Water Consumption	0.7%	1.6%
			Operational Assessment	0.7%	1.7%
			Green Education	1.7%	1.5%
D Resource-Efficient	0.313	0.220	Thermal Performance of Building Envelope	2.1%	2.3%
			Energy Efficiency of Cooling and Heating Systems	1.4%	1.7%
			Reduced energy consumption for air conditioning	0.7%	1.1%
			Energy-Saving Electrical Equipment	1.4%	1.4%
			Building Energy Consumption	1.4%	1.7%
			Renewable Energy	1.4%	1.0%

			Water Efficiency of Sanitary Appliances	2.1%	3.7%
			Water-Saving Equipment and Technology	1.7%	2.1%
			Integration of Civil Engineering and Decoration	1.1%	1.2%
			Structural Materials and Elements	1.4%	1.3%
			Selection of Decoration Items	1.1%	1.3%
			Recyclable Materials	1.7%	1.5%
			Green Building Materials	1.7%	1.6%
E Livable Environment	0.157	0.164	Control of stormwater runoff	1.4%	2.0%
			Outdoor Smoking Area	2.1%	1.2%
			Outdoor Green Space	1.1%	2.7%
			Green Rainwater Management Facilities	1.4%	2.6%
			Light Pollution	1.4%	2.5%
			Site Wind Environment	1.4%	3.0%
			Reduction of Urban Heat Island	1.7%	2.3%
F Sustainable Value	0.063	0.208	Preservation of Courtyard Layout	1.4%	5.6%
			Facade Aesthetics Harmonization	1.4%	5.8%
			Lifespan Extension of Brick and Timber Structures	1.4%	4.1%
			Enhancement of Functional Suitability	1.4%	5.2%

6. CONCLUSION

This study addresses the challenges of retrofitting bungalow courtyards in Beijing's old city, focusing on difficulties in achieving high green building ratings and supporting dual carbon goals. Each of the 60 items in the Green Building Evaluation Standard is assessed for compatibility with these courtyard houses, using expert interviews, field research, and the Analytic Hierarchy Process (AHP) with the Delphi method.

In terms of the indicators,17 indicators that do not align with the renovation of the old city courtyard houses are removed, while four new indicators reflecting the unique characteristics are added,including the inheritance of courtyard spatial patterns, coordination of facade styles, prolongation and utilization of brick-wood structures, and enhancement of functional suitability. The new evaluation index system conforms to the low-carbon renewal of bungalow courtyards in the Old City of Beijing which includes six aspects: durability, comfort, environment, energy, management, and value sustainability, with 47 scoring indicators.

In terms of weights, the adjusted weight reflects the comprehensive consideration of low-carbon and heritage conservation. "Resource Conservation" retains the highest weight, while "Value Sustainability" has increased by 14.5%. Over 70% of the bottom-level indicators have seen weight increases, the weight of the indicators that are less important or difficult to implement in the retrofit of the bungalow courtyard has been reduced, leading to more effective guidance for the sustainable renewal.

ACKNOWLEDGEMENTS

Gratitude is extended to the professors and colleagues for their collective efforts, and to the experts for their support in the data collection for the new evaluation system. Writing assistance were provided by National Key R&D Program of China (2022YFC3803801 in 2022YFC3803800).

SUMMARY
This study focuses on clarifying the thermal environment created by different air-conditioning (AC) systems and developing a simulation method to analyze the coupled heat transfer and airflow processes. Field measurements were conducted to evaluate the performance of radiant floor, floor-supplied, and ceiling-supplied AC systems, providing insights into the temperature control efficiency and distribution characteristics of different AC systems. Furthermore, a coupling simulation method combining building energy simulation (BES) and computational fluid dynamics (CFD) was established to accurately reproduce the thermal and airflow dynamics. Validation through transitional, cooling, and heating seasons showed strong agreement between the simulated and measured data. This approach enables detailed predictions and assessments of thermal comfort and energy efficiency. These findings will contribute to the development of efficient AC system designs, support energy-saving strategies, and enhance the thermal comfort in large-scale buildings.

Keywords: large space building, air-conditioning systems, thermal environment, coupling simulation

1. INTRODUCTION

In Japan, achieving carbon neutrality by 2050 has become a national priority. The building sector accounts for approximately 40% of the total primary energy use and 38% of energy-related CO_2 emissions (Wang and Hong, 2020). Among these, large-scale buildings (over 10,000 m²) constitute only 1% of the building stock but consume 36% of the total energy. Addressing this imbalance is critical, and the adoption of high-efficiency equipment in such buildings is expected to significantly advance the transition to a decarbonized society.

Stratified air conditioning has become a widely used technique to promote energy efficiency in large-scale buildings because of its advantages in reducing energy consumption and improving indoor air quality. Radiant floor cooling and floor-supplied air conditioning (AC) systems are commonly employed to achieve stratified AC. A key feature of these systems is the vertical temperature distribution, which is essential for optimizing energy efficiency and ensuring thermal comfort. However, the accurate prediction of the thermal environment and energy-saving

performance of stratified AC systems during the design phase remains challenging.

In this study, we analyzed the thermal environment of a large-scale building certified to achieve at least 50% reduction in primary energy consumption compared to the reference value during the design phase. The building features a high-efficiency AC system that combines radiant floor, floor-supplied, and ceiling-supplied AC systems, designed to ensure thermal comfort while reducing energy use.

The primary objectives of this study were to clarify the thermal environment and verify the performance of the AC systems. This research is structured around two main components: (1) field measurements to capture the actual thermal conditions in the target building and (2) the development of a coupling simulation method for further assessment of the complex AC system. Numerical simulations that consider coupled heat transfer and airflow processes were conducted using the BES-CFD coupling method. This method leverages the advantages of building energy simulations (BES) and computational fluid dynamics (CFD). As an initial step, this study verifies the effectiveness and predictive accuracy of the method, laying the groundwork for future design applications and assessments.

2. TARGET BUILDING

Fig. 1 shows photographs of the target building located in Fukuoka, Japan. Designed as a public administration building, it has a total floor area of 11,716 m² and is constructed to achieve significant energy savings through a highly insulated exterior envelope and highly efficient equipment. In addition to its thermal insulation performance, the facade design incorporates strategies to reduce external skin loads while maximizing the use of natural light.

Fig. 2 shows the AC zoning diagrams for each floor, illustrating the use of different AC systems according to the purpose and scale of each area. Notably, on the first floor, the zoning diagram shows a combination of radiant floor AC (Fig. 2(a)) and floor-supplied AC systems (Fig. 2(b)) in the entrance lobby area, while the office area was equipped with a ceiling-supplied AC system. The lobby and office areas were integrated into a connected large open space. Consequently, three types of AC systems—radiant floor AC, floor-supplied AC, and ceiling-supplied AC—operate simultaneously in this large-scale space, potentially creating complex temperature and airflow distributions. Notably, an outdoor air handling unit was integrated into the ventilation system.

3. METHODOLOGY

3.1. Field Measurement

In the first stage, field measurements were conducted in a target building. The measurements included air temperature, humidity, and floor surface temperature. As shown in Fig. 3, the measurement locations were established on the first and third floors. The measured areas comprised areas with a combination of floor-supplied AC and radiant floor AC (Locations 1 and 2), an area with ceiling-supplied AC (Location 3), and an area with only a floor-supplied AC system (Location 4). Furthermore, measurement points were set up at different heights at each location to capture the vertical temperature stratification. The measurements began in the summer of 2024, with data collected at 10-minute intervals, providing a comprehensive dataset for evaluating the thermal environment under typical operational conditions.

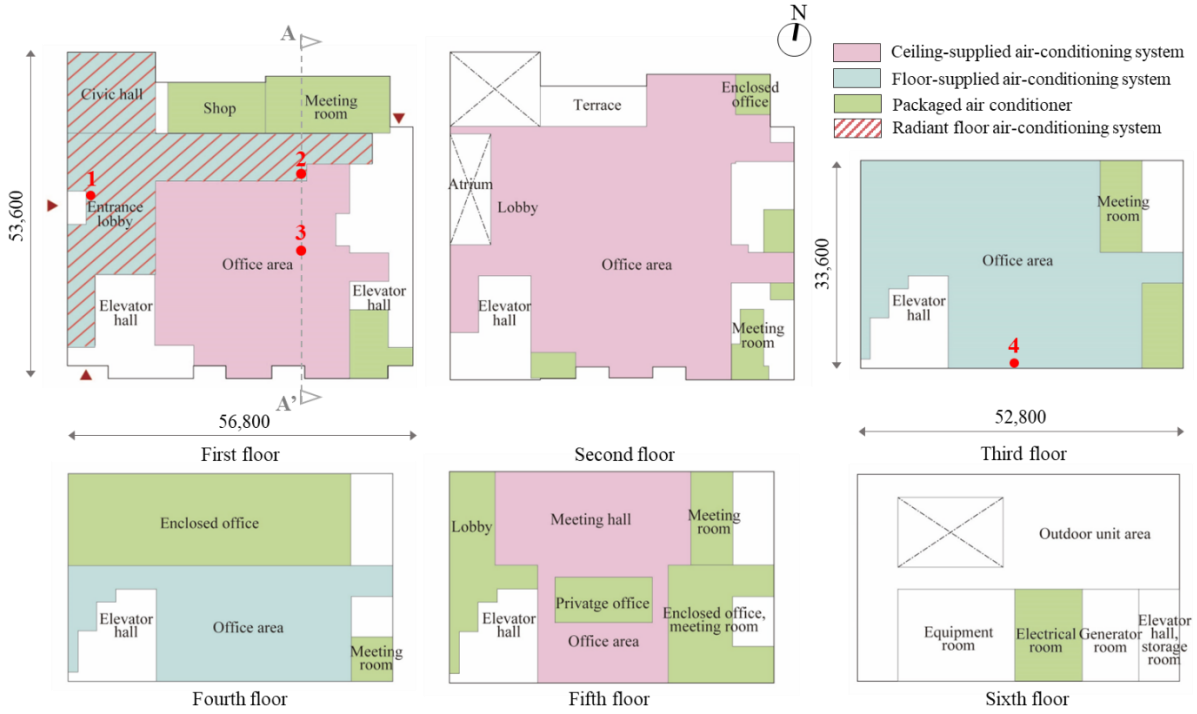

Figure 3. Air conditioning zoning plan.

3.2. Numerical Simulation

In this study, we employed the BES tool THERB for HAM to simulate the thermal environment (Ozaki and Tsujimaru, 2006). THERB for HAM models each room as a node and calculates the spatial temperature, humidity, and heat load over time and periods, strictly concerning conduction, convection, and radiation. The software was validated through standardized Japanese tests and officially approved by the Japanese government. Numerous studies have demonstrated the predictive accuracy of THERB for HAM across buildings of varying scales (Lee et al., 2019; Ozaki and Tsujimaru, 2006.; Yang et al., 2024).

The accurate prediction of the thermal environment of a target building requires the reproduction of coupled heat transfer and airflow processes. THERB for HAM effectively predicts environments dominated by natural convection but struggles in spaces with forced convection,

such as those with an operating AC system, owing to its inability to account for airflow. Conversely, although CFD provides detailed insights into the airflow and temperature distribution, it relies on simplified thermal boundary conditions, limiting its accuracy in accounting for thermal storage and external influences.

Thus, to precisely predict the temperature and airflow distribution in the large space of a target building, we employed a static coupling strategy using a one-step approach (Zhai et al., 2002). To address the limitations of CFD, surface temperature data from THERB for HAM were provided as the thermal boundary conditions to CFD (Zhai and Chen, 2003). This coupling method enhanced the reliability of predictions regarding heat transfer and airflow dynamics, enabling a detailed assessment of the thermal environment created by various AC systems.

In this study, we focused on developing a coupling simulation method to accurately reproduce the thermal environment of a complex AC system and validate its accuracy. The accuracy of the method was assessed in two steps: (1) by comparing THERB for HAM-simulated results with measured data during the transitional season when the AC system was off and (2) by comparing THERB for HAM-CFD-simulated results with measured data during the cooling and heating seasons to validate the reproduction of coupled heat transfer and airflow processes. The simulation conditions are listed in Tables 1 and 2.

4. RESULTS OF FIELD MEASUREMENT

4.1. Cooling season

Fig. 4 presents a comparison of the temperature variations over time at different locations during the cooling season. For the first-floor locations (Locations 1–3), the observation period spanned three days, from September 17 to 19, 2024, whereas for the third-floor location (Location 4), it spanned from October 8 to 10, 2024. Fig. 4(b) and 4(c) clearly demonstrate the vertical temperature stratification at Locations 1 and 2, where floor-supplied AC and radiant floor AC systems were applied. The temperature variation over time indicated that the temperature began to decrease at approximately 9:00, when the AC system started, and continued to drop until 17:00, when the

system was turned off. This trend is likely influenced by the thermal storage effect of the floor. However, at Location 3, which used a ceiling-supplied AC system, the temperature decreased sharply after the start of cooling and remained relatively stable until cooling was stopped. As shown in Fig. 4(f), at Location 4, where a floor-supplied AC system was applied, the vertical temperature stratification was the most significant. The temperature at a height of 1000 mm drops markedly when the AC system starts operating, showing a difference of approximately 2 °C compared to the temperature at 2000 mm. This indicates that the floor-supplied AC system efficiently conditions the occupied zone in the workspace, effectively providing localized cooling where it is most required. While such stratification can enhance energy efficiency by targeting cooling to where it's needed, it may also suppress vertical mixing under strong inversion conditions, potentially reducing convective cooling effectiveness. Airflow dynamics should therefore be considered to ensure both thermal comfort and energy performance.

Fig. 5 shows the humidity measured at a consistent height of 1000 mm across all locations. The results showed that while the AC system was operating, the relative humidity differences among the locations were minimal. Additionally, the relative humidity consistently remained within the range of 40–60% at all locations, ensuring a comfortable indoor humidity environment.

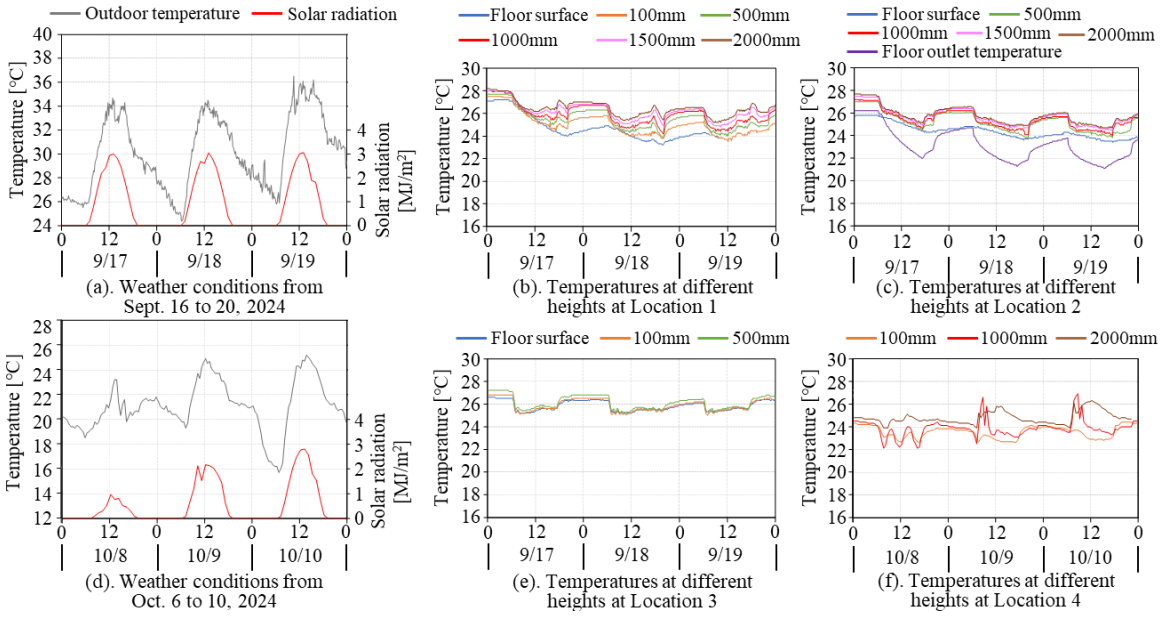

Figure 4. Measured temperatures at different locations alongside outdoor conditions during the summer season.

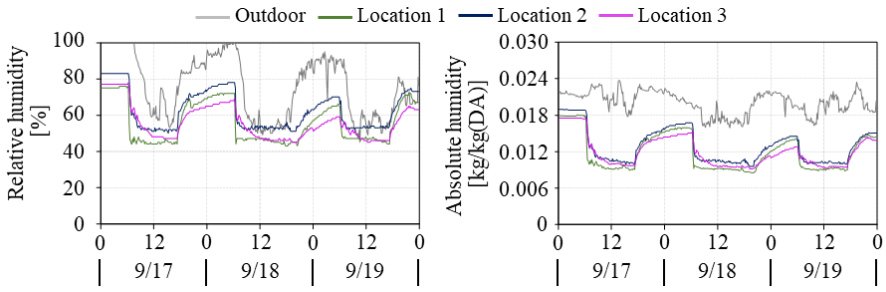

Figure 5. Measured humidity at different locations alongside outdoor conditions during the summer season.

4.2. Heating season

Fig. 6 compares the temperature variations at different locations during the heating season based on data measured from December 24 to 26, 2024. As presented in Fig. 6(b) and 6(c), the vertical temperature differences at the same locations were relatively small during the heating season at Locations 1 and 2, where floor-supplied AC and radiant floor AC systems were used. Temperatures in these locations increased gradually after the AC system started and continued to rise until it stopped, with the effect being particularly notable in Location 1, which was situated in the entrance lobby, an area prone to significant heat loss. At Location 3 (Fig. 6(d)), which used a ceiling-supplied AC system, the temperatures increased sharply after heating began and remained relatively stable throughout the operation. At Location 4 (Fig. 6(e)), where a floor-supplied AC system was applied, the temperatures increased significantly within approximately three hours of heating. Notably, Location 2, despite being in the interior zone like Location 3, exhibited about 1°C higher temperatures attributed to the use of floor-supplied and radiant floor AC systems.

Regarding the humidity environment, Fig. 7 demonstrates that, similar to the findings during the cooling season, there was a minimal difference in the humidity levels between the various air-conditioning systems across different locations.

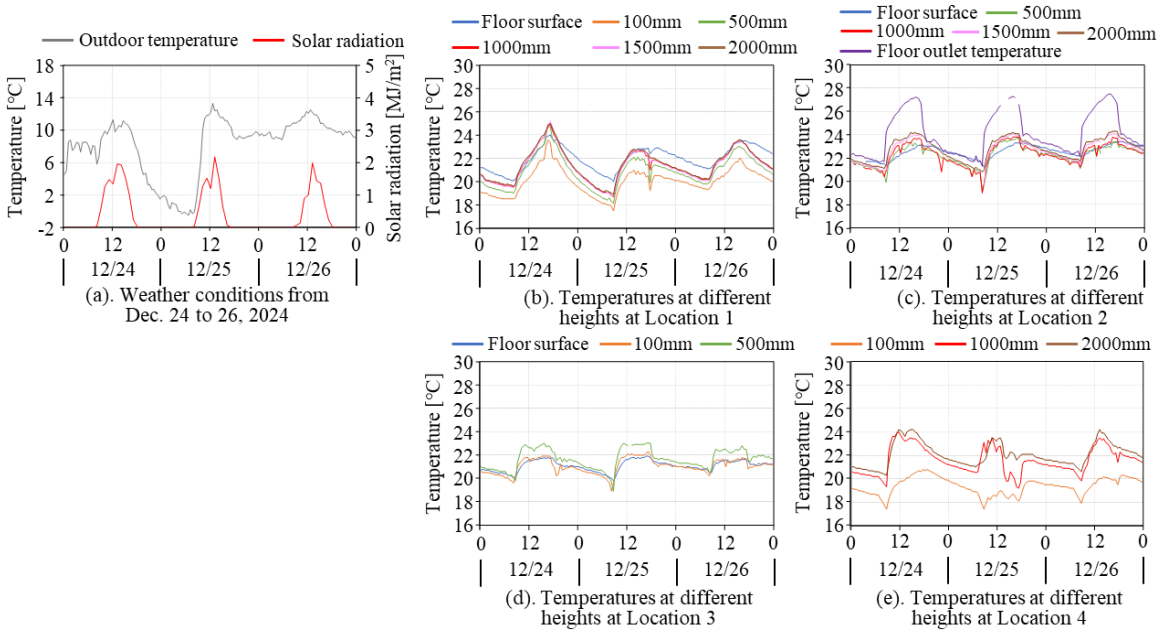

Figure 6. Measured temperatures at different locations alongside outdoor conditions during the winter season.

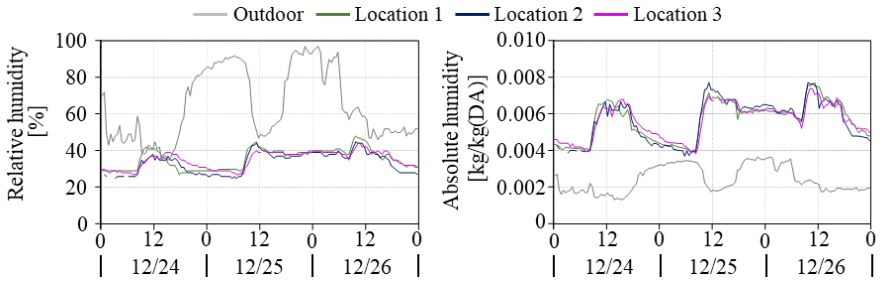

Figure 7. Measured humidity at different locations alongside outdoor conditions during the summer season.

5. RESULTS OF SIMULATION

Fig. 8 compares the air and floor surface temperatures at Locations 2 and 3 simulated using THERB for HAM with the measured data obtained during the transitional season when the AC system was off. The results show a strong agreement between the simulated and measured data, validating capability of THERB for HAM to accurately predict the thermal environment in indoor spaces dominated by natural convection.

To predict the heat transfer and airflow dynamics in the target space during the cooling season, an unsteady simulation using THERB for HAM was conducted on September 18, 2024. The surface temperatures calculated at 12:00 were extracted and set as the boundary conditions for CFD. Fig. 9 shows the THERB for the HAM-CFD-simulated temperature distribution under these conditions. Vertical temperature stratification was particularly pronounced at Location 2, which is consistent with the field measurement findings. A comparison of the simulated and measured temperatures at various heights at Locations 2 and 3 further demonstrated strong agreement.

Similarly, during the heating season, the surface temperatures at 12:00, simulated by THERB for the HAM on December 27, 2024, were provided to the CFD. Fig. 10 shows the THERB for the HAM-CFD-simulated temperature distribution under these conditions, which aligns closely with the measured data at Locations 2 and 3. Moreover, the vertical temperature stratification throughout the space during the heating season was more pronounced than that during the cooling season, as illustrated in the distribution figure.

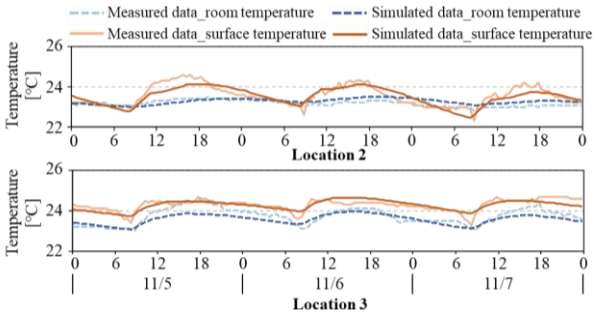

Figure 8. Comparison of temperature between measured and simulated data in transitional season.

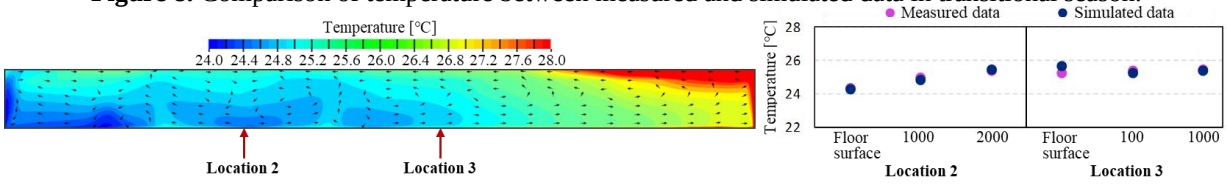

Figure 9. Temperature distribution predicted by THERB for HAM-CFD and comparison with measured data in cooling season.

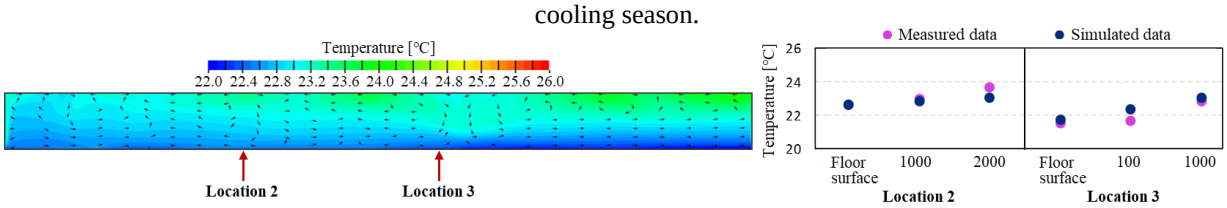

Figure 10. Temperature distribution predicted by THERB for HAM-CFD and comparison with measured data in heating season.

6. CONCLUSIONS

This study aimed to analyze the thermal environment of a space equipped with a combined AC system that integrates radiant floor AC, floor-supplied AC, and ceiling-supplied AC systems. Field measurements were conducted to capture the thermal characteristics generated by the different AC systems. Additionally, a simulation method accounting for coupled heat transfer and airflow processes was developed, and its predictive accuracy was validated.

Field measurements highlighted the unique thermal behaviors of each AC system. The combination of radiant floor and floor-supplied AC resulted in a gradual temperature rise after activation, demonstrating the floor's thermal storage capacity—an aspect that can be leveraged for energy-efficient heating/cooling strategies. The ceiling-supplied AC system maintained a stable and uniform temperature, making it suitable for spaces requiring consistent thermal conditions. Meanwhile, the floor-supplied AC system effectively regulated the temperature in occupied zones, suggesting its potential for improving occupant comfort with localized control. Across all systems, humidity distribution remained relatively uniform, reinforcing the overall stability of indoor air conditions.

A coupled simulation method was established and shown to effectively reproduce the heat transfer and airflow dynamics during AC operation. Future studies will focus on analyzing the characteristics of different AC systems and their efficiencies in terms of both thermal comfort and energy consumption through parameter sensitivity analyses. This study can serve as a reference for future AC system design applications.

ABSTRACT

This paper presents the experimental results of a heat recovery ventilator (HRV) preheated by a building integrated photovoltaic thermal (BIPV/T) system, carried out during the winter in a test cell of the Future Buildings Laboratory (FBL) at Concordia University in Montreal, Canada. First, the influence of the various airflow rates on the operation and performance of the integrated BIPV/T and HRV system is investigated, for the fault-free case, including 1) supply air temperature from HRV, 2) HRV fans power input, and 3) sensible heat transfer effectiveness of HRV. Second, the HRV filters clogging is introduced through the manual blockage with aluminium adhesive tape and its impact on the thermal efficiency of HRV is evaluated. The following physical variables are measured: the air temperature, relative humidity, and airflow rate at the inlets and outlets of HRV, and the electric power input to HRV fans. The derived variables are sensible heat transfer effectiveness of HRV and heat recovery rate of HRV. The variation of the measured and derived variables is presented with respect to various airflow rates and severity of filters clogging. The results show that the increase of airflow rate increases the heat recovery rate of HRV at the cost of the increased energy consumptions of fans and reduced sensible heat transfer effectiveness of HRV. Moreover, compared with fault-free HRV operation, HRV filters clogging reduces the energy consumptions of HRV fans and required to reheat the supply air.

Keywords: Heat recovery ventilator, Building integrated photovoltaics/thermal, Faults, Various airflow rates.

1. INTRODUCTION

Heat recovery ventilators (HRVs) are increasingly being used in cold climate housing to deliver fresh air to occupied spaces while simultaneously recovering heat from the exhaust air.
The proper ventilation rate is required by the standard. The inadequate ventilation rate leads to the potential health risk to the occupants and deteriorates the indoor air quality (IAQ). Hereby, a number of publications have investigated the impact of various airflow rates on the HRV operation. HRVs enhanced ventilation and decreased the risk of wheezing and rhinitis in this population (Kovesi et al., 2009). A recent systematic review revealed that reduced ventilation results in an increased risk of respiratory infection with several infectious agents, including influenza virus (Li et al., 2007).

A simulation study of the HRV preheated by BIPV/T systems operating in the low Arctic climate of Nunavik reveals that higher flow rates result in lower supply air temperatures, while lower flow rates lead to higher supply air temperatures(Baril et al., 2021). The performance of three types of heat pipe ~~heat~~ recovery unit were tested (Riffat and Gan, 1998). It can be noted that the effectiveness decreases with the increase of air velocity. Similar findings were found by (Kim., 2022): the heat transfer effectiveness decreases with the increase of the airflow rate. Moreover,

the pressure drops and heat transfer rate of HRV increased with the increased airflow rate (Kim., 2022; Akbari and Oman. 2013)

A simulation study, conducted at three cities: Winnipeg, Seattle and Lake Charles at the house developed based on the Canada Mortgage and Housing Cooperation, showed that the energy savings varied from 3300 to 12,000 kWh per year for ventilation rates ranging 20–70 L/s, and the annual saving was approximately $165 to $600 (Barringer and McGugan, 1989). The increase of the airflow rate can significantly reduce the level of the radon (Akbari and Oman. 2013) Moreover, the fans power drop as the reduction of the airflow rate. Ventilation heat lossesare increasing due to the new indoor air quality standards and the focus on reducing indoor radon concentration in cold climates. The ventilation losses increase with the increased airflow rate of HRV (Akbari and Oman. 2013).

A regular replacement of the air filters should be undertaken to prevent the filter clogging. The resistance increases when the filter is fouled and causes higher energy consumption (Liu et al, 2017). A clogged HRV filter increased the allergen exposure, reduced its ability to remove stale air and pollutants, leading to stagnant air and higher concentrations of indoor air contaminants (Penney, M. 2024). However, to our knowledge, there hasn't been studies investigating the thermal and energy impact of the HRV air filter clogging.

Building upon these findings, this study first investigates the influence of the various airflow rates on the operation and performance of the integrated BIPV/T and HRV system in cold climate under the fault-free conditions. the analysis includes 1) supply air temperature from HRV to the building, 2) HRV fans power input, and 3) sensible heat transfer effectiveness of HRV. Second, the HRV filters clogging is introduced through the manual blockage with aluminums adhesive tape and its impact on the thermal efficiency of HRV is evaluated.

2. METHODS AND MATERIALS

2.1. Test setup and materials

The testing of the HRV preheated by the BIPV/T system is carried out in a test cell located at the Future Building Lab (FBL) at Concordia University, Montreal, Canada. The HRV test setup, illustrated in Fig.1, consists of one HRV unit, three flexible ducts, and a test-duct station installed on each duct. Before entering the HRV, the outside air passes through the cavity of the BIPV/T system.

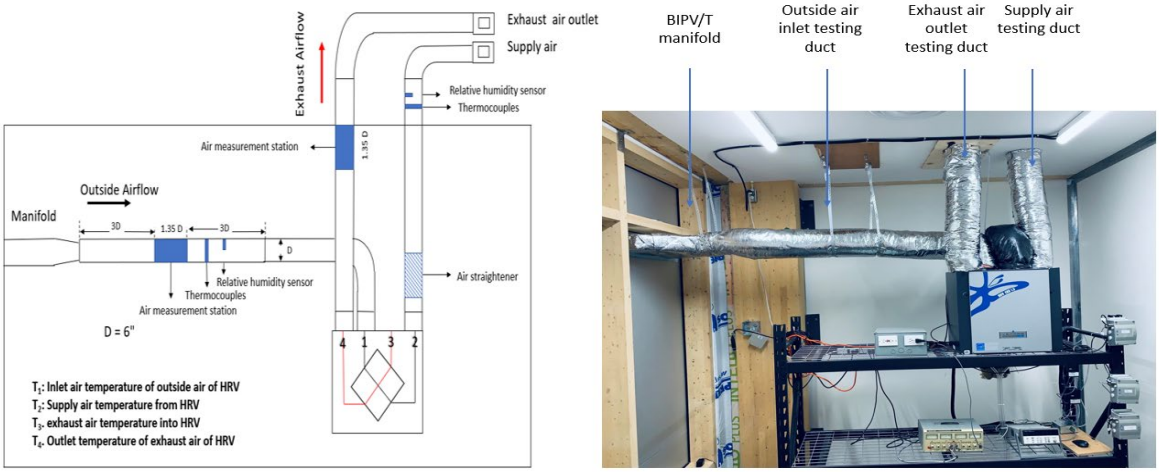

Figure 1: The schematics of the HRV test setup

This study utilizes the Venmar AVS EKO 1.5 heat exchanger, a cross-flow heat exchanger with an apparent sensible heat recovery effectiveness ranging from 72% to 89%, depending on the outdoor air temperature and airflow rate. The HRV unit includes four airstream ports: outside air inlet, supply airflow, exhaust airflow, and exhaust air outlet. Additionally, it operates under the high/medium high/medium low/low fans speed modes. In each fans speed mode, the HRV fans can be set at maximum or minimum fans speed mode.

The details of the BIPV/T panels were presented in detail in the previous publication (Li et al., 2023). A test-duct setup, designed based on ASHRAE standard (ASHRAE Stand. 41.2, 1987) and recommendation from the manual of the Dwyer air measurement station (Dwyer Instruments, n.d), is used for the measurements of air temperature (T), relative humidity (RH), and airflow rate ($\dot{m}$). The test duct is 152.4 mm in diameter (D) and constructed of galvanized steel. The test-ducts are wrapped with mineral wool insulation and vapour barrier in order to reduce the heat loss/gains from the ambient air in the laboratory and reduce the potential for condensation on the ducts. There are three testing duct setups: (a) one for the outside air inlet (Fig. 2 (a)), (b) one for the supply airflow (Fig. 2 (b)), and (c) one for the exhaust air outlet (Fig. 2 (c)). The relative humidity and temperature in the exhaust air inlet is obtained by measuring the room air temperature and relative humidity. All the specifications of sensors used are presented in the previous publication (Li et al., 2023)

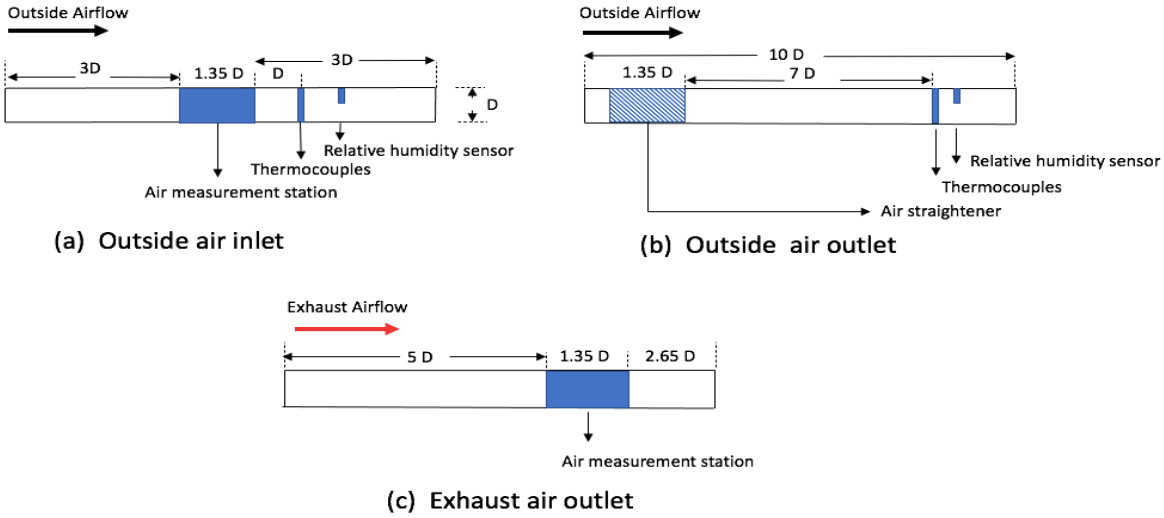

Figure 2: The testing duct configurations for the outside air inlet, outside air outlet and exhaust air outlet.

The HRV tests are carried out at four fan speeds: 1) low speed (minimum), 2) medium low (maximum), 3) medium high (maximum) and high (maximum). Then the supply airflow filter is blocked by the Aluminium foil thermal insulation by 25%, 50% and 75% to simulate the minimum, medium and serious filter clogging. After the HRV reached steady-state, measurements were taken for 30 min at each airflow setting and each supply airflow clogging level.

2.3. Performance monitoring

The sensible heat recovery effectiveness $\in_{sens}$, and heat recovery rate, Q_{hrv} are used as performance indicators to evaluate the thermal performance of HRV using measurements taken on a minute-by-minute basis.

The sensible heat recovery effectiveness (**Equation 1**).

$$\in_{sens} = \frac{\dot{m}_1 \cdot Cp \cdot (T_2 - T_1)}{\dot{m}_{min} \cdot Cp \cdot (T_3 - T_1)} \quad (1)$$

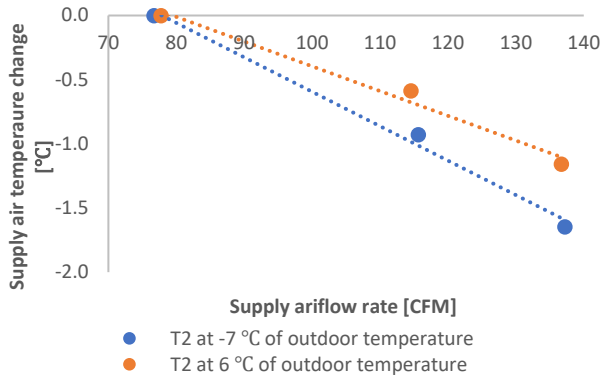
Where T_1 is the outside air inlet temperature leaving the BIPVT and entering the HRV; T_2 is the supply air temperature of the HRV; and T_3 is the room temperature; $\dot{m}_1$ is the outside air mass flow rate, kg/s; $\dot{m}_{min}$ is the lowest of the mass flow rate of $\dot{m}_1$ and $\dot{m}_4$, kg/s and Cp is the specific heat capacity of air at average temperature, J/kg K. $\dot{m}_1 \cdot Cp \cdot (T_2 - T_1)$ represent the heat recovery rate of HRV.

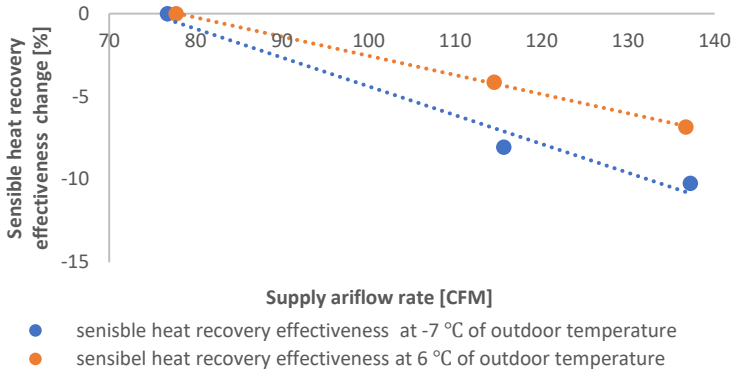
3. RESULTS

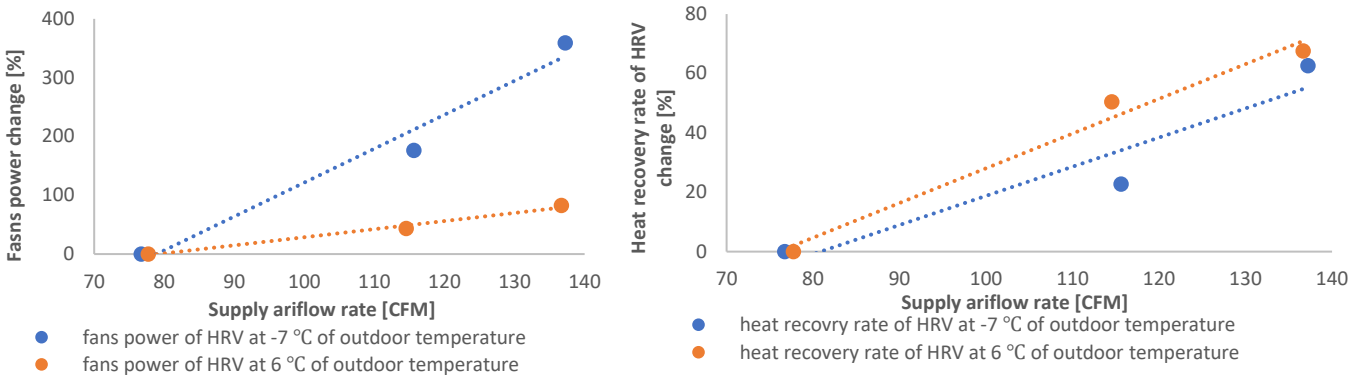
The performance of the HRV at various airflow rates at "fault-free" and supply air filter clogging operation conditions are monitored from November 15th, 2024 to January 10th, 2025. The test cell is conditioned by an air handling unit located in the FBL building, maintaining a room setpoint temperature of 20°C and a relative humidity of 35%. All measurements are recorded at 1-minute intervals using an Agilent 34970A data logger.

The measurements at the time of non-solar irradiance are used for the HRV thermal performance analysis to prevent the impact of the BIPV/T preheating. The comparison of the HRV at various airflow rates and supply air filter clogging is presented here (Fig. 3 and Fig. 4) at 6℃ and -7℃ of outdoor temperature respectively.

The parameters compared include the sensible heat recovery effectiveness, $\in_{sens}$, supply air temperature, T_2, outside air flow rate, $\dot{m}_1$ and exhaust air flow rate, $\dot{m}_4$ as well as the heat recovery rate of HRV averaged over the entire period at each outdoor temperature.







Monitored parameters	Correlation-based models	R_2
-7 ℃ of outdoor temperature		
Supply air temperature T_2	y = -0.027x+2.09	0.99
Sensible heat recovery effectiveness of HRV, $\in_{sens}$	y = -0.17x+12.98	0.98
Fans power of HRV	y = 5.77x-455.16	0.97
Heat recovery rate of HRV	y = 0.98x-79.39	0.90
6 ℃ of outdoor temperature		
Supply air temperature T_2	y = -0.02x+1.53	0.98
Sensible heat recovery effectiveness of HRV, $\in_{sens}$	y = -0.12x+9.01	0.99
Fans power of HRV	y = 1.38x-108.95	0.99
Heat recovery rate of HRV	y = 1.17x-88.89	0.98

Figure 3: Comparison of sensible heat recovery effectiveness $\in_{sens}$, supply air temperature, T_2, airflow rate and heat recovery rate of HRV at different HRV fans speed setting at 6 ℃ and -7℃ outdoor air temperatures at "fault-free" operation condition.

As shown in Fig. 3, the supply air temperature T_2 reduces with the increase of airflow rate of HRV by a maximum of -1.2℃ and -1.9℃ at 6℃ and -7℃ of outdoor temperature, respectively . The sensible heat recovery effectiveness decreases with the increase of airflow rate by a maximum of -6.8% and -10.2% at high fan speed (maximum) at 6℃ and -7℃ of outdoor temperature, respectively.

Due to the increased airflow rate, a maximum increase of the fans power of HRV is by 359% and 39% (Fig. 3) at 6◦C and -7℃ of outdoor temperature, respectively. Although the sensible heat recovery effectiveness drops, the increased supply airflow rate results in the greater heat recovery rate at higher airflow rate, a maximum increase by 67% and 62% at 6℃ and -7℃ of outdoor temperature.

Moreover, the above-mentioned thermal performance variation due to the airflow rate change is associated with the outdoor temperature. For example, both the supply air temperature and

sensible heat recovery effectiveness experience the greater reduction at -7°C of outdoor temperature than that at 6°C of outdoor temperature. Fan power of HRV increases more significantly at -7°C of outdoor temperature than that of 6°C of outdoor temperature due to the increased static pressure of HRV at colder outdoor temperature.

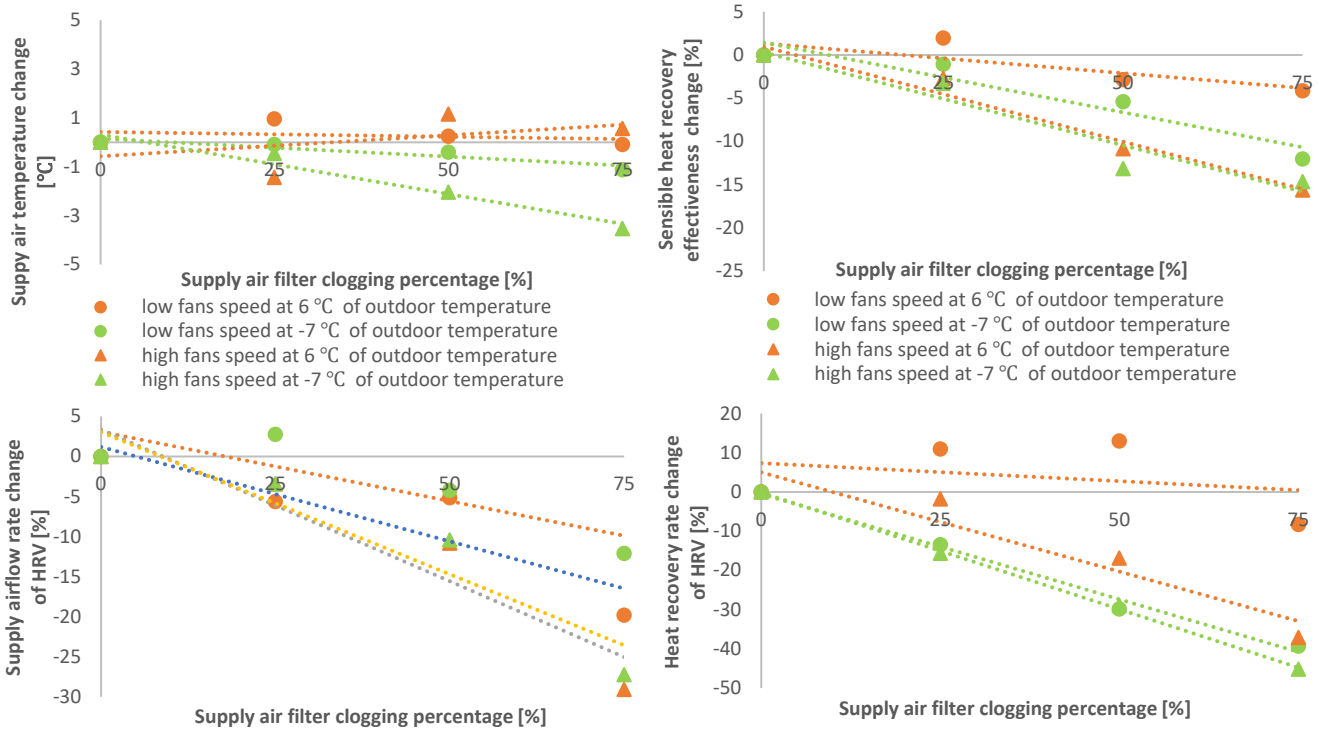


Figure 4: The comparison of sensible heat recovery effectiveness $\in_{sens}$, supply air temperature, T_2, airflow rate of HRV and heat recovery rate of HRV at different severity of HRV supply filter clogging at 6°C and -7°C of different outdoor air temperatures

Compared to the "fault free" HRV operation, the supply air temperature (T_2) decreases with the increase of supply air filter clogging at high fans speed mode by a maximum of -1°C and -3.5°C at 6°C and -7°C of outdoor temperature, respectively. The sensible heat recovery effectiveness drops with the increase of the supply air filter clogging at high fans speed mode of HRV by a maximum of -20.8% and -17.7% at 6°C and -7°C of outdoor temperature.

Supply air filter clogging leads to significant reduction of the supply airflow rate for both high and low fans speed setting, a maximum of -27.2% and -29.1% at 6°C and -7°C of outdoor temperature, respectively. The exhaust airflow and fans power of HRV remains constant for different severity of the supply filter clogging. Furthermore, due to the significant reduction of the supply air flow rate, the heat recovery rate of the HRV reduces greatly with the increased supply filter clogging at high fans speed mode of HRV by a maximum of 37.2% and 45.2% at 6°C and -7°C of outdoor temperature.

Moreover, the above-mentioned thermal performance variation due to the supply filer clogging is associated with the fans speed of HRV. For example, the supply air temperature, sensible heat recovery effectiveness and heat recovery rate are influenced more significantly at high fans

speed mode, compared with low (min) fan speed mode. The change of the thermal performance due to the supply filer clogging is not influenced by the outdoor temperature.

4. CONCLUSIONS

The aim of this study is to investigate the influence of the various airflow rates on the operation and performance of the integrated BIPV/T and HRV system in cold climate, and thermal efficiency of HRV with the filter clogging issue. The HRV preheated by the BIPV/T system is tested in the Future Buildings Lab (FBL) at Concordia University, Montreal during the winter period from November 15th, 2024 to January 10th, 2025. The experimental setup of the HRV and BIPV/T system is first presented. Then, the key performance indicators and parameter measured are presented, including the sensible heat recovery effectiveness $\in_{sens}$, supply air temperature T_2 and outside air flow rate, $\dot{m}_1$ and exhaust air flow rate $\dot{m}_4$ and heat recovery rate of HRV.

For the "fault-free" case, the increased fans speed of the HRV can lead to the increased supply and exhaust airflow rateat the cost of the significant increase of the fans power. In the meantime, compared with the low airflow rate of HRV, the supply air temperature (T_2) and sensible heat recovery effectiveness reduce with the increased airflow rate of HRV at 6◦C and -7◦C of outdoor temperature. Furthermore, the increased supply airflow rate results in the greater heat recovery rate at higher airflow rate, a maximum increase by 67% and 62% at 6℃ and -7℃ of outdoor temperature. The thermal performance variation due to the airflow rate change is associated with the outdoor temperature, the lower outdoor temperature, the greater influence on the thermal performance by varying the airflow flow rate.

For the faulty HRV operation of supply filter clogging, compared to the "fault-free" HRV operation, supply air filter clogging leads to the great reduction of supply air temperature by -3.5℃, the supply airflow rate by a maximum of -29.1%, and sensible heat recovery effectiveness of HRV by -20.8% as well as the heat recovery rate of HRV by -45.2%. Moreover, the above-mentioned thermal performance variation due to the supply filer clogging is associated with the fans speed of HRV, the higher fans speed of HRV, the greater impact on the thermal performance of HRV. The change of the thermal performance due to the supply filer clogging has nothing to do with the outdoor temperature.

The monitoring of the experimental setup of HRV preheated by the BIPV/T will continue throughout winter 2026. This further monitoring data will be used to analyse the defrosting hours, post-heater energy consumption and potentially the electricity generation efficiency impact of BIPV/T by preheating the HRV at different air flow rates

SUMMARY
The paper outlines a framework for community-scale building retrofits aimed at reducing greenhouse gas emissions. Retrofitting existing buildings is a key strategy to meet Canada's 2030 and 2050 emissions reduction targets. The framework involves: assessing the current status of community buildings, identifying potential retrofit measures, analysing the measures for retrofit performance, recommending retrofit scenarios, implementing and verifying the retrofits, and engaging the community throughout the process. The approach integrates grid interaction and emphasises the importance of incorporating innovative technologies and life cycle cost assessment. The paper highlights research gaps, including the need for standardised emissions baselines and methods to account for microclimate effects and cross-sector decarbonisation strategies. It calls for tools to optimise energy, affordability, and resiliency in retrofit models, aiming for a holistic guideline for community-scale retrofits.

Keywords: community retrofit, emissions reduction plans, grid integrated buildings.

1. INTRODUCTION

In Canada's Emissions Reduction Plan, the government of Canada has committed to reducing greenhouse gas (GHG) emissions by 40-45% from 2005 levels by 2030, with a goal of achieving net-zero emissions by 2050. Large portions of Canada's existing emissions stem from energy use in residential, commercial, and institutional buildings [Statistics Canada 2023]. Since a majority of buildings in Canada that will be in use until 2050 are already built, and new buildings are being built to higher standards, the focus for emissions reductions needs to be on retrofits. Retrofitting buildings can generally be defined as "modification of existing equipment, systems, or buildings to improve performance, update operation, improve energy performance, or all three" [ASHRAE 2024]. In the context of this work, the goal is to ensure that modifications lead to lowest life cycle GHG emissions, minimised over the life cycle of the buildings, and that ideally includes emissions associated with raw materials extraction, manufacturing or processing, transportation, building use, and end-of-life management of buildings and all their individual components. Given that for existing buildings, the energy consumption during their use phase makes up a large portion of those emissions, it becomes clear that the energy supply to the buildings plays a pivotal role in minimising emissions, which can be achieved either by reducing energy use or by reducing emissions from the energy source.

The energy source that has the highest potential for emissions reduction is electricity, since it can be generated from renewable energy sources. However, there are limits to harvesting renewable

energy, like the intermittence of availability, geographical access limitations and finite resources for the production of renewable electricity generators. Although many Canadian provinces have the advantage of large resources of hydro power, a renewable energy source that allows for dispatchable electricity supply, even in regions with on average low-emission intensity electricity supply, peak electricity load may come from non-renewable, high emitting sources [Ghobadi 2023]. Further, as demand increases due to electrification of heating, transport and industrial processes, the frequency of hours of high peak demand on the grid will increase further and peak load will shift from summer to winter. Also, existing load profiles are expected to change. As an integral part of the Emissions Reduction Plan, the government of Canada is developing Clean Electricity Regulations to help achieve decarbonisation targets and progress towards clean electricity grids in all Canadian provinces, with a target to be Net-Zero by 2050 [GoC2025]. In this landscape, buildings as main users of electricity from the grid can actively support those decarbonisation targets by shaping the electricity demand profiles in coordination with the grid's clean electricity supply potential [ASHRAE 2023]. To assess the interactions between buildings and the electricity grid, the scope of a retrofit study should encompass several buildings of various use types and sizes in a mix that is representative of consumers of the electricity supplied by the grid. It is on the aggregate level that the buildings' electricity use profile will have an impact on the electricity supply and the variability in use profiles of various buildings can further help reduce the stress on the electricity grid. Hence does the proposed framework follow a community scale approach for retrofit planning.

The goal is to develop optimised pathways of community retrofits for lowest GHG emissions. This paper will outline the required steps, and discuss existing gaps in the framework for low carbon building and energy retrofits on community scale.

2. WORK FLOW FOR RETROFITS – A COMMUNITY SCALE APPROACH

For the development of a retrofit pathway buildings in a community we propose the outlined workflow shown in Fig. 1: (1) assessment of status quo of the community and buildings within; (2) identification of retrofit measures; (3) analysis of the identified measures; (4) developing recommendations of retrofit scenarios; and finally, (5) plan implementation and verification of the retrofit packages and their actual performance. Each step has to be performed in close consultation with the community, property owners and occupants (6) in order to: (a) understand

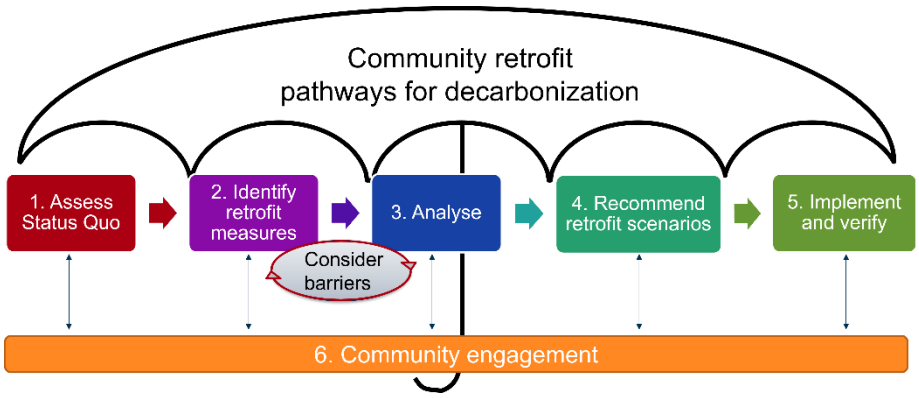

Figure 1. Work flow for community retrofits

their requirements and constraints; (b) ensure buy in for the proposed solutions and the necessary engagement to implement; (c) maintain the benefits of any form of retrofit over the long term; and (d) ensure that the proposed solutions optimally satisfy both low embodied carbon and low operational carbon. Steps (1)-(6) are detailed further in the following subsections.

2.1. Assessment of the status quo

The assessment of the status quo of the community aims to identify the condition and energy performance of the buildings to understand retrofit needs and technical constraints. The performance assessment identifies the current emissions profile of the buildings in the community (baseline emissions), by assessing the current demand profiles for heating, cooling, domestic hot water, and the associated energy sources/energy supply structure, as well as the electricity demand profile and the current electricity grid source energy characteristics. The first comprehensive standard to measure, manage and report GHG emissions on a community level was published by World Resources Institute [Fong 2021]. Relevant to this framework is the guidance on how to calculate the emissions from residential, commercial and institutional buildings and facilities. The data required can come from various sources, such as energy use data from utility bills, survey data, home rating data and energy audits. Establishing retrofit recommendations for the buildings in the community requires knowledge of building attributes which may or may not be available in these datasets. Accordingly, there is a need for advanced methods to complete building specific auditing using cost effective, non-intrusive, rapid, sensing techniques and remote auditing tools. These methods are relatively novel to the market, but have great potential for scalability. Some examples include use of infrared cameras and unmanned aerial vehicles to identify thermal losses from building envelopes and use of smart thermostat data (indoor air temperature, temperature set point, and heating/cooling scheduling) to characterise a buildings thermal performance [Doma and Ouf 2023]. These methods still require research like validation through traditional building auditing techniques, such as submetering, envelope instrumentation (e.g., blower door tests), occupant surveys, utility bills, etc., to demonstrate the ability to derive quantitative assessment data. Once building specific data has been derived, methods to generate community specific archetypes, such as those commonly used in building energy modelling tools, need to be developed.

The assessment leads to building and site condition reports that define status quo of the existing building envelope (thermally and structurally), mechanical systems, indoor environmental quality, energy demand and supply structure and renewables potential within the community.

2.2. Identification of retrofit measures

The initial assessment defines the baseline for the retrofit pathways: Modifications of the status quo should lead to improvements that can be assessed in comparison to this baseline and improvement targets can be set accordingly. Those targets depend on the purpose of the retrofit. Typically, the incentive for a community to undergo retrofit would be to increase the resilience of buildings and occupants to withstand disaster and changes in climate, enhance the durability of built assets and reduce the cost of operating the buildings. The additional goal for a low carbon retrofit is to achieve these upgrades while reducing emissions. Utilities can also benefit from community retrofits in terms of grid side management. Demand reduction, especially during critical peaks will reduce the stress on the grid, leading to a more resilient, self-sufficient utility grid. Furthermore, it will reduce the utility’s operational costs. Self-sufficiency means

reduced costs of importing electricity from nearby jurisdictions. Since resilience upgrades and energy efficiency measures have the potential to lead to GHG emissions reductions over the life of the community, those solutions should be preferred.

Based on the initial assessment of the community and its buildings, location and energy supply structure, suitable retrofit measures need to be identified. Retrofit measures would include upgrades to enhance resilience, energy efficiency, environmental quality and energy supply on both individual building and community level: Examples of typical building retrofit measures include: i. Structural upgrades (as needed); ii. Building envelope upgrades to reduce energy use and increase resiliency; iii. Resilient HVAC solutions to increase efficiency of heating and cooling; and, iv. Smart technologies such as smart thermostats and smart meters. However, there is a need to move beyond these traditional technologies, and include technologies which provide: adaptive building operations, smart controls and demand side management including dispatchable loads that enable micro-grid and community energy systems strategies through integration of distributed energy resources (DER) including renewables and energy storage.

To effectively make recommendations for low carbon and resilient retrofit measures, data is needed that specifies: technological specifications and performance, costing data, supply availabilities, timelines of implementation and service life, potential interactions and symbiosis between measures for all retrofit technologies being considered.

2.3. Analysis

Once the baseline of community performance and condition is established, and potential retrofit measures have been identified, analyses will take place to estimate the improvement that can be achieved through retrofitting the community. The analysis of retrofit scenarios currently focuses on energy savings and cost. For the energy analysis, (urban) building energy modelling tools can be used, which mostly are based on physics-based modelling with a bottom-up approach [Reinhart 2016]. Further to data from the initial assessment, the analysis will consider climate data, ideally future weather data, to ensure retrofit measures meet resiliency requirements.

For low carbon retrofits, the analysis should expand, at minimum to include GHG emissions associated with the energy use in the buildings. To calculate emissions from building energy use and consider integration with the electricity grid, it is essential to have grid carbon intensity data and, importantly, forecasts of this intensity. The grid carbon intensity refers to GHG emissions produced per unit of electricity generated and supplied to the power grid, and is also called grid emissions factor. Accurate emissions factors are a foundational input to emissions reduction pathways since they are used to calculate the changes in emissions caused by retrofit measures that affect electricity use [Sotes 2021]. To calculate future emissions factors, predictions of the future electricity supply structure are needed. Hence, the development of a retrofit pathway for buildings in a community should incorporate the emissions reduction plan of the local utility.

Ideally, the goal is to optimise the solutions space for lowest life cycle carbon, which would include so called embodied emissions associated with the materials and systems that are added and construction practices that are involved in the retrofit process. Practically, considering locally sourced, low embodied carbon retrofit materials, minimal transportation of materials, as well as efficient construction operations, can potentially reduce embodied GHG emissions.

To achieve the scale of low carbon retrofit that is needed for Canada's emissions reduction targets, the proposed retrofit solutions should ideally have an economic incentive for the building owners and/or occupants. Considerations of the economic viability of the retrofit via life cycle costing (LCC) tools should thus be integrated with life cycle assessment (LCA) in life cycle cost assessment (LCCA) [Prabatha 2020]. LCA is needed to comprehensively examine the environmental impacts over the life span of buildings and communities. LCA is standardised in ISO 14040 [ISO 2006a] and ISO 14044 [ISO 2006b] from the International Organisation for Standardisation, which provide guidelines how to conduct LCA and define the scope for LCA, i.e. the stages in the life cycle to be assessed and the impact categories to use in the assessment.

Optimisation tools, like MANGOret [Petkov 2022] or python-based frameworks [Zhang 2021], have become popular in LCA studies [Toosi 2020]; and could be used to identify optimal retrofit pathways. The defined targets from section 2.2 are the objective function for this optimisation, which also needs to consider technical constraints and barriers that may limit the solutions space. Besides technical constraints of the given properties, the community may face other constraints that need to be taken into consideration when analysing retrofit options, such as i. Consideration of practical and budgetary barriers; ii. Access to occupied buildings; iii. Heritage, cultural, or historical significance of the asset; iv. Supply chain issues; v. Skilled trades shortage. Richarz [2023] et al suggest a method to incorporate skilled trades shortages into optimising retrofit roadmaps. Similar approaches could be taken to account for supply chain issues. With consideration of cost and technical constraints and other barriers, iterations may be required between step 2, identification of measures, and 3, analysis. To mitigate the impacts of retrofit site work on tenants, faster and less intrusive construction practices should be enhanced. For example, the use of 3D scanning technology to scan damaged building envelopes, and construction of replacements through off-site methods could increase production and reliability.

2.4. Recommendation of retrofit scenarios

Through the analysis and optimisation described in the last section, pareto optimal solutions sets for least cost and emissions pathways can be provided [Prabatha 2024]. From this solution space, an implementation plan for the retrofits in the community can be developed. Depending on cost and financing constraints, this plan can entail a staged approach to retrofitting portions of buildings in the community at a time. Again, the local utility should be included in the planning of retrofits since the measures will impact its operations.

2.5. Implementation and verification

The last step in the framework is to plan for implementation and verification of the retrofit packages and their performance. The retrofit implementation or construction phase should be minimally disruptive to building occupants. While this may drive up costs of the retrofit measures, it could be crucial to acceptance of the implementation plan by occupants. Innovative construction practices, such as panelised construction methods and robotics and automation, may speed up the retrofit process and minimise the disruptions affecting the occupants.

In order to verify the emissions savings that are achieved through the retrofit, post measurements will be required. The results from the post assessment can provide valuable insights for future retrofits and lessons learned can be shared, in particular if a staged approach has been chosen for retrofit implementation while similar measures are being planned for similar groups of buildings.

2.6. Community engagement

The base for a successful community retrofit pathway is engagement with the community stakeholders, which include, broadly speaking, building owners, occupants, building operators, local authorities, community associations, utility providers and business owners and operators. This engagement is required from the very first step to ensure community buy-in and sustained involvement throughout the retrofit process [Shwashreh 2024]. While required at all times, engagement is crucial during the initial stages when the potential solution space is being defined. For highest chance of success, the retrofit measures need to be those that are readily adoptable by the community, which may not necessarily be the optimal scenarios. This highlights the need to increase retrofit literacy in the community previous to providing final recommendations.

3. DISCUSSION OF RESEARCH GAPS

Presently in Canada, there is a considerable number of publications for guidance on energy retrofit strategies in buildings, including not limited to: NRCan's Major Energy Retrofit Guidelines [NRCan 2024], derived from a similar publication by the US Office of Energy, retrofit guidelines for developers, builders and operators by Sustainable Buildings Canada, a not-for-profit organisation [SBC 2025], and resources for homeowners [DER 2025, BDC 2025]. These documents help identify retrofit strategies for singular building types; however, guidance on methods to complete this in an optimised fashion at the community scale for the purposes of energy, decarbonisation and resiliency are lacking. This is especially true when considering the impacts of building retrofits on other sectors, such as the electricity generation sector. This necessitates a holistic framework to be developed, which can leverage and build on, the methods described previously in this paper. To enable the development of a holistic guideline that can be used to encourage resilient and low carbon retrofits at scale, i.e., move beyond the one size fits all approach, there is a need to develop tools and methods to address many barriers. Presently the following barriers are the focus of research at NRC Construction Research Centre in Canada:

3.1 Establishing pre- and post-retrofit performance

A major barrier to rapid deployment of retrofit strategies is establishing the condition and performance of the initial building, as this dictates the options for retrofit. This is needed to move from our current state of one-size fits all recommendations for retrofits, to a tailored approach that can accelerate optimised retrofit decision making. Additionally, post-retrofit performance is rarely documented. There is a need to increase data gathering to determine the accuracy of modelling and planning methods that currently exist, to understand their validity in retrofit planning and identify areas of improvement or gaps.

3.2 Establishing the impact of microclimate and resiliency requirements

Microclimate effects can result in different adaptation strategies on individual buildings, even within the same city. A prime example is urban heat island effect, where the overheating risk in buildings could be significantly different, even for two buildings of the same construction type and occupants, based on surrounding topography, greenery and exposure to water bodies. The same differences in microclimate that effect adaptation considerations would also affect the energy use to heat and cool buildings. Thus, scientific based methods to generate, and incorporate microclimate effects into retrofit planning are needed.

Resiliency can be achieved through exhaust heat exchange between proximity buildings and water bodies within a community. For example, data centres or buildings with large boilers, such as sports facilities and hotels: Exhaust heat can be captured and utilised, in order to reduce heating demands in target buildings.

3.3 Establish standard methods to determine baseline emissions at the community scale

There are standards for determining GHG emissions for different community processes [Fong, 2021], but limited guidance on what to count and how to reach Net Zero emission goals. Guidance on a consistent, and standardised metric needs to be determined. To understand the effect of building retrofits on a community scale, knowledge of the temporal variance in emissions due to electricity use, now and in the future, is needed [Bontekoe 2024]. Presently, in Canada, this is only possible in Ontario and Alberta due to open electricity markets. However – other provinces could enable this through better data sharing requirements.

3.4 Optimisation for affordability, resiliency and energy use of buildings and LCA analysis

While guidance may exist to complete each of these analyses separately, little guidance is provided on how to optimise for these design requirements in practice. Further case studies are needed to derive best practices.

Reviews for LCA studies specific to building retrofits have shown that in practice, the applied LCA scope varies from study to study, making the results incomparable [Fahlstedt 2024]. This emphasises the need to standardise the LCA methods and scope [Fahlstedt 2024], which has huge impact on the outcomes and comparability of building retrofit studies. For example, the assumption of the building lifespan significantly changes the results [Leichter 2024]. In the same sense, the actual service life of building components is necessary for accurate LCA results [Fahlstedt 2024], so there is the need to establish and standardise test methods to predict (remaining) service life and durability of building components under the changing climate.

3.5 Cross Sector data considerations

The community decarbonisation lens extends beyond buildings and the electricity sector. Electrification of other sectors, such as transport (road and marine) may necessitate a more holistic view of community decarbonisation strategies. Therefore, decarbonisation studies of buildings need to consider how the data and conclusions are gathered and presented, such that they can be fed up to a broader model, which considers all cross-sector decarbonisation potential.

4. CONCLUSION

This paper proposes a framework for guidance on developing optimised pathways to retrofit buildings in a community to achieve resiliency and low GHG emissions. The framework consists of (1) Assessing status quo; (2) Identifying retrofit measures; (3) Analysing identified measures; (4) Recommending retrofit scenarios; and finally, (5) Implementing and verifying retrofit packages and their actual performance. Each step has to be performed in close consultation with the community, property owners and occupants (6). Further, research areas to enable resilient low carbon retrofits of buildings at the community scale were identified, with some examples provided. Ultimately, the purpose of this paper is to present the framework and solicit feedback and guidance on missing areas, tools or considerations as this research project progresses.

A novel air distribution system to humidify an aircraft cabin while minimizing water vapor condensation on cabin walls

SUMMARY
Commercial aircraft cabins have long been criticized for the air dryness inside. On the one hand, aircraft cabin requires humidification to improve the comfort feeling. But on the other hand, the aircraft cabin walls must be maintained in a relatively dry status to refrain water vapor condensation. To resolve the above paradox, this investigation proposed a new air system by suppling the humidified, outboard conditioned air into the interior passenger zone, while circulating the relatively warm, dry air along the cabin walls. The validated CFD was adopted to solve the airflow, temperature, and relative humidity distribution. The results revealed that the new air system is able to enhance the relative humidity of the interior passenger zone from the existent 6-8% on inter-continent flights to approximately 22%. Meanwhile, the water vapor content near the cabin walls is maintained 3 g/m^3 lower than the interior passenger zone.

Keywords: Aircraft cabin, Air distribution, Humidification, Moisture condensation, Draught risk

1. INTRODUCTION

Commercial aircraft cabins have long been criticized for the air dryness inside. Low moisture content may induce the headache, skin itching, nose dryness or stuffiness, eye irritation, tiredness and many other non-specific symptoms (Derby et al. 2017). Consequently, scholars strongly recommend increasing the relative humidity in aircraft cabins by 5% to 10% to alleviate the discomfort associated with the air dryness (Nagda et al. 2001). However, even without carrying out humidification, a twin-engine aircraft was claimed having increased its weight by 680 kg due to condensation of water vapor on the internal fuselage skins (Specht et al. 1999). The enhanced humidity inside the cabin will inevitably lead more condensation of water vapor on the fuselage skins. An air distribution system by delivering the humid air into the passenger zone while circulating the relatively dry air along the cabin walls seems a good strategy to resolve the paradox (Zhang et al. 2010). However, such air system was proposed only based on the displacement ventilation (Zhang et al. 2010), which has not been put to practical use yet. There is still a pressing need of a novel air distribution system that can resolve the paradox of the water vapor in aircraft cabin based on the widely used mixing ventilation system. This investigation presents our efforts to address the challenges.

2. METHODS

The new system consists of five slot vents (as labeled by Inlet-1 to Inlet-5) and three gaspers (as labelled by Inlet-6) in half a cabin of a wide-body aircraft as shown in Fig. 1. Inlet-1, Inlet-3, and Inlet-5 supply only the conditioned outboard dry air, with the former two discharging air nearly horizontally and the last discharging air nearly vertically. Inlet-2 and Inlet-4 supply the recirculated, humid air slightly downward to the cabin. The gaspers are located at relatively lower

positions, as highlighted by Inlet-6. These gaspers deliver the humidified, outboard air at a relatively high speed but with a very small volumetric rate to the breathing zones, and the air jets are directed to the both passengers seated close to the aisle and the middle passenger seated in the side. No gasper is toward the passenger seated near window and the central passenger of the cabin.

The total ventilation rates of Inlet-1 to Inlet-5 are 10 L/s per passenger, as shown in Table 1. In the total ventilation rate, a half is from the outboard air and the other half from the recirculated air. The CO_2 concentration of the outboard air is fixed to 350 ppm, while the recirculated air is 1350 ppm. Because Inlet-2 and Inlet-4 discharge the fully recirculated air, the supplied air has a relative humidity of 30.7%. The supplied air from Inlet-6 has a relative humidity of 81.3%, which corresponds to a humidification rate of 40 g/h per passenger. Regarding to temperature, Inlet-5 supplies the warm air at 32 ℃ to heat the cold sidewall and window panels. Inlet-6 (gaspers) discharges air at 24 ℃, while the remaining inlets deliver air at 19 ℃. More details of the design parameters can be found in Table 1.

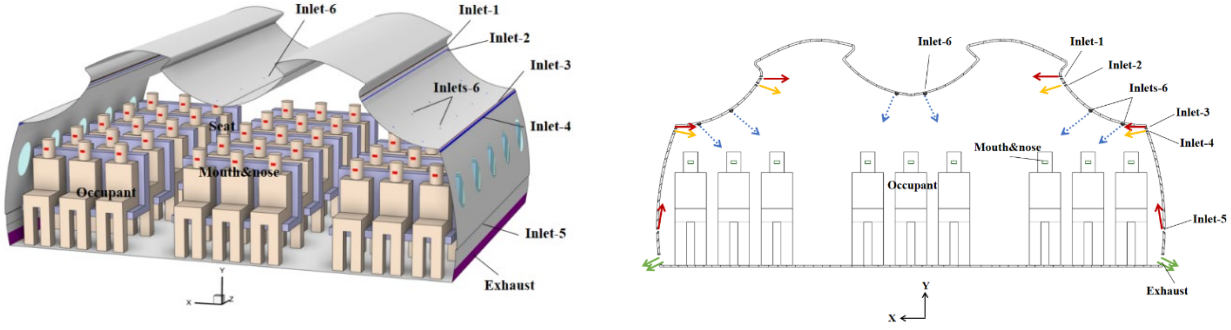

Figure 1. Novel air distribution system in a wide-body aircraft: (a) overview of the geometry and multiple air-supply inlets, (b) sectional view of the aircraft cabin and the air-supply directions form different inlets.

Table 1. Major design parameters of the multiple air supply inlets

Item	Inlet-1	Inlet-2	Inlet-3	Inlet-4	Inlet-5	Inlet-6
Supply air rate per person (l/s)	2.25	2	1.25	3	1.5	0.615
Supply air velocity (m/s)	1.985	1.323	1.324	0.793	1.324	3.059
Supply air temperature (℃)	19	19	19	19	32	24
Supply CO_2 concentration (ppm)	350	1350	350	1350	350	350
Supply air RH	0	30.7%	0	30.7%	0	81.3%

The new air system in a section of a wide-body aircraft with five rows was modelled by the validated computational fluid dynamics (CFD) program. All of the seats were seated by a thermal manikin with the skin temperature of 30.3 ℃. Each passenger was assumed to release the water vapor at a rate of 50 g/h and CO_2 at 18 L/h. The ceiling temperature was set to 23 ℃, the sidewall 18 ℃, and the floor near 24 ℃. All of the seats were treated as adiabatic. The front and rear cross sections were assumed to be periodic.

The RNG k-ε model with the enhanced wall function was adopted to resolve the turbulence. The thermal buoyancy was represented by the Boussinesq approximation. All of the physical variables were discretized by the second-order upwind scheme. The pressure and velocity were solved by the SIMPLE algorithm. The space claim direct modeler (SCDM) software was used to create the

geometric model and generation of the unstructured grid meshes with the "polyhedra" scheme. The mesh size at the air supply inlets was 0.2 cm, around the passenger skins was 2.5 cm, and at the passenger's mouth and nose was 0.5 cm. The maximum mesh size in space did not exceed 6 cm. Because the enhanced wall function was adopted to resolve the wall effect, in order to achieve $y+$ less than 5, three boundary layers were added near the walls. The type of the boundary layer was the smooth-transition, with the transition ratio of 0.272 and the growth rate of 1.15. The total grid cell number was 4,321,034. Once the relative residual of the energy was less than 1.0e-6, the concentration of water vapor and CO_2 was less than 1.0e-3, and the ratio of the sum of mass gain and loss on all boundaries to the total mass gain in the cabin was less than 1.0e-6, the solutions were judged having reached numerical convergence.

The CFD model was first validated with the experimental data obtained in a wide-body aircraft cabin mockup. More details of the model validation can be found in the appendix. Then the distribution of airflow, temperature, CO_2 concentration, and relative humidity were solved. The draught risk (ASHRAE 2021) to the passengers was also evaluated.

$$PD = (34 - t_a) \cdot (V - 0.05)^{0.62} \cdot (0.37 \cdot V \cdot Tu + 3.14)$$

where t_a--- local air temperature, °C
V--- local mean air velocity, m/s
Tu--- local turbulence intensity, %

For V< 0.05 m/s, force V= 0.05 m/s; and for PD > 100%, force PD =100%.

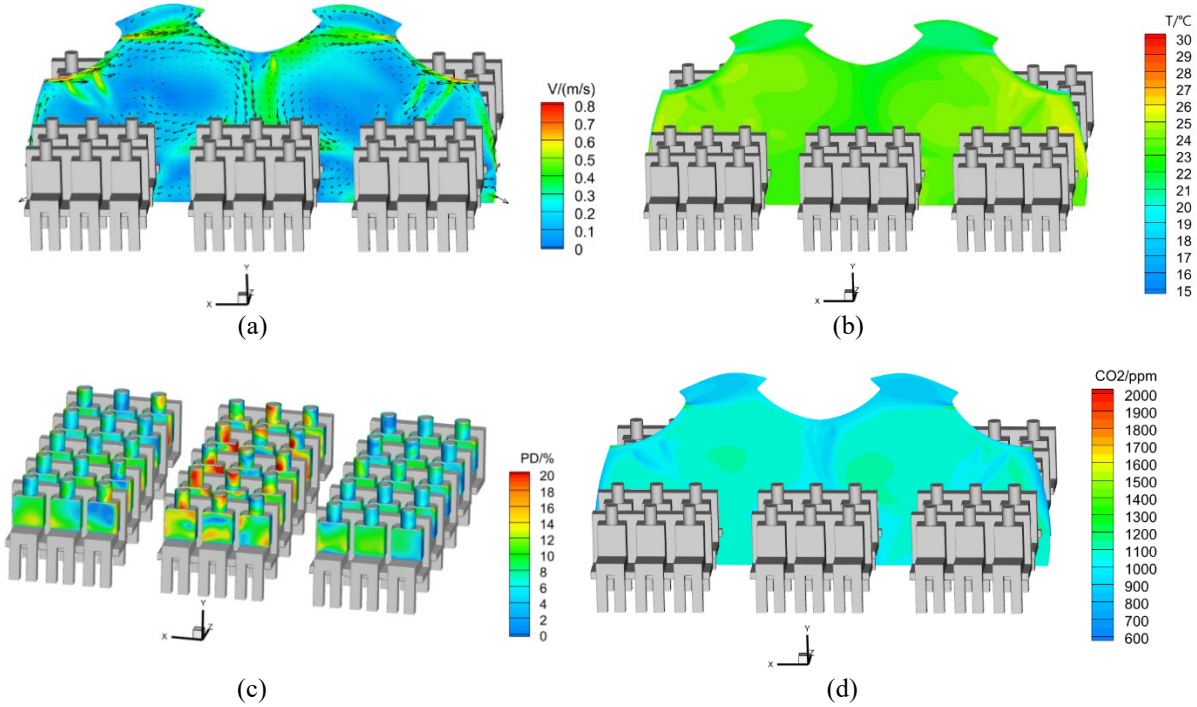

Figure 2. Thermal environment and CO_2 concentration distribution inside the aircraft cabin with the new air system: (a) airflow distribution, (b) air temperature, (c) percentage of dissatisfied (PD), (d) CO_2 concentration.

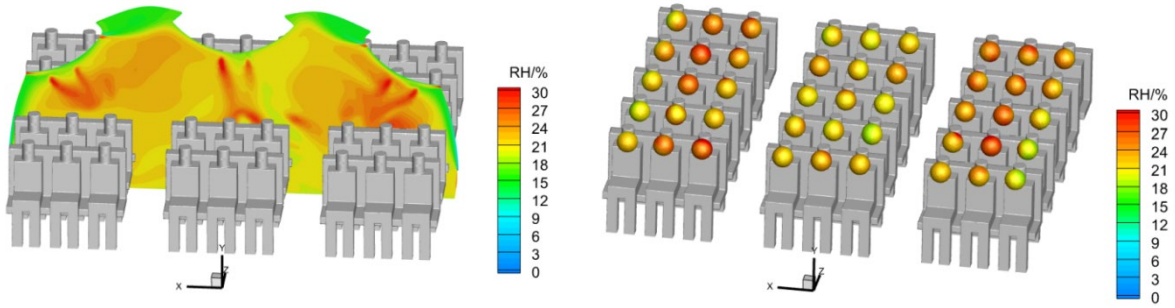
3. RESULTS

Fig. 2(a) presents the airflow distribution in a cross section across the third row. The supplied air into the aircraft cabin formed two big vortices in both sides. The high speed airflow from the gaspers to the side passengers, across the upper aisle region, and in the central region above the middle passengers can be viewed. Fig. 2(b) presents the air temperature distribution, in which the temperature is relatively uniform. However, the slightly high temperature (approximately 26 °C) near the cabin sidewalls and in the region above the side passengers can also be observed. Fig. 2(c) shows distribution of the percentage of dissatisfied (PD) on the upper body surfaces of each passenger. The local PD on the faces of the middle seated passengers is slightly higher, approaching nearly 20%. However, the PD on the faces of the side-seated passengers are less than 15%. Fig. 2(d) shows the CO_2 concentration is generally lower than 1200 ppm. The slightly lower CO_2 concentration due to the downward jets can also be seen.

Fig. 3(a) presents the relative humidity distribution in the cross section across the third row. The relative humidity in the interior passenger zone is much higher, especially in the region with the downward jets from the gaspers. The average humidity inside the internal passenger zone is approximately 22%. In contrast, the low relative humidity (around 15% RH) along the cabin walls can be clearly seen. If converting the relative humidity into the water vapor content, the water vapor content near the cabin walls is 3 g/m^3 lower than that in the interior zone. This shows the good capability of the new air system in minimizing condensation of the water vapor along the cabin walls. Fig. 3(d) presents the relative humidity in the breathing zone of each passenger. The breathing zone is represented by a sphere with a diameter of 0.26 m attached to the face of each passenger. The relative humidities inside the breathing zone of each passenger are not identical, with the relative humidities ranging from 18% to 30%. Note that the relative humidity on the surveyed inter-continent flights is approximately 6-8% (Water et al., 2002).



(a) (b)

Figure 3. Relative humidity distribution inside the aircraft cabin with the new air system: (a) relative humidity in a cross section across the third row, (b) relative humidity in the breathing zone of each passenger.

4. CONCLUSIONS

This investigation adopted the validated CFD modeling to evaluate performance of a newly proposed air distribution system. The system supplies the humidified, outboard conditioned air into the interior passenger zone, while circulating the relatively warm, dry air along the cabin walls. The new air system is found being able to enhance the relative humidity of the interior passenger zone from the existent 6-8% to approximately 22%. Meanwhile, the water vapor content near the cabin walls is maintained 3 g/m^3 lower than the interior passenger zone. The water consumption rate for humidification is 40 g/h per passenger. These justify the good performance of the proposed air system to enhance the relative humidity around passengers while minimizing the water

condensation risk along the cabin walls.

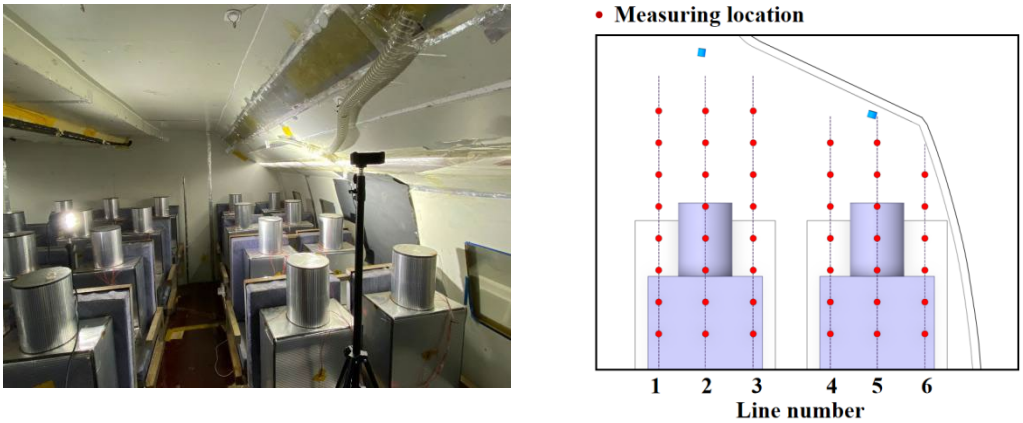
APPENDIX (Validation of CFD modeling)

To assure the CFD modeling accuracy, validation of the CFD modeling for numerically solving spatial distribution of the airflow, relative humidity, and air temperature in a wide-body aircraft cabin, as shown in Fig. A.1, was carried out. In addition to the same geometric settings as the B767 aircraft, two gaspers were adopted to deliver the humid air to the both passengers seated near the side. The ultrasonic anemometer (type: DA-650&TR-92T; Kaijo Sonic, Japan) was adopted to measure the 3-D velocity distribution and air temperature. The relative humidity was measured by a high precision humidity sensor (type: HMT333; Vaisala, Finland). The relative humidity inside the cabin without carrying out humidification was 10.7% RH. The humidification rate to each of the both passengers was 76.2 g/h.



(a) (b)

Figure A.1 Measurement test in a wide-body aircraft cabin similar to B767 for validation of the CFD modeling: (a) picture of the cabin mockup, (b) points for measuring velocity, air temperature, and relative humidity

Fig. A.2(a) compares the CFD solved airflow with the measurement data in a cross section across the third row and in front of the two side passengers. The big vortex of the flow was well resolved by both methods, with a very minimal difference between each other. Fig. A.2(b) presents the relative humidity along line 2, as shown in Fig. A.1(b). The relative humidity increases with the

height, since the humidified air was supplied from the gaspers on ceiling. The CFD provided the relative humidity profile more or less similar to the measurement. Fig. A.2(c) compares the air temperature also along line 2, where the temperature was quite uniform. The CFD provided air temperatures in excellent agreement with the measurement. The above comparison between both methods validated the CFD modeling performing well and having good accuracy in this investigation.

SUMMARY
Forecasting residential building energy demand is crucial due to its impact on energy use and emissions. This study proposes a method to predict thermal energy demand for heating (TED_h) using building envelope characteristics and the heating stress index (*HSI*). A 200-building stock made up by multi-family and apartment block typologies is simulated in 63 Italian climatic locations with EnergyPlus. The two-step method involves: (1) developing a polynomial TED_h - *HSI* regression and (2) a first order double regression linking the polynomial coefficient to building features like dispersing surface/conditioned volume ratio, inter-floor height and global heat exchange coefficient. With an average coefficient of determination of 0.97 and coefficient of variance of root mean square error of 9.32%, the method achieves high accuracy, adhering to ASHRAE Guidelines 14-2002 standards. This approach provides climatic stress curves with TED_h predictions based on climatic conditions and building geometric/thermophysical characteristics.

Keywords*: climatic stress indices, energy demand forecasting, residential building stock, space heating.*

1. INTRODUCTION

Buildings play a crucial role in global energy consumption and carbon emissions. Around 40% of European final energy consumption and 36% of global energy-related CO_2 emissions are attributed to building operations, and these values are expected to rise in the coming years (Directive (EU) 2024/1275, 2024). Given the pressing challenges of global warming and non-renewable resources depletion, improving building energy performance is essential to mitigating the construction sector environmental impact. In response to these challenges, significant efforts have been made to enhance energy efficiency. Over recent years, European policies have increasingly prioritized sustainability to promote renewable energy use, reduce pollution, and lower energy costs (Recast, E. P. B. D., 2010; Directive (EU) 2024/1275, 2024). In Italy, national legislative incentives, e.g., Ecobonus and Superbonus 110%, have been introduced to support energy retrofit costs (Magnani et al., 2020), thus encouraging large-scale renovation, particularly in older buildings (dating back to before 1970s), which dominate the Italian residential sector. Notably, targeted interventions can achieve energy savings of up to 30% in the residential sector and 27% in commercial buildings (de Haan et al., 2007; Sorrell & Dimitropoulos, 2008). Given that the civil sector accounts for 41.6% of Italy's final energy consumption (Annual Energy Efficiency Report, 2023), improving energy efficiency remains a national priority. To maximize the impact of these policies and ensure that retrofit strategies are data-driven and effective, it is essential to develop accurate methods for predicting building thermal energy demand (*TED*). Building energy performance prediction is

fundamental to designing effective global retrofit strategies, ensuring that interventions yield maximum efficiency gains. The Green Houses Directive (Directive (EU) 2024/1275, 2024) highlights the role of intelligent technologies, e.g., automated heating/cooling, in optimizing energy use. As regulatory frameworks increasingly mandate energy efficiency improvements, the ability to accurately forecast *TED* becomes essential to support effective decision-making. However, *TED* forecasting remains a complex challenge due to multiple influencing factors as weather conditions, building characteristics, occupancy patterns, and HVAC system schedules (Zhao & Magoulès, 2012). To address these challenges, there are three commonly used *TED* prediction approaches, i.e., engineering methods, regression-based models, and artificial intelligence techniques. The first rely on physical principles to assess building energy performance in dynamic simulation tools such as EnergyPlus (US Department of Energy. EnergyPlus (Version 8.4)., n.d.), TRNSYS (Transient System Simulation Program, University of Wisconsin., n.d.), ESP-r (*ESP-r.*, n.d.), and IDA ICE (*IDA-ICE, IDA Indoor Climate and Energy.*, n.d.) providing high accuracy but greater computational complexity. Regression-based models, on the other hand, uses historical data, for weather too, to predict energy consumption trends, making them useful for evaluating climate change impacts. Finally, artificial intelligence techniques, i.e., machine/deep learning approaches, can autonomously develop analytical models by learning directly from data. By integrating predictive models with policy-driven incentives, building energy efficiency is enhanced. Accurate energy consumption forecasts can lead policymakers, designers, and stakeholders to more cost-effective energy strategies.

1.1 Literary review

Regression-based methods are frequently used for predicting building energy performance/consumption. *TED* forecasting can help energy efficiency/sustainability, especially if related to thermal and geometric parameters as well as climatic indices. This review explores the state-of-the-art approaches for *TED* prediction, focusing on the application of regression-based methods, which range from simple linear models to more complex ones, to capture the complex interplay between building characteristics and external climatic factors. The integration of climatic stress indices that account for the current rise in temperatures is crucial for improving *TED* prediction accuracy, as conventional regulatory climatic indices do not incorporate this aspect (Mazzaferro et al., 2020). There are various studies that define new climatic indices, such as that of Ascione et al. (2021) and De Masi et al. (2023), focused on novel climatic stress indices and curves, or Salmeron et al. (2013) that proposed a climatic severity index for *TED* for heating forecasting. A comparable approach was adopted by De Rosa et al. (2014), who performed a regression analysis between energy consumption (dependent variable) and degree days (independent variable), incorporating adjustments to account for additional influencing factors such as solar irradiation and thermal inertia. The correlation between *TED* and building characteristics is more complex than the correlation with external climatic conditions since it requires an analysis of building features that can substantially influence the output. Multiple linear regression can establish relationships between building *TED* and the most influencing building variables, as done in the research by Ciulla et al. (2019), with promising results, i.e., a coefficient of determination up to 0.9. Linear regression is one of the most common methods used to model the energy demand in buildings, since it combines the speed of a simple method and the precision of a dynamic thermal simulation. Building *TED* can be combined with key design and operational parameters, e.g., insulation, glazing type, how the building is positioned with respect to the sun, occupant schedules (Amiri et al., 2015). Bayesian regression, offering improved accuracy, can also

be employed for *TED* forecasting by integrating historical energy consumptions and temperature data (Su et al., 2024). A more specialized form of regression analysis is lasso regression (Khosravi et al., 2023), which applies a penalty to linear regression models to reduce complexity and eliminate irrelevant variables, making it useful for energy consumption prediction only considering the most influential building characteristics. A novel contribution of the proposed approach lies in the application of a double-step polynomial regression approach to derive specific climatic stress curves for each building, tailored to its envelope characteristics. This method correlates thermal energy demand for heating (TED_h) with a new heating stress index (*HSI*) and some building parameters. The resulting curves will offer TED_h predictions for any location based on the corresponding *HSI*.

2. MATERIALS AND METHODS

The study examines multi-family building (a) and apartment block (b) constructed in 1961-1975. They have a structural frame in reinforced concrete, walls in hollow bricks with air cavities and a horizontal envelope in mixed brick-reinforced concrete. The main geometric/thermos-physical characteristics are taken from TABULA project (Corrado et al., 2012) and are summarized in Figure 1. The heating system is a centralized natural gas boiler connected to hot water radiators while cooling is provided by electric air-source split air conditioners. The heating setpoint temperature is set equal to 20°C.

Figure 1. Reference buildings of TABULA

This research is based on a previous one by the authors, where building energy demand was predicted using new climatic stress indices (De Masi et al., 2023). It was founded on the SLABE (simulation-based large-scale uncertainty/sensitivity analysis of building energy performance) methodology (Mauro et al., 2015) designed to conduct sensitivity and uncertainty analyses on building stocks energy performance. A climatic stress index investigated was the heating stress index (*HSI*) in Eq. (1), to fit building's thermal energy demand for heating (TED_h). Its calculation followed the normative methodology for heating degree days but the outdoor air temperature is replaced by the sol-air temperature ($T_{sol\text{-}air}$) in Eq. (2), to consider the effects of solar radiation too.

$$HSI = \sum_{heating\ period}(T_b - T_{sol-air})^+ \quad (1)$$

$$T_{sol-air} = T_{out} + G \cdot \frac{\alpha_{sol}}{h_e} \quad (2)$$

Where T_b was the base temperature that assures thermal comfort with plant off, T_{out} was the outdoor temperature, G was the solar irradiance, the solar radiation absorption coefficient α_{sol} was set equal to 0.5 (typical mean value for the external opaque envelope) while the external liminal conductance h_{ext} was set equal to 25 W/m^{2}K, as recommended by Italian standards.

By varying several building parameters within suitable ranges, the random sampling building (RBS-a) dataset is generated, which consists of 100 buildings. A similar methodology is applied to the RBS-b. The combination of the two RBS from the initial buildings consists in a total of 200 buildings. After the RBS creation, energy performance simulations are conducted by integrating MATLAB® (MathWorks, MATLAB – (Version 2022)., n.d.) with EnergyPlus for 63 climatic locations to cover all typical Italian climatic conditions. Figure 2 shows the input parameters for the RBS generation, divided into two groups related to geometry ($v_1 – v_6$) and envelope ($v_7 – v_{19}$), as well as the 63 cities for the energy simulations and a schematic flowchart of the RBS creation. The main aim is to establish a correlation between current TED_h and the following geometric/thermo-physical characteristics of individual buildings in the stock:

- S/V [m^{-1}], ratio between the dispersing surface area (S [m^2]) and the gross volume (V [m^3]);
- h [m], inter-floor building height, i.e., the ratio between the air-conditioned volume (V_c [m^3]) and the air-conditioned area (A_c [m^2]);
- H_{ts} [$W \cdot K^{-1} \cdot m^{-2}$], global heat transfer coefficient specific to A_c, sum of heat transfer coefficient of the building transparent (H_{tr}) and opaque (H_{op}) envelope, as in Eq. (3). It depends on the thermal transmittance (U [W/m^2K]) and the surface areas (S [m^2]) of opaque (subscript "*op*") and transparent (subscript "*tr*") envelope elements.

$$H_{ts} = \frac{\sum(U \cdot S)_{tr} + \sum(U \cdot S)_{op}}{A_c} \quad (3)$$

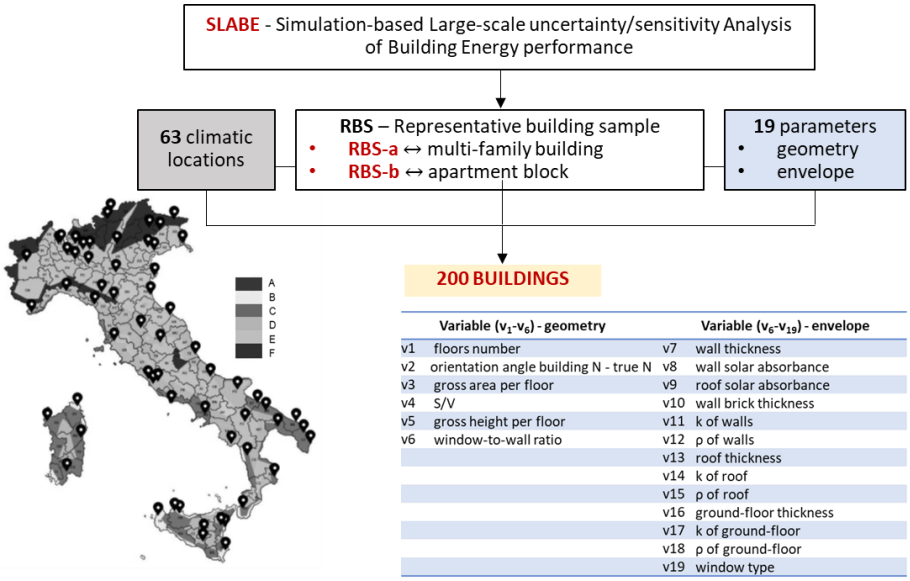

Figure 2. 200 buildings creation flowchart, 63 climatic locations and input parameters for RBS creation

The methodology follows a two-step regression process. First, a polynomial regression is performed to establish the relationship between TED_h and the *HSI* climatic index. Once this relationship is determined, the second step refines the prediction by correlating the polynomial coefficients obtained in the first step with key building envelope characteristics. To relate TED_h and *HSI*, a polynomial regression is done, i.e., a comparison is made among first, second and third order polynomial regressions. Since *HSI* equal to zero means the absence of heating need, the polynomial regression curves are forced to pass through zero. This facilitates the analysis too,

deleting one polynomial term. Figure 3 shows the 3 polynomial regression orders for 4 random buildings in the RBS, i.e., buildings number 21 and 99 for the RBS-a and buildings number 107 and 174 for the RBS-b.

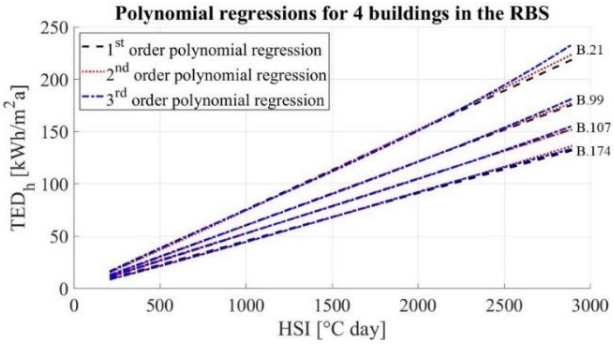

Figure 3. First, second and third order polynomial regressions: TED_h vs *HSI*

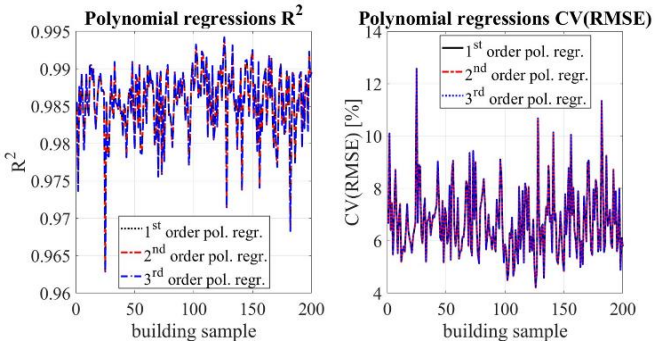
In the second step, the focus shifts to understanding how building envelope characteristics (*S/V*, *h*, and H_{ts}) influence TED_h. To achieve this, a multiple linear regression is conducted between the polynomial coefficients obtained in the first step and these geometric and thermo-physical parameters. This step refines the model, ensuring that TED_h predictions account for both climatic influences and building-specific properties. Finally, a climatic stress curve is obtained for each RBS building to predict TED_h as a function of *HSI*.

3. RESULTS AND DISCUSSION

The first order regression provides correlation comparable to the second and third order ones, as shown in the figures below, where the curves for the three regressions are almost coincident. Two error indices have been evaluated: the correlation coefficient (R^2) and the coefficient of variation of the root mean square error (*CV(RMSE)*) – see Eq. (4). In particular, Figure 4 shows the trend in the values of R^2 and *CV(RMSE)* for the three polynomial regressions related to the 200 buildings of the RBS. Since error indices for the three considered regressions are very similar, it is possible to proceed with a first order regression, i.e., $TED_h = p_1 \cdot HSI$, where the TED_h is a function of *HSI* via the only polynomial coefficient p_1. The first order regression TED_h - *HSI* thus provides a climatic stress curve for each building in the RBS. From the first order polynomial regression to correlate TED_h and *HSI*, minimum and maximum R^2 values are 0.963 (in correspondence of the building number 25) and 0.994 (in correspondence of the building number 126) respectively while the average R^2 is equal to 0.986 for the RBS sample. High R^2 values indicate a strong correlation TED_h - *HSI* across the entire sample. In addition, *CV(RMSE)* minimum and maximum values are 4.22% and 12.6% while its average is 6.73%. These values are in accordance with the ASHRAE Guideline 14-2002, for which regressions with *CV(RMSE)* values less than 15% are acceptable (ASHRAE Guideline 14, Measurement of Energy and Demand Savings, 2002).

$$R^2 = 1 - \frac{\sum_N (x_i - y_i)^2}{\sum_N (x_i - \bar{x})^2}; CV(RMSE) = \frac{1}{\bar{x}} \cdot \sqrt{\frac{1}{N} \cdot \sum_N (x_i - y_i)^2} \quad (4)$$



Regression order	R^2 min	R^2 max	R^2 mean
I	0.963	0.994	0.986
II	0.979	0.995	0.989
III	0.982	0.995	0.990

Regression order	CV(RMSE) min	CV(RMSE) max	CV(RMSE) mean
I	4.21 %	12.56 %	6.73 %
II	4.04 %	8.89 %	5.85 %
III	4.02 %	8.11 %	5.64 %

Figure 4. Polynomial regressions: R^2 and *CV(RMSE)*

From the second step, the only polynomial coefficient p_1 of the first order regression is related to building geometric/thermo-physical features, i.e., *S/V*, *h* and H_{ts}. The double regression reports the trends in Figure 5 for R^2 and *CV(RMSE)* in comparison with the trends from the first order polynomial regression. R^2 is still high, with minimum, maximum and average values equal to 0.846, 0.992 and 0.970 respectively. Similarly, *CV(RMSE)* values are still acceptable, with an average value equal to 9.32%. The proposed method shows that these curves have good reliability in terms of R^2 and *CV(RMSE)*. Figure 6 shows the first order double regression for the 4 test buildings. The curves proposed in this paper have the expression in Eq. (5).

$$TED_h = \left(0.0819 \cdot \frac{S}{V} + 0.0177 \cdot h + 0.003 \cdot H_{ts} - 0.042\right) * HSI \quad (5)$$

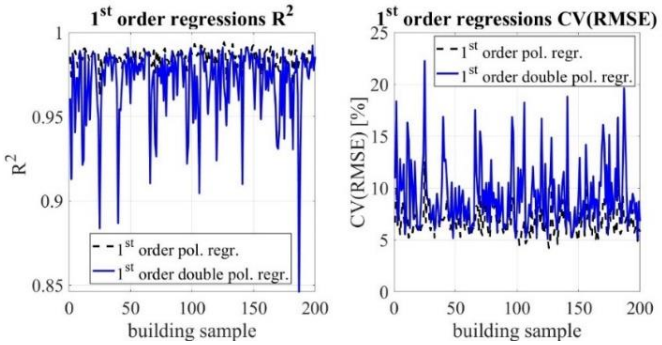


Figure 5. First order regression: R^2 and CV(RMSE)

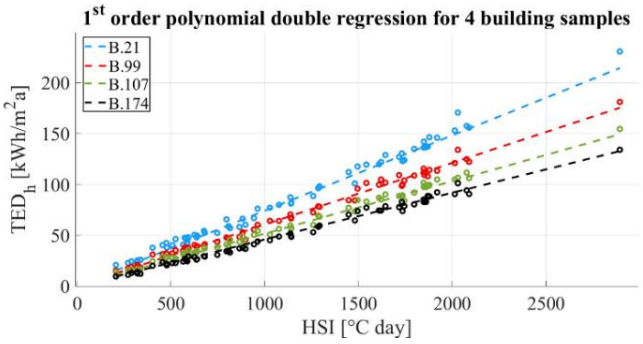

Figure 6. First order polynomial double regression for 4 random buildings in the RBS dataset

The proposed curves can be a user-friendly tool to forecast the building thermal energy demand for heating as a function of the climatic stress. This approach can be adapted to the climate change by updating the *HSI* value can with the novel outdoor temperature and the solar irradiance.

4. CONCLUSIONS

The proposed method, based on the SLABE methodology from previous research, enables the creation of a representative building sample (RBS) using two typologies, i.e., multi-family buildings and apartment blocks, whose characteristics are derived from the TABULA project. The RBS consists of 200 buildings, with energy simulations conducted for 63 Italian locations across all national climatic zones. The approach involves two regression steps: 1) a polynomial regression correlates thermal energy demand for heating (TED_h) with the novel heating stress index (*HSI*); 2) a multiple regression links the polynomial coefficients to building envelope characteristics (*S/V*, inter-floor height, and thermal exchange coefficient). The first-order polynomial regression achieves high accuracy (R^2 = 0.963–0.994, average 0.986; CV(RMSE) = 4.22%–12.6%, average 6.73%), within ASHRAE Guideline 14-2002 limits (15%). The second step further refines predictions (R^2 = 0.846–0.992), ensuring robustness across the RBS. This method is adaptable to evolving climatic conditions by updating HSI with new temperature and solar irradiance values, making it a practical tool for TED_h forecasting. It can assist both private users, by accurately predicting TED_h and assessing retrofit impacts, and policymakers, by informing large-scale energy strategies. Future research should validate the method in different climatic contexts to enhance its global applicability. Additionally, further investigation is needed to assess the link between the simplification to a first-order polynomial and predictive accuracy in extreme climatic conditions. Expanding to cooling energy demand and energy retrofit scenarios could make the proposed approach a more comprehensive method.

SUMMARY
The Energiesprong method of installing prefabricated highly insulated and airtight exterior panels onto existing buildings has been shown to be effective at delivering net zero energy retrofits around the world. These retrofits dramatically reduce the energy consumption of a building once deployed. As the global climate continues to change, extreme weather events are becoming more common. This paper aims to investigate the impact of future climate scenarios on the performance of a building that has undergone a panelized retrofit. A calibrated building energy model is created in TRNSYS to compare the thermal energy consumption, and thermal comfort of the building occupants before and after it has undergone a panelized retrofit in various future climate scenarios. It was found that there was a 7.3% decrease in energy savings and a decrease in thermally comfortable hours from the retrofit in the most extreme climate scenario when compared to the historical scenario.

Keywords: TRNSYS, Panelized retrofit, Thermal resilience, Energy modelling

1. INTRODUCTION & BACKGROUND

Buildings account for nearly 30% of consumed energy in Canada. Energy consumption from commercial and institutional buildings equated to almost 1258 PJ of energy in 2019 alone (Environment and Climate Change Canada, 2022). More stringent energy efficiency codes and technologies are being adopted in new construction, however since about 64% of the current commercial and institutional building stock in Canada was built before the national energy building code was developed in 1997, many existing buildings will need to be retrofitted to achieve a significant reduction in building sector energy consumption.

To meet Canada's emission reduction and climate goals for 2050, the rate at which buildings are being retrofitted needs to accelerate. Currently only 1.4% of commercial building floor area is being retrofitted per year in Canada, which at that pace, is not sufficient to meet Canada's 2050 emission targets for the buildings sector (Efficiency Canada, 2021). The Energiesprong method, developed in the Netherlands, offers a scalable solution to delivering net zero energy retrofits to buildings by using off-site construction that results in a fast project delivery. The Energiesprong method uses prefabricated exterior insulated retrofit panels that drastically increase the thermal insulation and airtightness of the building. Combined with mechanical upgrades, these retrofits can result in a reduction of up to 80% of heating and cooling energy consumption (Biega & Krarti, 2024). The Energiesprong method, and by extension, panelized retrofits offer great potential in reducing energy consumption in the existing building stock. However, the impact of climate change on retrofit analysis is significant (Shen et al., 2019) and so this paper will use a

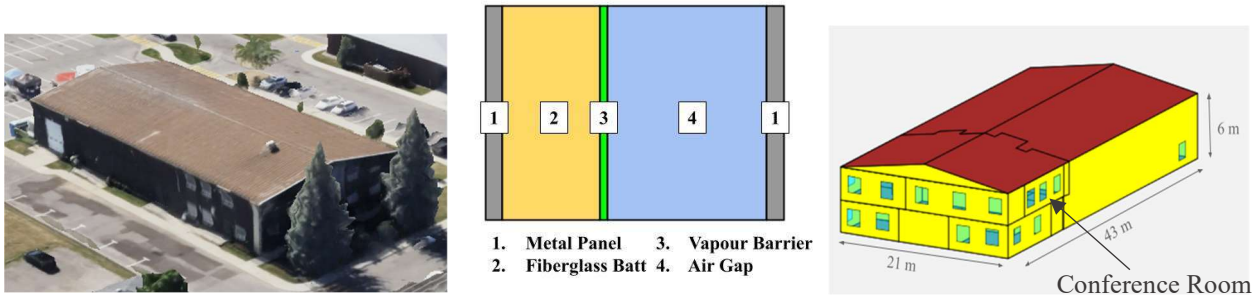
calibrated TRNSYS energy model of a community centre in Quebec, Canada to model the effects of future climate scenarios on building energy usage and thermal comfort before and after a panelized retrofit. This study advances research by creating a calibrated energy model of a real-world building that is a candidate for a panelized retrofit and investigating the impacts of future climate scenarios. This study offers a unique opportunity for future research to compare the calibrated simulation results of this study with real post-retrofit monitored data once the planned panelized retrofit is complete.

2. METHODOLOGY

Transient System Simulation Software, commonly referred to as TRNSYS is a tool developed by the University of Wisconsin that can simulate the behaviour of transient systems such as multizone buildings (Solar Energy Laboratory, University of Wisconsin-Madison, 1975). This study uses TRNSYS to create a calibrated building energy model of a community centre located in Île Bizard, in the jurisdiction of Montreal. The community centre was chosen as a candidate for a panelized deep energy retrofit due to its simple architectural form, high existing EUI, and available space to stage a panelized construction project. The Île Bizard community centre (hereafter: IBCC) consists of a general assembly space, and offices that serve as working space for employees and other community groups. Fig. 1a shows a satellite derived image of the IBCC. The literature relating to calibrating building energy model simulations in the context of retrofits is well established (Coakley et al., 2014; Sharma et al., 2022), as well as the methods for using future climate data in building energy models (Moazami et al., 2019).

2.1 Base case energy model

An energy model was created to represent the pre retrofit case of the IBCC. This model was then calibrated using sub metered energy usage and monthly utility bills from 2023 and 2024. The model's geometry was based off as-built drawings and has 11 thermal zones and a window-to-wall ratio (WWR) of 6.6%. Fig. 1b and 1c shows the IBCC wall assembly, and a 3D representation of the energy model as constructed in TRNSYS respectively.



(a) (b) (c)

Figure 1. (a) IBCC (Google Earth, 2025) (b) IBCC wall assembly and (c) TRNSYS model of the IBCC.

2.1.1 Existing building

The IBCC was constructed in 1978 at a time when energy codes were in their infancy in North America. The structure is steel framed with corrugated metal panels covering the exterior walls and roof. The building envelope assembly consists of a 140 mm layer of fiberglass insulation, a vapour barrier, and an air gap which ranges between 114 mm and 216 mm throughout the

building (Dalkowski, 2024). 21 double glazed windows are located primarily in the office section of the building. The HVAC systems in the building include a single AHU that provides conditioning and ventilation and is complimented with auxiliary wall-mounted space heaters that meet additional heating demand that the AHU cannot meet on its own. The offices are conditioned with two centrally ducted AC units and electric baseboard heaters.

2.1.2 Building survey

A building survey was conducted to inspect the buildings condition and interview building occupants to better ascertain building operation, systems, setpoints, and occupancy trends. The survey was a critical step in verifying the information received from the building drawings and developing occupancy schedules for the energy model.

2.1.3 Energy modelling inputs

The previously mentioned wall composition was determined from investigations during site visits. Typical thermophysical values for conductivity, density, and specific heat for the relevant materials, were obtained from the ASHRAE handbook of fundamentals (The American Society of Heating, Refrigerating, and Air-Conditioning Engineers, 2021). This process was repeated for the concrete slab floor and roof. Because the slab floor and roof composition were not known, typical constructions were assumed for those assemblies. Additionally, as outlined by Amiri et al., thermal imaging and in-situ heat flux sensors were used to estimate the RSI of the walls using a spatial averaging method (Amiri et al., 2022). The insulation thickness of the walls was then modified in the model to match the calculated RSI obtained from the spatially averaged method. Table 1 below shows the RSI values of each envelope component.

Table 1. RSI value of envelope components

Envelope component	RSI ($m^2 \cdot K/W$)	Method
177 mm Wall	1.30	Thermal imaging and in-situ sensors
330 mm Wall	2.35	Thermal imaging and in-situ sensors
Ground Floor	1.78	ASHRAE area weighted method
Roof	2.82	ASHRAE area weighted method

The community centre hosts groups such as summer camps, badminton players, daycares, and staff. The IBCC is also known to host large events with a capacity of 450 people. Based off interviews with occupants, occupancy schedules were developed for the staff, daycare, and badminton players. Typical occupant, lighting, and equipment heat gains were obtained from the 2021 ASHRAE handbook. A blower door test was completed to determine the airtightness of the building and the results of the test showed that the building has an air change rate of 3.27 ACH50 with a unit leakage area of 2.3 cm^2/m^2. The Sherman Grimsrud infiltration model – an empirically derived method that accounts for wind speed and temperature difference – was used in the TRNSYS energy model. However, during the discussion with the occupants, it was revealed that the occupants commonly open doors or windows to allow for increased natural ventilation during both the summer and winter months to avoid overheating. Finally, ideal heating and cooling was added to the energy model with set points of 21°C and 23°C based off site visit information.

2.1.4 Energy model calibration

To improve the accuracy of the model, measured data was used to calibrate the model following

the ASHRAE 14 guideline (The American Society of Heating, Refrigerating, and Air-Conditioning Engineers, 2014). Real time sub metered data for the building heating systems was monitored and recorded. This included the power consumption of the AHU, as well as the electric resistance heaters in the gym and offices. The measured cooling data was derived via a regression analysis that used the relationship between recorded outdoor temperature and power consumption obtained from the monthly utility bills. As per the guideline, two metrics were used for calibrating the heating and cooling loads of the IBCC. The net mean bias error (NMBE) and the coefficient of the variation of the root mean square error (CVRMSE). To meet the calibration standards the NMBE and CVRMSE between the simulated and measured data was required to be less than 5% and 15% respectively.

The calibration procedure was to run the simulation, check if the calibration requirements were satisfied, and if not, adjust the calibration parameters. This iteration was continued until the calibration threshold was achieved. Calibration parameters were chosen based off their uncertainty and impact on energy use. These included the natural ventilation rate and the number of occupants in the building. The natural ventilation rate was included due to the previously mentioned unpredictability of the occupants opening and closing windows and doors, whereas the occupant number was chosen based off the uncertainty associated with the occupant schedule. The monthly adjustments made to each calibration parameter is summarized in Table 2. The simulated heating and cooling demand of the calibrated model is compared to the measured data on Fig. 2. The calibration procedure yielded a NMBE of -4% and 15% for heating load and a CVRMSE of 4% and 14% for cooling load.

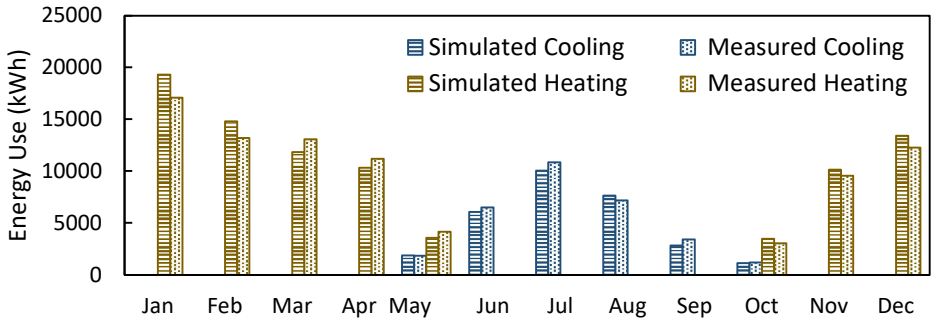


Figure 2. Comparison of simulated and measured heating and cooling energy use of calibrated model.

2.2 Post retrofit energy model

The proposed exterior panels that are to be installed over the existing envelope consist of an additional layer of mineral wool batt insulation, as well as an air and moisture resistive barrier. The addition of these highly insulated exterior panels will result in an improvement in the thermal insulation of the building. The new overall thermal resistance values for the envelope components are listed in Table 3. A THERM model was created to estimate the overall post retrofit RSI of the wall assemblies (Amiri et al., 2022). The post retrofit RSI of the roof was estimated based off the proposed roof assembly. Finally, since airtightness of the building after the panelized retrofit is unknown, the post retrofit airtightness was assumed to be the same as the pre-retrofit scenario as measured by the blower door test.

Table 2. Calibration parameter adjustments

Month	Pre-Calibration Occupancy	Post-Calibration Occupancy	Post-Calibration Infiltration Adjustments
January	65 building occupants	110 building occupants	No changes
February	65 building occupants	110 building occupants	No changes
March	65 building occupants	65 building occupants	No changes
April	65 building occupants	65 building occupants	+150% infiltration in whole building
May	65 building occupants	65 building occupants	+200% infiltration in gym, front office, and side office zones
June	65 building occupants	110 building occupants	No changes
July	118 building occupants	163 building occupants	No changes
August	118 building occupants	143 building occupants	No changes
September	65 building occupants	65 building occupants	+100% infiltration in gym zone
October	65 building occupants	90 building occupants	No changes
November	65 building occupants	90 building occupants	No changes
December	65 building occupants	90 building occupants	No changes

Table 3. Post retrofit parameters

Parameter	Value	Method
177mm Wall post retrofit RSI	4.95 m^2·K/W	THERM model
330mm Wall post retrofit RSI	5.35 m^2·K/W	THERM model
Roof post retrofit RSI	13.2 m2·K/W	ASHRAE area weighted method

2.1 Weather files

To assess the vulnerability of the IBCC before and after the panelized retrofit, six Montreal weather files were used with the TRNSYS energy model to investigate the behaviour of the building under different climate scenarios. Future climate weather files developed by Gaur and Lacasse were used for the purpose of this study (Gaur & Lacasse, 2022). These scenarios included typical meteorological year (TMY) weather files that represent an increase of 1.5 °C, 2.5 °C, and 3.5 °C in global temperatures. An extreme warm year (EWY) for the 3.5 °C scenario was also included in the analysis. A historical TMY file representing the years 1991 – 2021 and the actual meteorological year (AMY) weather file used for the model calibration was also included. The AMY file is referred to as the 'baseline' scenario hereafter. The TMY future climate weather files were created from climate simulations from a group of Canadian Regional Climate Models by dynamically downscaling Canadian Earth System model large ensemble simulations. The six weather files were run in both pre and post retrofit scenarios for a total of twelve simulations.

3. RESULTS

Thermal energy consumption and thermal comfort were both analyzed in each simulation scenario to investigate how the behaviour of the building changed both before and after the panelized retrofit, and in different future climate scenarios. The metric that was used to quantify thermal comfort is the predicted mean vote (PMV). Developed by P.O. Fanger, PMV is a measure of a humans thermal comfort that takes into account their metabolic rate (met), clothing insulation (clo), air speed, and ambient conditions (Fanger, 1988). The PMV is a scale that ranges from -3 to +3. -3 indicates that the occupant is cold, whereas +3 indicates that the occupant is hot. A value of 0 indicates the occupant is thermally comfortable. ASHRAE 55 recommends a PMV between -0.5 and 0.5, although these recommendations vary depending on

the standard. In the TRNSYS energy model, occupants were assumed to have a 0.61 clo and 1.1 met to match the typical values of an office occupant as listed in ASHRAE standard 55. The airspeed was set to a typical value for office zones of 0.1 *m/s*. The PMV TRNSYS output was measured from the 'conference room' zone as this zone had multiple windows, and is adjacent to outdoor conditions, conditioned, and non-conditioned zones.

3.1 Thermal Energy Consumption

Fig. 3 shows the TRNSYS simulation results for the thermal energy consumption for all climate scenarios before and after the proposed panelized retrofit. In both retrofit scenarios, as the global warming scenarios intensify, the heating load decreases, and the cooling load increases. This is consistent with many studies on the effect of a warming climate on thermal energy consumption in cold climates (Chidiac et al., 2022), (Li et al., 2012). As key climate parameters such as temperature increase due to climate change, traditionally heating dominated cities like Montreal will see less heating and more cooling demand required. Since panelized retrofits typically yield the greatest energy savings in heating, the projected reduction in heating demand under future climate scenarios may diminish the panelized retrofits overall energy-saving potential. This is apparent when comparing the percent reduction in total thermal energy use due to the retrofit for different climate scenarios. The total thermal energy savings from the retrofit is 29.9% for the historical climate scenario compared to only 22.6% for the 3.5 °C EWY scenario, yielding a 7.3% drop in estimated energy savings. This loss in energy savings equates to roughly 13,170 kWh.

3.2 Thermal comfort

The thermal comfort measured in PMV was simulated for an occupant in the conference room zone. Annual simulations were conducted for each climate scenario before and after the panelized retrofit. A heat map is shown in Fig. 4 which displays a visualization of the average PMV at any given hour of the day in all simulations. Blue, green, and red indicate low, neutral, and high PMV values respectively. The retrofit measure in the historical scenario results in an additional 1418 hours of acceptable comfort hours (-0.5 < PMV < 0.5), whereas the retrofit in the 3.5 °C EWY scenario decreases the number of comfortable hours in the year by 7 hours.

4. DISCUSSION

Panelized retrofits are a promising emerging retrofit solution that can reduce energy consumption of existing buildings. However, as global temperatures continue to rise, it is important to study how buildings that have undergone these panelized retrofits will behave in future climate scenarios. While panelized retrofits result in reduced thermal energy demand, the total thermal energy savings are diminished as global warming scenarios intensify due to a lower overall heating demand. However, significant reductions in energy were still achieved in the worst climate scenario simulated. Simulated PMV values indicate that after the panelized retrofit, the building occupants are more vulnerable to feeling the effects of extreme weather compared to occupants in the pre-retrofit building. These findings suggest that buildings that undergo panelized retrofits must be equipped with sufficient, low-energy, cooling and ventilation systems that can satisfy increased energy and comfort demand due to climate change induced warming. These findings also suggest that the lifetime energy savings from these retrofits should account for the variability of future climate scenarios and extreme weather events.

5. CONCLUSIONS

This paper studied how a panelized retrofit would affect the heating, cooling, and thermal comfort of the building occupants in a community centre during future climate scenarios. A building in Montreal was modelled and calibrated in TRNSYS and a set of simulations were run using future climate and historical weather files to investigate how different climate scenarios impact the behaviour of the building. It was found that energy savings from a panelized retrofit could have diminishing returns as the building becomes less heating dominated due to climate change. The PMV, which represents the thermal comfort of the occupants also risks increasing past the comfort threshold during extreme heat wave events. Future research should further explore this avenue by testing more extreme future climate scenarios and testing various levels of insulation on the post-retrofit model to further understand the behaviour of these retrofitted buildings in the context of future climate scenarios. Additional research could also compare the results of these simulations with measured data upon the completion of the IBCC panelized retrofit.

SUMMARY
The built environment plays a major role in global energy consumption and carbon emissions, with Building Automation and Control Systems (BACS) offering significant potential for improving energy efficiency. These systems include the control of HVAC, lighting, and shading, yet reliable data on their energy-saving potential remains scarce. Standard EN 52120-1 provides generic BACS efficiency factors but overlooks building-specific factors affecting performance. This study uses EnergyPlus simulations to assess energy savings across 1,944 variants of an case study office building, incorporating stochastic occupancy behavior. Results show that the BAC-factor method fails to accurately estimate heating and cooling savings, as it ignores building characteristics. Heating savings of around 20% to 30% were observed for individual room thermostats with time setback, and up to 40% for occupancy setback. Cooling savings were up to 20% in buildings with high initial cooling demand but were less significant in those with lower initial consumption.

Keywords: BACS, BEPS, Emission control

1. INTRODUCTION

The operation of buildings is accountable for 30% of the global final energy consumption which empathizes the need for an increased retrofitting rate (Delmastro et al., 2023). Beyond conventional measures, i.e. lowering thermal transmittance of envelope constructions or increasing the efficiency of technical installations, novel polices, notably the European Energy performance of Buildings Directive (EPBD), also include provisions on BACS (European Commission, 2024).

BACS are an asset for buildings to monito and automatically adjust energy using technologies (eu.bac, n.d.). EN 52120-1, part of the EPBD series of standards, divides the functionalities of BACS into heating, hot water, cooling, ventilation/air conditioning, lighting, blinds and technical home and building management (European Committee for Standardization, 2022). For each control domain, multiple functionalities are listed which are subdivided into automation functions and classes ranging from class D to class A. Class D represents non energy efficient BAC systems, class C standard BACS, class B advanced BACS and class A high-energy performance BACS. EN52120-1 provides saving factors for space heating and cooling ($f_{BAC,H}$ & $f_{BAC,C}$), domestic hot water generation ($f_{BAC,DHW}$) and electric energy for ventilation, lighting and auxiliary devices ($f_{BAC,el}$). These factors allow to easily assess the energy performance of BACS implementation compared to the reference scenario.

Table 1: BAC-factors for office buildings from EN52120-1

	Class D	Class C	Class B	Class A
Thermal	1.51	1	0.80	0.70
Electric	1.10	1	0.93	0.87
$f_{BAC,H}$	1.44	1	0.79	0.70
$f_{BAC,C}$	1.57	1	0.80	0.57
$f_{BAC,DHW}$	1.11	1	0.90	0.80
$f_{BAC,,el,L}$	1.10	1	0.85	0.72
$f_{BAC,,el,aux}$	1.15	1	0.86	0.72

These factors enable facility managers, building owners, and portfolio managers to easily evaluate the potential of integrating (advanced) BACS. However, as these factors have originally been derived from single-zone simulations without accounting for additional boundary conditions, they represent only a rough estimate which might not be applicable to all buildings and contexts. This study will explore emission control strategies for heating and cooling into a case study office building.

2. METHODOLOGY

The case study analysed in this paper is a single floor office, part of a mixed-use building. The floor is showed in figure 1 below, the boundary condition of the roof is adiabatic, as are the two sidewalls. The floor area of this case study is 382.5 m², of which 81.4 m² is a corridor, 85.1 m² are auxiliary rooms, 99.0 m² is assigned to meeting rooms and 117.0 m² are office spaces. The heating and cooling demand is met using an 'ideal load air system' with unlimited heat and cold supply capacity, ensuring that the heating and cooling requirements corresponding to different automation functions are precisely satisfied.

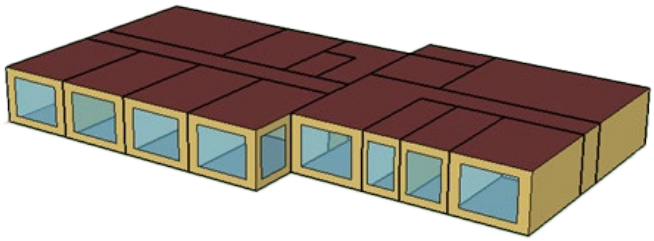

Figure 1: Geometry of the case study typology

A fixed occupancy schedule is used throughout the variations, generated by the LBNL stochastic occupancy generator (Chen et al., 2018). In the office zones, an occupancy assumption of 10 m² per person is applied in the office spaces, resulting in a maximum of 10 occupants in this case study building. The figure below illustrates occupancy on the first three days.

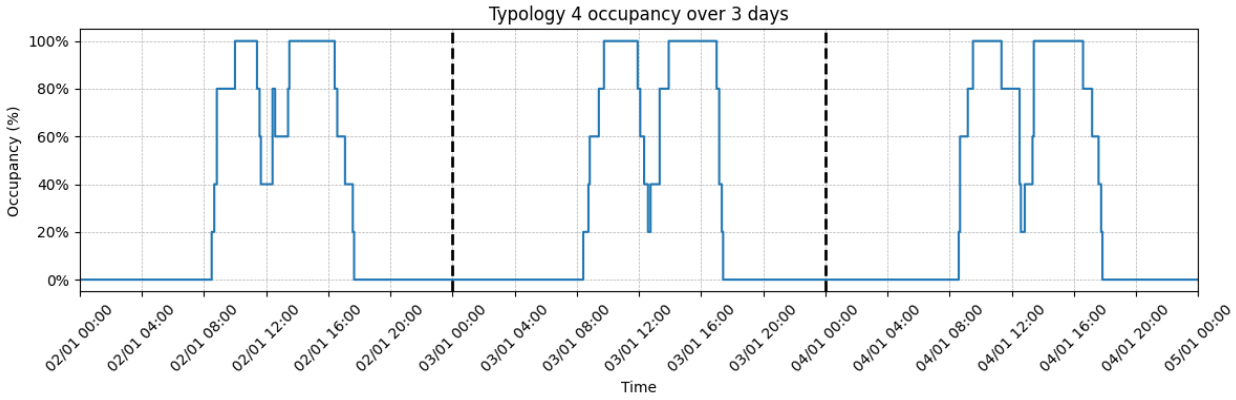

Figure 2: Extract of the occupancy profile generated with the LBNL occupancy simulator.

EnergyPlus[1] is utilized as the simulation engine to evaluate energy consumption in a case study building under various BACS functions. The study explores variations in the window-to-wall ratio (WWR), envelope characteristics (U-values and infiltration rates), and equipment and lighting power.

- Window-to-wall ratio: variations of 20%, 50%, and 80% are considered.
- Envelope characteristics: three categories are evaluated: pre-EPB (1970s properties), EPB-compliant (2006 standards), and passive house standards (Flemish Energy Decree: Annex VII, 2006; Gevorgian et al., 2021; Hines, 2015). The following table summarizes the corresponding U-values and infiltration rates:

Table 2: Thermal characteristics for the different envelope scenarios

	Pre-EPB	**EPB (2006)**	**Passive**
U-Value floor & roof	2.2 W/m².K	0.4 W/m².K	0.1 W/m².K
U-Value wall	1.75 W/m².K	0.6 W/m².K	0.1 W/m².K
U-Value window	4.2 W/m².K	1.6 W/m².K	0.8 W/m².K
Infiltration rate	0.00027 m³/s.m²	0.00013 m³/s.m²	0.08 ACH

- Equipment and lighting power: high-power scenarios are based on the lighting power density outlined in ASHRAE 90.1-2022 (ASHRAE, 2022). Low-power scenarios use half this value. Additionally, equipment power settings are defined as 5.83 W/m² for 100% desktop use and 3.67 W/m² for laptop use with docking stations, assuming 15.5 m²/person (ASHRAE, 2021).

The functionalities assessed include emission control for heating and cooling, shading control, ventilation flow control, and lighting control. In combination with the boundary condition variations, this results in 1,944 unique simulation scenarios. This paper specifically examines the emission control strategies for heating and cooling as in function 1.1 and 3.1 as described in EN52120-1. Three control scenarios are analysed:

[1] https://energyplus.net/

Table 3: details of the thermostat control scenarios in this research

Control strategy	Controlled zones	Heating activation	Cooling activation	Comments
Central thermostat (Class D)	Single zone (kitchenette, central control)	Below 20.5°C (in central zone)	Above 24.5°C (in central zone)	Heating Setpoint: 22°C Cooling Setpoint: 23°C (hysteresis buffer between 21°C and 24°C in central zone)
Individual room thermostat with time setback (Class B)	Individual room control (except corridor & auxiliary rooms)	7AM–5PM: 21°C 5PM–7AM: 16°C Weekends: 16°C	7AM–5PM: 24°C 5PM–7AM: 28°C Weekends: 28°C	
Individual room thermostat with occupancy setback (Class A)	Individual room control (except corridor & auxiliary rooms)	Occupied: 21°C Unoccupied: 18°C Weekends: 16°C	Occupied: 24°C Unoccupied: 26°C Weekends: 28°C	

Infiltration rates are based on BLAST values, producing a rate of x1 for a ΔT (inside-outside) of 0 °C and wind speed of 3.35 m/s (Gowri et al., 2009). The ventilation flow rate is set to 22 m^3/h per person for occupied rooms and 1.3 $m^3/h \cdot m^2$ for restrooms, in line with Flemish design requirements for non-residential buildings (European Committee for Standardization, 2004).

The weather data used in this study is derived from a typical meteorological year (TMY) for Uccle, (Brussels, Belgium). Manual control of lighting, shading, and windows is modeled using established occupancy behavior models, specifically those developed by Reinhart and Haldi & Robinson. These models predict user interactions based on various environmental conditions.

- Lighting control follows Reinhart's model, where switching behaviour is influenced by workplane illuminance and occupancy events, such as arrival, intermediate presence, and departure (Reinhart, 2004).
- Window operation is modelled using Haldi & Robinson's approach, where opening and closing probabilities depend on indoor and outdoor temperatures, with additional influence from rain in certain cases (Haldi & Robinson, 2009).
- Shading control is based on a combination of Reinhart and Haldi & Robinson, where shading adjustments are triggered by outdoor temperature and occupant presence (Haldi & Robinson, 2008; Reinhart, 2004).

3. RESULTS

First of all, the savings of individual room thermostat control with time setback and occupancy setback are compared to a central thermostat. The graph below shows the consumption of both scenarios in $kWh/y.m^2$ and the scale factors. The data is categorized by envelope characteristic and ventilation automation type as these parameters seem to have the greatest influence on the initial heating consumption and savings.

Figure 3a

Figure 3b

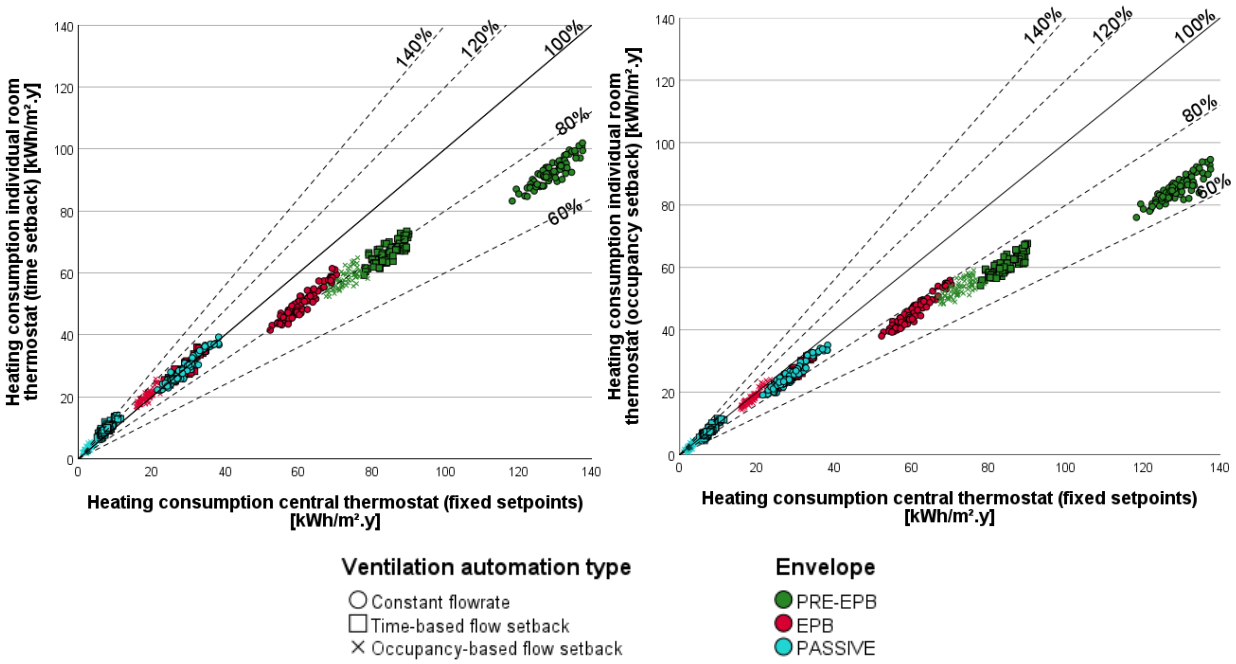

Figure 3: (a) heating consumption of a central thermostat compared to individual room control with time setback. (b) heating consumption of a central thermostat compared to individual room control with occupancy setback.

The results indicate that initial heating energy consumption, categorized by thermal transmission of the envelope and ventilation automation strategies, significantly impacts the achievable energy savings. In buildings with minimal heating demand, i.e. those with passive envelopes and advanced ventilation control, individual room control with temperature setbacks has a negligible effect in absolute terms.

On average, buildings with pre-EPB envelope characteristics achieve energy savings of 22.8%, whereas buildings with EPB-compliant envelopes exhibit a significantly lower savings potential of only 2.8%. The results further reveal a clear trend in savings relative to initial consumption: cases with heating demands exceeding 100 kWh/m²·y achieve savings of approximately 30%, while cases with initial consumption between 50 and 100 kWh/m²·y show savings around 20%. In contrast, buildings with an initial consumption below 50 kWh/m²·y exhibit negligible savings, fluctuating around 0%.

The time based and occupancy based temperature setback also affect the cooling demand. The cooling consumption data is categorized according to envelope characteristics and window-to-wall ratio.

Figure 4a

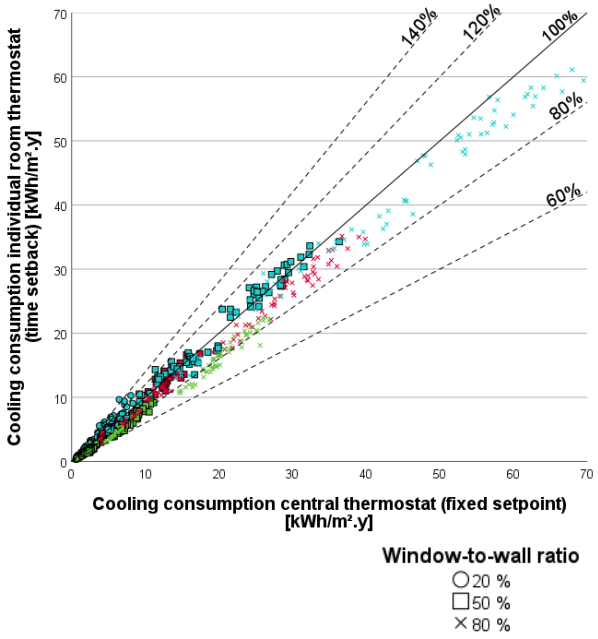

Figure 4b

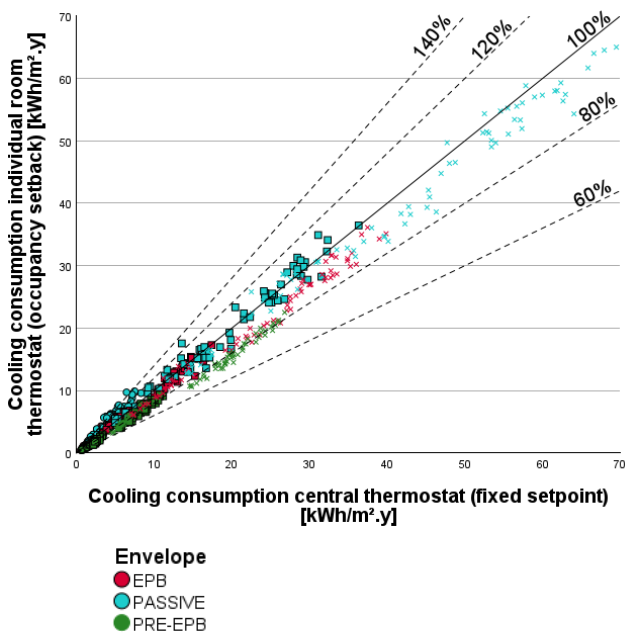

Figure 4: (a) cooling consumption of a central thermostat compared to individual room control with time setback. (b) cooling consumption of a central thermostat compared to individual room control with occupancy setback.

It is evident that buildings with a high WWR exhibit higher initial cooling loads. In these cases, the implementation of a time-based temperature setback generally results in energy savings between 0% and 20%. Buildings with a pre-EPB envelope, despite having relatively low initial cooling consumption, achieve relative savings of up to 40%. In contrast, cases with passive envelopes and a WWR of 20% or 50% are predominantly positioned around the 100% scaling factor, indicating negligible energy savings. A similar trend is observed when comparing a central thermostat with individual room control incorporating occupancy-based temperature setback; however, in this case, most scenarios demonstrate positive energy savings. In the case of heating consumption, the cases with the highest initial consumption could achieve high savings by thermostat controls, i.e., between 20% and 40%. This effect is less pronounced for cooling energy, where cases with the highest cooling demand demonstrate a savings potential of only 0% to 20%.

4. DISCUSSION

A direct comparison between the case study results and the BAC factors from the EN 52120-1 standard cannot be made in its entirety, as this paper focuses solely on functions 1.1 and 3.1 described in EN 52120-1 , which pertain specifically to 'emission control' for heating and cooling systems. The standard presents various functions within each domain to evaluate BACS performance. To be able to compare with the BAC-factor for, e.g., heating control, other functions to consider are control of hot water temperature, control of pumps, hydronic balancing, intermittent control of emission and/or distribution and heat generator control.

Therefore, it is a logic result that the savings obtained in this research is less profound than what

the BAC-factor estimates, as shown in table 3 below. Though these scaling factors provide generalized energy saving estimates but do not take into account variations in specific building characteristics, i.e. the building envelope, HVAC-system configuration, efficiency of lighting and appliances, or occupant behavior. As this research shows the impact of these various parameters on the results, the BAC-factors are limited in only providing a single scaling factor.

Table 4: The BAC-factors for yearly heating and cooling energy consumption savings.

	Class D	**Class B**	**Class A**
$\mathbf{f_{BAC,H}}$	1.44	0.79	0.70
Heating energy savings compared to non-energy efficiency BACS (class D) [%]	0.0%	45.1%	51.4%
$\mathbf{f_{BAC,C}}$	1.57	0.80	0.57
Heating energy savings compared to non-energy efficiency BACS (class D) [%]	0.0%	49.0%	63.7%

In cases with low heating or cooling demand, the scaling factors from the BAC guidelines may be particularly confusing. This is because the absolute energy savings are minimal, and even small variations in building characteristics, occupancy patterns, or control strategies can lead to relatively large relative changes. In such cases, the BAC factors may suggest a more significant impact than what is realistically achievable, given the low absolute baseline consumption.

It is noteworthy that the BAC factors suggest higher cooling energy savings than heating energy savings, with figures up to 63.7% for cooling, compared to 51.4% for heating. In contrast, the results from this study indicate a reversed trend, with higher savings observed in heating energy consumption than in cooling.

This research only focuses on 1 specific case study typology, a small office building with only 5 office spaces and 2 meeting rooms. As the geometry, amount of offices and meeting rooms and office space types (private office or open-plan office) could affect the saving potential, it is an important parameter to vary in further research endeavours. In addition, other parameters could affect the saving potential, e.g. climate, HVAC-configuration (no ideal heating or cooling conditions as in this research), occupancy patterns and thermal mass. A detailed statistical analysis can reveal which parameters have major influence on the saving potential and should be taken into account into assessment methodologies.

5. CONCLUSION

This study evaluated the impact of different emission control strategies for heating and cooling in a case study office building, comparing a central thermostat (Class D), individual room thermostats with time-based setback (Class B), and occupancy-based setback control (Class A). The extent of savings is highly dependent on various building characteristics, i.e. envelope characteristics, ventilation strategies, and window-to-wall ratio. Although the results of this research could not be directly compared to the BAC-factors of EN 52120-1, it is clear that variating building characteristics have an effect on the saving potential which is disregarded in the single number BAC-factors.

The case study of a single-floor office building demonstrates that individual room thermostat control with time or occupancy-based setbacks can lead to notable energy savings, particularly in buildings with high initial heating demands. However, the savings are less pronounced in buildings with low heating or cooling demands, highlighting the limitations of generalized BAC factors. The study also reveals that while BAC factors suggest higher cooling energy savings, the actual results indicate greater savings in heating energy consumption.

Future research should consider varying building geometries, HVAC configurations, occupancy patterns, and climates to better understand the potential energy savings of BACS. A detailed statistical analysis could identify the most influential parameters, leading to more accurate assessment methodologies.

SUMMARY
Daylighting is an effective and sustainable development strategy to alleviate problems in energy and the environment. It is also useful for enhancing visual comfort and health. Climate-based daylight metrics (CBDMs) have recently been adopted for providing additional information by considering the hours of real situations and actual weather conditions for a given location. Thus, the use of CBDMs offers a substantial functional account of true daylighting environments for a building in a certain location. However, CBDMs are typically determined in full-scale computer simulations using sophisticated software, which are laborious and require technical skills. Traditionally, daylight factor (DF) only represents the daylight condition under the overcast sky. Until recently, DF calculations have been extended for all sky conditions. It means that the daylight factor-based metric (DFBM) can also be another dynamic metric and it can take into account the building directions, solar positions and the effects of direct and reflected sunlight. Indoor daylight illuminance is the product of a (DFM) and a horizontal sky-diffuse component, which means that the absolute indoor daylight illuminance can be predicted from the DFMs. This paper reviews the existing daylight metrics and proposes further studies to correlate CBDMs and DFMs for buildings facing various directions. The findings and recommendations could be useful for architects and practitioners involved in architectural and daylighting design and evaluations. It will also significantly contribute to the educational landscape by enriching the curriculum for students.

Keywords: Daylight performance, climate daylight factor metrics, visual comfort

1. INSTRUCTIONS

Daylighting is recognized as a useful sustainable strategy, green building development (Kwong, 2020), visual comfort enhancement (Xue et al., 2014) and energy-efficient building designs (Mavromatidis et al., 2014). Natural lighting is an essential aspect that requires examination in depth during the early stages of building designs (Freewan, 2015; Petersen et al., 2014). Various rules of thumb and design metrics are commonly used by architects and architectural engineers for predicting and assessing daylighting capability.

Recently, climate-based daylight metrics (CBDMs) have gained traction as valuable tools for assessing diverse daylight conditions over the course of a year. These metrics specifically focus on the actual working hours and prevailing weather conditions of a specific location, enabling a comprehensive evaluation of authentic daylighting environments.

Daylight factor metrics (DFMs) have been adopted in assessing the indoor daylighting designs.

Due to its simplicity, DF can be determined by simple equations, tables or calculation steps, which is particularly useful in the early design stage. This paper reviews the strengths and weaknesses of DFMs and CBDMs and proposes appropriate schemes to link up these two essential metrics for architectural and daylighting designs and evaluations.

2. DAYLIGHT METRICS

In general, the DFMs include point daylight factor (PDF), average daylight factor (ADF) and vertical daylight factor (VDF). The CBDMs contain daylight autonomy (DA), continuous daylight autonomy (cDA), spatial daylight autonomy (sDA), annual sunlight exposure (ASE) and useful daylight illuminance (UDI). The major characteristics, strengths and limitations are elaborated as follows.

2.1. Daylight factor metrics

The PDF is the ratio of illuminance due to daylight at a point without direct sunlight on an indoor working plane to the simultaneous outdoor illuminance on a horizontal surface (E_{HD}) from an unobstructed hemisphere of the International Commission on Illumination (CIE) overcast sky. The PDF can be used to predict the reduction in electrical lighting achievable from the use of daylighting controls (Mattoni et al., 2018). An ADF indicates the visual adequacy for an interior area rather than any specific point within the area (Longmore, 1975). As an ADF directly relates to window openings and requires input data less detailed than those required by the PDF, the ADF is useful in developing building envelope schemes during a preliminary design phase (Lynes & Littlefair, 1990). The VDF accounts for light from the sky and daylight reflected from the surrounding buildings and ground onto a vertical plane and is applied to compact city regions with vast external obstructions.

DFM has been employed by different design manuals for providing criteria which are widely adopted in many places (Hraska, 2011). In Norway, for example, a DF of 2% is taken as the criterion in sizing windows in architectural design practice (Moscoso et al., 2020). In Iran, the ratio of the window area to floor area is taken as the criterion in assessing the DF (Vaisi & Kharvari, 2019). In 2018, European standard EN17037 (Daylight in Building) was established and its criteria were expressed as DFs (European Committee for (Standardization, 2018). In Hong Kong, VDFs are used to quantify the daylighting performance of buildings (Buildings & Department, 2015). Currently, ADFs, VDFs and PDFs remain in use for daylighting schemes.

However, DFMs, despite their valuable contributions, exhibit limited adaptability in accurately forecasting variations in daylight conditions caused by the sun's movement during non-overcast periods. It can lead to overglazed buildings under clear sky conditions (Mardaljevic et al., 2009). Therefore, although high values of DFMs indicate well-daylit spaces with low demands for artificial lighting, DFMs cannot be used to identify spaces of visual discomfort, such as daylight glare.

2.2. Climate based daylight metrics

CBDMs have been developed and adopted to assess the daylighting performance on annual and seasonal bases. CBDMs mainly contain DA, cDA, sDA, ASE and UDI. The DA is the percentage of daylight hours on an annual basis during which the daylight illuminance at a given interior point

(E_{DL}) exceeds a specified minimum illuminance (E_{SMI}). It can be used to predict artificial-lighting energy savings under standard daylighting controls. Mathematically, it can be expressed as Eq. (1) (Carlucci et al., 2015):

$$DA = \frac{\sum_i (wf_i \times t_i)}{\sum_i t_i} \in [0,1] \quad (1)$$
$$with\ wf_i = \begin{cases} 1\ if\ E_{DL} \geq E_{SMI} \\ 0\ if\ E_{DL} < E_{SMI} \end{cases}$$

where t_i is every occupied hour in a year; wf_i is a weighting factor depending on values of E_{DL} and E_{SMI}.

The cDA is a modification of the DA that awards partial credit for daylight levels below a user-defined threshold in a linear fraction as shown in Eq. (2) (Carlucci et al., 2015). It is useful for computing the energy savings for top-up or multi-level on–off controls.

$$cDA = \frac{\sum_i (wf_i \times t_i)}{\sum_i t_i} \in [0,1] \quad (2)$$
$$with\ wf_i = \begin{cases} 1\ if\ E_{DL} \geq E_{SMI} \\ \dfrac{E_{DL}}{E_{SMI}}\ if\ E_{DL} < E_{SMI} \end{cases}$$

The sDA expresses the percentage of floor area that exceeds a given illuminance level (e.g., 300 lux) for a norm percentage (e.g., 75%) of the annual occupied daily hours (e.g., 8 am to 6 pm) of a space. The Illuminating Engineering Society guidelines recommend the use of two different sDAs: (1) the preferred daylight sufficiency, which is when at least 75% of an analysis area meets the standards, and (2) the nominally accepted daylight sufficiency, which is when 55% of an analysis area meets the standards (IES, 2012). The ASE is the sum of sunlight (≥1000 lux) incident on a given point over the course of a year (recorded in lux hours) and indicates the fraction of a space that is exposed to too much glare-generating direct sunlight. A credit offered by the Leadership in Energy and Environmental Design (LEED) rating system (USGBC, 2018) requires that the ASE not be exceeded for more than 250 hours a year for more than 10% of a space.

The UDI indicates the daylight levels that are useful for an occupant and is described by a set of three metrics for every point in a space, namely the percentage of times that a point is below the minimum threshold (<100 lux), within the useful range (100–2000 lux), and above the maximum threshold (>2000 lux). Eq. (3) presents its formulation (Carlucci et al., 2015):

$$UDI = \frac{\sum_i (wf_i \times t_i)}{\sum_i t_i} \in [0,1] \quad (3)$$
$$with\ wf_i = \begin{cases} 1\ if\ E_{Ut} \geq E_{DL} \geq E_{Lt} \\ 0\ if\ E_{Ut} > E_{DL}\ or\ E_{Lt} < E_{DL} \end{cases}$$

The lower threshold (E_{Lt}) is useful for determining the perception of the visual environment whereas the upper threshold (E_{Ut}) indicates the times when there is a daylight oversupply that may cause glare.

CBDMs reflect real daytime conditions and are determined using weather databases for a given location, which means that they represent actual daylight surroundings and are appropriate for determining luminous comfort, daylight glare and settings for daylighting controls. In order to achieve results that closely resemble real-life daylight conditions, the appropriate approach is to employ lighting simulations (Navvab, 2014). However, conducting a comprehensive hour-by-hour computer simulation for an entire year is a time-consuming and costly, as it involves modelling the building's geometry over an extended simulation period and extensive input and post-processing procedures. The LEED rating system recommends three options for daylighting based on CBDMs (USGBC, 2018). Option 1 is to determine sDA and the annual ASE using calculation cells of not more than 600 mm. However, the application of such cells in an hourly time-step parametric analysis using typical weather-year data and a sophisticated simulation package would take an enormous amount of time. In addition, CBDMs are simulated using representative annual daylight data, which may not be readily obtainable for many locations or may not reflect current daylighting criteria and situations at a location (Li et al., 2017). In recent years, there has been a development of user-friendly design tools that aim to simplify the complex process of designing buildings. These tools, including simplified geometry maps, regression equations, and charts, have been created through extensive examinations utilizing advanced simulation techniques (Kleindienst et al., 2008; Petersen et al., 2014; Šprah & Košir, 2019). They are intended to be utilized during the initial planning phase of a project, providing architects, engineers, and students with fundamental and concise insights into the interconnectedness of various daylight parameters. Once a preliminary design has been established, more detailed information is sought through full-scale building simulations. Previous studies have attempted to establish links between DA and sDA metrics with DFs (Acosta et al., 2019; Asfour, 2020). However, no straightforward formulas have been recommended. Lo Verso et al. (Lo Verso et al., 2017) have developed mathematical models that estimate various daylight autonomy and energy demands for lighting during the early stages of building design. However, these models require a substantial number of input variables, such as architectural features, leading to the generation of complex mathematical expressions and associated uncertainties.

3. WORKS FOR AMELIORATING DAYLIGHT METRICS

In view of the features of CBDMs and DFMs, it is necessary to take advantage of the merits of DFMs to overcome the shortcomings of the approaches usually adopted to determine CBDMs. The determination of the absolute daylight illuminance at various reference points, simulations could be conducted, and DFMs could be calculated by dividing the modelled daylight illuminance by the corresponding E_{HD} under CIE Sky 1 condition (CIE, 2003; Kittler et al., 1998). The VDFs could be calculated at the centre point of the window, while the PDFs could be represented by the values of individual interior grid points. The ADF could be determined as the mean value of the PDFs across all grid points. By simulating the year-round indoor daylight illuminance, the DA and UDI could be obtained. Since DFMs remain constant regardless of solar position and orientation under overcast-sky conditions, their correlation with UDI and DA values should reflect their correlation with CIE Sky 1. Consequently, the required DFMs would only need to be simulated once for a specific E_{HD}, resulting in significantly reduced simulation time. Furthermore, all data could be generated using the same simulation programs and techniques. Alternatively, DFMs under Sky 1 can also be calculated from room parameter inputs using simple formulas, diagrams, or calculation aids (Hopkinson et al., 1966). Figures 1 to 3 display the correlations between

CBDMs and DFMs for rooms located in Hong Kong facing different cardinal orientations (Li et al., 2023). As shown in the figures, the CBDMs and DFMs are strongly correlated.

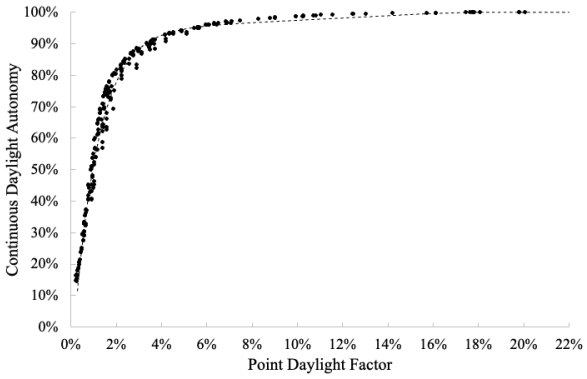

Figure 1. Example of figure.

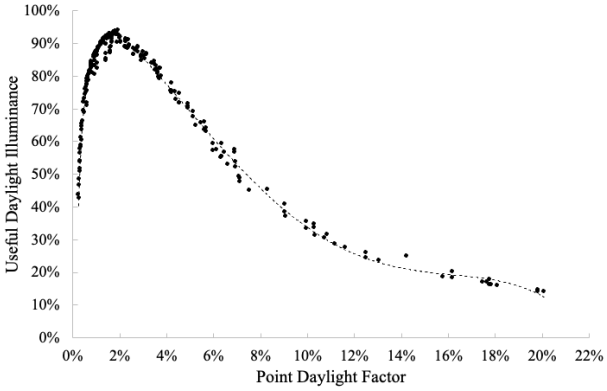

Figure 2. Correlation between PDF and UDI facing south.

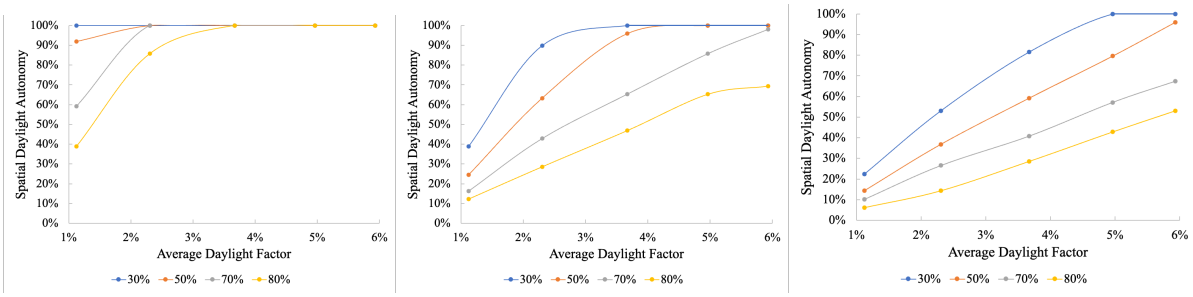

(a) 100 lux (b) 300 lux (c) 500 lux

Figure 3. Correlation between ADF and sDA facing south with three illuminance thresholds (a) 100 lux; (b) 300 lux; (c) 500 lux.

It has been reported that the CIE Overcast Sky offers the best performance among many models applied worldwide for various climates under overcast conditions (Enarun & Littlefair, 1995; Li et al., 2001). The outdoor illuminance of a particular location is mainly determined by the solar position and local sky conditions. Sensitivity analyses should be applied to all inputs to account for the fact that various locations have different sky-diffuse and direct sunlight datasets. Importantly, as the proposed method using DFMs under CIE Sky 1 could afford suitable architectural and daylighting designs based on inputs from ADFs, it would be possible to accurately predict CBDMs for a given location. Contrarily, individual room parameters in a simple general CBDMs mathematical model may not be mutually exclusive (Lo Verso et al., 2017). To enhance the generalisability and representative, places of miscellaneous latitudes containing typical weather files with diffuse and direct sunlight data should be dealt with. Reference should be made to guidebooks and research publications in adopting the usual ranges of these parameters.

Shading devices such as overhangs, side-fins and recessed windows should be studied for topmost floor of high-rise blocks facing unobstructed skies. The VDFs for various overhang projection factors, side-fins projection factors, and recessed window depths would be simulated and

correlated with the scattering angle (χ), which is the shortest distance between the sun and the sky element that the window is facing normally, under the 15 CIE standard skies (15 CIESS). The corresponding ADFs and PDFs would be computed for subsequent analysis. This would allow building and daylighting design implications to be investigated and clarified. Shading by surrounding buildings can substantially decrease light coming from the sky into a building interior, particularly into rooms on the lower floors of a building. In contrast, under obstructed skies, the externally reflected component (ERC) of daylight can be relatively large. The magnitude of the ERC is dependent on how well surrounding buildings' surfaces are illuminated and on these surfaces' reflectance. The layout affecting the ERC in terms of the upper obstruction angle of a target window (α_U), the lower obstruction angle of the window (α_L) and the obstruction angle of the reference building (α_B) should be described. Figure 4 presents such angles. The correlations between DFMs could also aid multi-point internal daylight illuminance measurements as proposed by the LEED rating system Option 3 (USGBC, 2018), as they will allow the minimum number of illuminance meters to be reduced. Daylight illuminance is the product of DF and the horizontal sky-diffuse component, and the total daylight illuminance in a room is the sum of sky-diffuse illuminance and the direct sunlight, if any. Accordingly, the DFMs obtained, and the simple equations devised by Tregenza (Tregenza, 1995) could be used to compute direct sunlight and thereby determine interior daylight. This will constitute a non-simulation approach to calculating the absolute daylight illuminance, thereby allowing CBDMs to be obtained from DFMs.

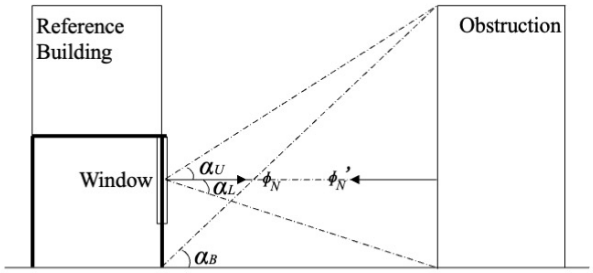

Figure 4. The angles for the centre point of the whole vertical window.

4. CONCLUSIONS

A review of DFMs and CBDMs in terms of their characteristics, advantages and drawbacks was conducted. The findings indicated that CBDMs could be linked with DFMs to eliminate their shortcomings and reinforce their strengths. Through the mathematical models, CBDMs could properly be estimated from DFMs of appropriate room parameters which are simple and fast calculation tools, attaining appropriate architectural and daylighting designs. It would be particularly useful for meeting the LEED Option-1. The strong correlations between PDF, VDF and ADF show that interior daylight illuminance can be calculated once the corresponding horizontal sky-diffuse illuminance and sky conditions have been determined. As direct sunlight can also be computed based on simple solar geometry, this will constitute a non-simulation method of calculating the absolute daylight illuminance, thereby allowing CBDMs to be obtained from DFMs. Such a study would also be advantageous to the actual measurement in LEED Option -3. For representative annual daylight data, it has been proposed to use 15 CIE Standard Skies and the three Representative Skies. It would be more appropriate for places without measured outdoor illuminance records for conducting daylight simulation in LEED Option-2. Visual comfort

variables such as glare and uniformity are important to daylighting design and evaluation and thus to establishing criteria for CBDMs. It is suggested that correlations between CBDMs and visual comfort factors should be made. To have a comprehensive daylighting design, building energy issues in terms of daylight-linked lighting controls are required. Further open- and closed-loops for daylighting switching and dimming controls using DA, cDA, VDF and PDF should be investigated. Besides having academic merit, the findings will have practical value in terms of developing architectural and daylighting schemes that are useful in the early design stage when various conceptual building façade plans are being considered. The tools developed will be of interest to local and overseas researchers and building professionals and particularly appropriate to novice students.

ACKNOWLEDGEMENTS

Work described was fully supported by a Faculty Development Scheme from the Research Grant Council of HKSAR [Project no. UGC/FDS16/E07/23] and Research Matching Grant Scheme from the Research Grant Council of HKSAR [Ref. no. 2021/3006]. The late Prof. Danny Li passed away during the conduct of research project. SUMMARY
Enhancing clean air systems to achieve improved indoor air quality and environmental sustainability is crucial. The COVID-19 pandemic has underscored the importance of portable air cleaners (PACs) and broadened the scope of clean air classification by integrating indoor and outdoor sources with purification technologies. This study examines particulate matter from 0.001 μm to 10 μm across three common clean air systems: mechanical ventilation and PACs. Natural ventilation was also included for comparison. A theoretical framework, validated by literature and experiments, alongside computational fluid dynamics, was developed to analyze the benefits and risks. Results indicated that over 70% of purification benefits were due to air changes per hour, with evident variation in deposition across particle sizes, affected by different indoor airflow diffusion designs. Infiltration was dual, while differences in the coagulation term were negligible. Additionally, penetration, deposition, and coagulation variations were significantly affected by building types and occupant behaviors.

Keywords: Clean air, mechanical ventilation, portable air cleaners, particles.

1. INTRODUCTION

Clean air is increasingly recognized as a fundamental human right, with the UN General Assembly declaring access to a clean, healthy, and sustainable environment a universal right in 2022. While significant efforts focus on managing outdoor air quality, equal attention is needed for indoor air, as people spend most of their time indoors (Wargocki, 2021). Ventilation is key to ensuring clean indoor air, essential for human cognitive ability and well-being (Carrer et al., 2018). Outdoor air, often deemed "fresh," can be introduced indoors through natural ventilation (NV) or mechanical ventilation (MV), with MV systems playing a crucial role in modern buildings. Despite established air change rates (ACHs) in building codes, the actual effectiveness of MV in delivering clean air can also face challenges as increasing ventilation needs and heavy energy burdens appear. Sometimes, the quality of the incoming air can also introduce health risks (Riederer et al., 2021), underscoring the need for a greater focus on the quality of air supplied indoors.

Among the various methods for providing clean air, i.e., MV, NV, and purified indoor air by

portable air cleaners (PACs), each adopts distinct principles and relies on different sources. These differences can result in variations in indoor air pollutants (IAPs) and energy consumption. Although integrating different clean air systems is becoming increasingly common, most efforts focus on simple combinations rather than evaluating their collective cleaning efficiency and corresponding air change per hour (ACH) (Li et al., 2024). An investigation into optimizing the integration is crucial to improve indoor air quality (IAQ) while maintaining energy efficiency.

In this study, theoretical methods validated through experiments and literature were employed to compare the cleaning efficiencies of MV, NV, and PAC(s) concerning particulate matter (PM), which is a well-recognized IAP with significant health risks.

2. METHODS

Eq. (1) was established to quantify the differences between the composition of clean air provided by MV, NV, or PACs. The first term on the right side of the equation represents the cleaning efficiency, which is fixed once the cleaning air systems and their corresponding filter classifications are determined. The second term accounts for the penetration rate (P), calculated using the method described by Ref (Alvin C. K. Lai and Nazaroff, 2000). Deposition and coagulation terms can be estimated based on the corresponding rates (h^{-1}), as detailed in Eq. (2) (Lv and Zhao, 2022) and Eq. (3) (Jeong et al., 2021). Secondary organic aerosol (SOA) and source terms are associated with gaseous pollutants, such as ozone, and typical occupant activities. These are models using $S_{\mathrm{SOA}}(i,t)$, as shown in Eq. (4) (Weschler and Nazaroff, 2023)), and $S(i,t)$.

$$\frac{\mathrm{d}C_{\mathrm{in}}(d_{\mathrm{p}},t)}{\mathrm{d}t} = \sum_{j=1}^{3}\{[(1-\eta_{\mathrm{PM,out},j})\cdot C_{\mathrm{out}}(d_{\mathrm{p}},t) - \eta_{\mathrm{PM,in},j}\cdot C_{\mathrm{in}}(d_{\mathrm{p}},t)]\cdot n_j\} + n_{\mathrm{s}}\cdot(P_{\mathrm{PM}} \cdot C_{\mathrm{out}}(d_{\mathrm{p}},t) - C_{\mathrm{in}}(d_{\mathrm{p}},t)) - (k_{\mathrm{d}}+k_{\mathrm{c}})\cdot C_{\mathrm{in}}(d_{\mathrm{p}},t) + \frac{S_{\mathrm{SOA}}(d_{\mathrm{p}},t)+S(d_{\mathrm{p}},t)}{V} \quad (1)$$

$$k_{\mathrm{d}} = \frac{v_{\mathrm{d,v}}\cdot A_{\mathrm{v}} + v_{\mathrm{d,u}}\cdot A_{\mathrm{u}} + v_{\mathrm{d,b}}\cdot A_{\mathrm{b}}}{V} \quad (2)$$

$$k_{\mathrm{c}}(d_{\mathrm{p}},t) = \frac{1}{C_{\mathrm{in}}(d_{\mathrm{p}},t)}[\frac{1}{2}\cdot\int_0^{d_{\mathrm{p}}}[\beta(d_{\mathrm{p}}-\overline{d_{\mathrm{p}}},\overline{d_{\mathrm{p}}})\cdot C_{\mathrm{in}}(d_{\mathrm{p}}-\overline{d_{\mathrm{p}}},t)\cdot C_{\mathrm{in}}(\overline{d_{\mathrm{p}}},t)]\mathrm{d}\overline{d_{\mathrm{p}}} - C_{\mathrm{in}}(d_{\mathrm{p}},t) \cdot\int_0^{\infty}[\beta(\overline{d_{\mathrm{p}}},d_{\mathrm{p}})\cdot C_{\mathrm{in}}(\overline{d_{\mathrm{p}}},t)]\mathrm{d}\overline{d_{\mathrm{p}}}] \quad (3)$$

$$C_{\mathrm{SOA}} \approx \xi \times C_{\mathrm{O_3,loss}} = \xi\times(C_{\mathrm{O_3,out}} - C_{\mathrm{O_3,in}}) \quad (4)$$

where $C_{\mathrm{in}}(d_{\mathrm{p}},t)$ and $C_{\mathrm{out}}(d_{\mathrm{p}},t)$ are the indoor and outdoor concentrations (#/m^3 or μg/m^3); $\eta_{\mathrm{out},j}$ and $\eta_{\mathrm{in},j}$ are the cleaning efficiencies of the j-th type of clean air for the inflow and outflow of the room; n_j is the ACH of the j-th clean air (h^{-1}); and n_{s} is the infiltration rate (h^{-1}), varied by different systems.

Computational fluid dynamics (CFD) simulations were conducted using a standardized room to analyze various clean air systems further. The dimensions of the model were based on an actual test cabin, as shown in Fig. 1. The renormalization group (RNG) $\boldsymbol{k-\varepsilon}$ turbulence model was used to obtain the friction velocity. Dimensionless factors were introduced to quantify the benefits and risks associated with each parameter per ACH of clean air, as outlined in Table 1.

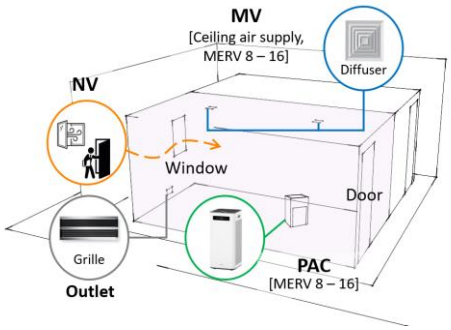

Figure 1. Schematic diagram of the room.

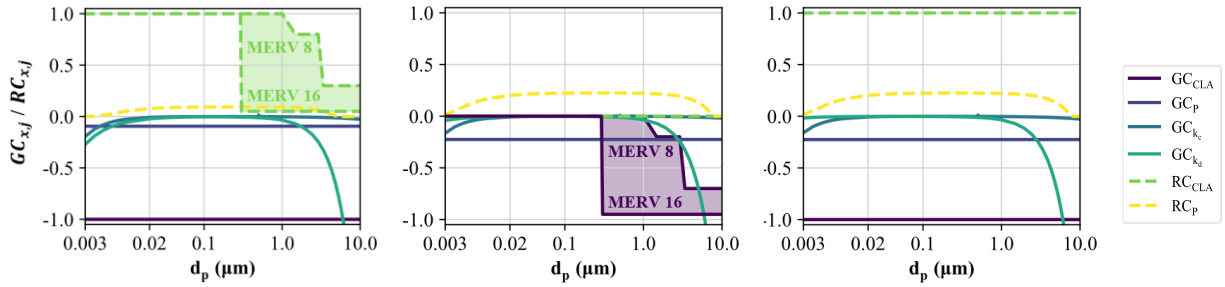
Table 1. Dimensionless factors

Terms	Gain Coefficient ($GC_{x,j}$)	Risk Coefficient ($RC_{x,j}$)
Clean air term	$-\eta_{\mathrm{PM,in},j}$	$(1-\eta_{\mathrm{PM,out},j})$
Penetration term	$-n_{\mathrm{s},j}/n_j$	$P_j \cdot n_{\mathrm{s},j}/n_j$
Deposition term	$k_{\mathrm{d},j}/n_j$	–
Coagulation term	$k_{\mathrm{c},j}/n_j$	–

3. RESULTS

3.1 Characterization of key factors in clean air systems

$GC_{x,j}$ and $RC_{x,j}$ across different bin sizes are shown in Fig. 2. Implementing equipped filters and improved classification systems significantly reduced the risks associated with outdoor air introduction. They enhanced the cleaning efficiency of PAC, which relied on internal recirculation. $RC_{P,MV}$ can be reduced by narrowing pressure differences, which may also diminish the dilution effects. The variation in $GC_{d,j}$ was evident across particle sizes and was affected by different air distributions. However, no significant differences were observed in $GC_{c,j}$.



(a) MV (b) PAC (c) NV

Figure 2. $GC_{x,j}$ and $RC_{x,j}$ for clean air systems.

3.2 Comparison of concentration variations

The removal quantities were compared based on the combination of $GC_{x,j}$, $RC_{x,j}$ and I/O ratios derived from Eq. (1), illustrated in Fig. 3. A consistent trend was observed across clean air systems despite key factors varying with particle size bins. Compared to other factors, the clean air term had the most significant impact on IAQ, contributing to 69% and 79% improvements for NV and MV on average, respectively. Although infiltration can be managed under MV, this often reduces dilution effects. Due to relatively high velocities within the room, the deposition term under MV also played a crucial role. Additionally, NV posed the highest introduction risks, whereas PAC presented the least risk, though its cleaning efficiency was limited by the filter classes used. Once the building scenarios (including occupant patterns and weather conditions) and clean air systems were established, the concentration patterns were similar across the systems.

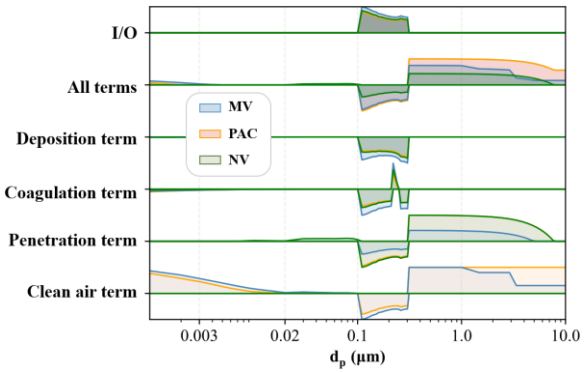


Figure 3. Variations in PM concentrations. (Positive values above the axis indicate beneficial effects).

4. CONCLUSIONS

This study employed a theoretical method to compare the cleaning efficiencies of MV, NV, and PAC concerning PM. Benefits and risk factors were evaluated, and the amounts of PM removed were calculated. The key conclusions are: 1) In the proposed model to quantify indoor air compositions, the clean air term was the most significant contributor to cleaning efficiencies, accounting for over 70% of MERV8 filters. However, the associated risks and benefits were closely linked to the classification of filters used, particularly for smaller particle size bins; 2) The performance of clean air systems was significantly affected by building types, outdoor environments, and occupant behaviors. Therefore, systems should be customized to the specific regional and building characteristics to optimize cleaning efficiency and energy consumption.

Flood resilience for Australian houses: The case for biomimetic wet-proofing to encourage building retention after flooding

Christopher Jensen [1], Jane Toner [2]

[1]*Melbourne School of Design, University of Melbourne, Melbourne, Australia, cjensen@unimelb.edu.au*

[2]*Griffith University, Brisbane, Australia, jane.toner@griffithuni.edu.au*

SUMMARY
Australian homes are increasingly vulnerable to flooding, often leading to demolition or costly repairs. Climate change is driving more frequent and severe flooding, and the impacts are compounded by poor land use planning and limited adoption of flood resilient construction practices. Despite the escalating risks, Australian building regulations are relatively simplistic and lag behind best practice for flood resilience. Biomimicry – the practice of emulating adaptive strategies from living systems – offers promising opportunities to enhance flood resilience in the built environment. By learning from nature's adaptations for managing water, biomimetic design can contribute to reducing the social, economic and environmental impacts of flooding in the built environment. This research investigates how biomimetic solutions could be integrated into the design, construction and operation of Australian residential construction to improve flood resilience within the constraints of the existing building code.

Keywords: flood, resilience, biomimicry, built environment, housing

1. INTRODUCTION

1.1 Flood Risk in Australia

Flood events are already causing significant damage across urban and regional areas of Australia (De Wilde, 2014), with climate models providing medium to high levels of confidence that climate change will further intensify extreme weather events (The Climate Council, 2017). In Australia, floods cause more damage on average than any other natural disaster. From 1967 to 1999, the total cost of floods is estimated at $10.4 billion or 29% of the average proportional annual cost of natural disasters. More recently in 2021 and 2022, flood events in Queensland and New South Wales caused $6.3 billion in damages making them Australia's most expensive natural disaster, much of which is due to unrecoverable building damage (Insurance Council of Australia, 2024). Between 2005 and 2022, the Australia government spent $24.5b on natural disasters, most of this ($23.99b) was for post disaster relief programs, while only $0.51b was for initiatives focused on building resilience (The McKell Institute, 2022). This reactive approach suggests a limited understanding of the opportunities available to reduce post-disaster relief costs by supporting resilient design. A recent report, 'Resilience, Durability in the National Construction Code (NCC)', highlights that the current Australian Building Codes Board (ABCB) flood standard " ...is designed to reflect the current NCC objectives of health, safety, amenity and sustainability, so it primarily focuses on structural safety and life safety, rather than building resilience" (The Centre for International Economics, 2023). This narrow focus overlooks the unsustainable impacts of post-flood building rectification, demolition and reconstruction.

1.2 Current Building Regulations in Australia

Flood mitigation in Australia typically focuses on urban-scale interventions. However, strategies at the building-scale, including material specifications are also critical for reducing flood damage. Flood resilience for new housing is currently addressed by two consecutive mechanisms (Victorian Building Authority, 2023). First, local planning provisions designate flood-prone zones developed in consultation with floodplain management authorities. Estimated flood heights are usually based on the 100-year average recurrence interval (ARI) derived from historical flood data. Second, the National Construction Code (NCC) specifies minimum floor heights and freeboard requirements for new construction. From an architectural perspective, compliance can be achieved by raising the habitable floor level above the minimum freeboard, as shown in Figure 1.

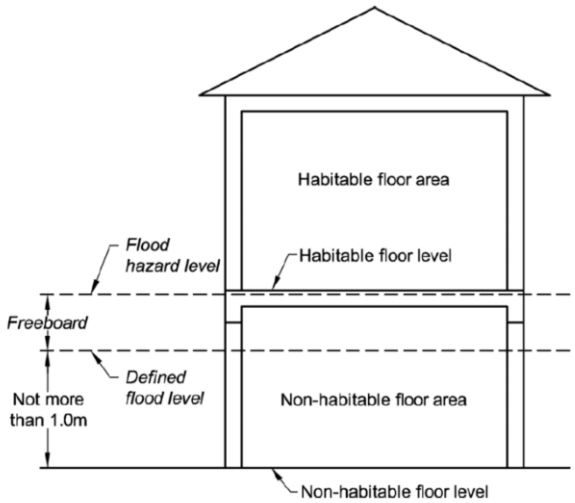

Figure 1: Current Australian building regulations define habitable floor levels based on historical flood data

This raises two key challenges: 1) current building regulations fail to address the increasing flood risks associated with climate change, and 2) they do not encourage or allow innovative alternative solutions. These limitations are compounded by standard construction practices in Australia, which rely on materials and methods poorly suited to flood resilience. Typical construction methods include concrete slab-on-ground floors, and materials vulnerable to water damage such as plasterboard, timber framing and low-lying electrical wiring. As a result, even minor flooding can lead to costly rectification works or demolition.

2. LITERATURE REVIEW

1.3 Existing Knowledge of Flood Resilience

Flood mitigation research has largely focused on ‘hard’ infrastructure solutions at the urban scale (Bignami et al., 2019), such as dykes and embankments in the Netherlands (Vis et al., 2003) and dams in Australia (Cook, 2023). More recently, attention has shifted towards exploring ‘soft’ green infrastructure alternatives, such as water sensitive urban design (DFAT AWP, 2022) and green roofs (Cook et al., 2019). China’s ‘sponge city’ concept, for example, is designed to detain and slow water flow by absorbing and storing rainwater, mitigating the effects of urban flooding, with a goal of enabling 80% of urban areas to harvest and reuse 70% of rainwater (Griffiths et al., 2020). While these strategies are proving effective at catchment scale, less attention has been given to improving flood resilience at property or building scale. Building scale mitigation strategies can be grouped in three categories: 1) elevation - raising buildings above a fixed flood level or by

allowing it to float, 2) dry-proofing to prevent water entry, and 3) wet-proofing - allowing controlled water entry while minimising damage through materials and design choices that optimise recoverability (Ameh et al., 2024). Each strategy presents design challenges for architects, including planning and site constraints, limited material options, and resistance to innovation within the construction industry.

From a design perspective, *elevation* above a defined flood level can be achieved with either a fixed elevated structural platform, or by allowing dynamic elevation (flotation) - a more complex solution. Elevation is the primary strategy for flood resilience defined in the National Construction Code (NCC) (ABCB, 2019), however, this creates limitations in design, such as maximum height limits to prevent overshadowing of neighbouring properties. The NCC currently has no provisions for floating structures, instead requiring footing systems to resist flotation or significant permanent movement. *Dry-proofing* involves sealing a building (or enclosures within it) to prevent water entry. Dry-proofing relies on resisting hydrostatic forces (the pressure from standing or slow-moving water) by sealing openings such as windows and doors; ensuring water-tight construction systems (especially at floor-to-wall junctions); applying waterproofing sealant to walls and floors to reduce seepage, and installing floor drains and sump pumps to manage residual water (USACE, 1995). However, typical Australian construction methods make dry-proofing hard to achieve, as the comprehensive sealing required often conflicts with other regulatory requirements, such as cavity ventilation and managing hydrostatic pressure. *Wet-proofing* offers a viable solution when flood is infrequent and of short duration (De Graaf et al., 2012). Key strategies include: installing flood openings to automatically equalize hydrostatic forces on exterior walls; anchoring buildings to resist flotation, collapse, and lateral movement; using water-resistant materials below the base flood elevation; and elevating mechanical and utility equipment or by configuring components to minimize damage (FEMA, 2022). While wet-proofing is widely used in flood prone regions globally, it is rarely adopted in Australian buildings.

1.4 Lessons from Nature

Guided by the overarching philosophy that ‘life creates conditions conducive to life’ (Benyus & Morrow, 1998), biomimicry is an innovative discipline that looks to the natural world for sustainable design solutions (Baumeister & Tocke, 2014). Biomimetic strategies are considered at three nested levels: organism, behaviour and ecosystem (Zari, 2018). Over deep time, nature has evolved materials, forms, processes and networked systems to meet complex dynamic challenges imposed by the environment, from macro to nanoscale (Bhushan, 2009). As living systems are dependent on water for survival, nature has adapted and evolved numerous functional strategies to manage it, such as harvesting, storing, distributing, absorbing and filtering. These natural strategies offer a wide range of innovative solutions that can be applied by biomimicry design thinking to address challenges in the built environment. In this paper, biomimicry is presented as a method for developing alternative solutions to enhance the flood resilience of buildings by emulating nature’s efficient and resilient strategies.

1.5 Knowledge Gap

Current building practices and regulations limit the adoption of alternate solutions for flood resilience in Australian housing. Biomimicry - innovation inspired by nature - offers significant potential to overcome these challenges, with a growing body of research and practical applications for responding to rising water levels at ecosystem scale. However, research on biomimetic

solutions specifically aimed at enhancing flood resilience at the building scale remains limited.

3. METHODOLOGY

This paper addresses the knowledge gap identified by exploring a biomimetic approach to translate nature's solutions for managing water into architectural design solutions. The aim is to apply biomimicry tools developed by Biomimicry 3.8, pioneers of the interdisciplinary process of translating nature's strategies into design principles for technological innovation (Vincent et al., 2006). 'Biomimicry Thinking' is an adaptive framework for integrating biomimicry into the design process across disciplines and scales (Biomimicry 3.8, 2015). The process is flexible, can begin at any stage, and iteration is encouraged to refine and optimise design solutions. In this study, the Biomimicry Thinking Challenge to Biology (Figure 2) is used to address the specific challenge of improving flood resilience in the built environment.

Figure 2: Biomimicry DesignLens. At left, Biomimicry Thinking - Challenge to Biology. At right, Life's Principles (2015 Biomimicry 3.8 CC-BY-NC-ND)

'Life's Principles' are overarching patterns that all living systems follows to survive and thrive (Biomimicry 3.8, 2015). They serve both as a guide and evaluation tool within the design process, encouraging alignment with living systems (Ilieva et al., 2022). For example, "cultivating cooperative relationships", encourages designers to adopt practices that encourage mutually beneficial relationships, much like those found in flourishing ecosystems (Stevens et al., 2022). Applying Life's Principles as evaluation criteria can reveal limitations in current practices and identify opportunities for more sustainable outcomes. For instance, the principle of 'recycling all materials', challenges the widespread use of building materials that end up in landfill after flood damage, indicating the need for new, regenerative material systems. This research applies the four main stages of the Biomimicry Thinking - Challenge to Biology process as outlined in Table 1.

Table 1: Biomimicry Thinking process and how it has been addressed at each design stage

Design Stage and Steps	**How this has been addressed**	**Structure of this research**
SCOPING: Define context. Identify functions needed to 'solve the challenge'.	Literature review established context and identified relevant functions	Literature review
DISCOVERING: Discover natural models (forms, processes, systems) that embody required functions. Abstract design principles from strategies.	Conducted 'biological brainstorm' to identify natural models addressing required functions. Generated abstracted design principles.	Results (See Table 2)

CREATING: Develop bio-inspired ideas from design principles. Design solutions that integrate abstracted design principles.	Explored human solutions like those identified in nature to identify gaps and opportunities for further research.	Discussion
EVALUATING: Apply Life's Principles to assess solutions and identify where they can be refined.	To be addressed in future research.	Future research

4. RESULTS

In the *Discovering* stage, a 'biological brainstorm' was conducted to identify organisms, processes and systems in nature that demonstrate effective flood resilience strategies. This involved reviewing relevant literature, consulting the AskNature database, and drawing on our own experience. The results are summarized in Table 2 under the three categories of flood resilient design: avoiding flood, dry-proofing and wet-proofing - with each functional strategy framed as a question for nature, such as, "How does nature anchor structures in water?"

Table 2: Biomimetic flood resilience strategies identified in the literature

Functional strategy	**Biological Inspiration (ref)**	**Abstracted design principles (biological references removed from description)**	**Similar Human Design Solution/s**
Avoiding Flood water			
Physically Avoid	Wombats (Triggs, 2009)	Leave accommodation during flooding and return when waters recede.	Behavioral - Occupants leave house
Physically avoid / Anchor	Mangrove dwelling ants (Nielsen, 1997)	Elevate critical openings above anticipated flood levels. Incorporate self-sealing and air-trapping mechanisms to adapt to flooding.	Elevate floor levels. Adaptive sealing systems.
Divert flow	Ground squirrels (Shuker, 2001)	Use raised circular barriers around openings to divert water away and prevent water ingress.	Hard structures (dykes). Make-shift structures (sandbags)
Anchor / Float	Peatland Plants (Rydin et al., 2013)	Platforms with adjustable buoyancy, interconnected anchoring systems that allow vertical movement while remaining in place	Amphibious Architecture
Dry-proofing			
Prevent water penetration	Platypus & Sea Otter fur	Dual layer, high-density, textured materials that combine water repellency with air-trapping insulation.	Closed cell foam insulation
Repel water	Lotus effect (Nature's Raincoats, 2025)	Micro- and nano-scale textures enhance water resistance of surfaces and promote self-cleaning.	Super-Hydrophobic, self-cleaning materials (Hsu & Sigmund, 2010)
Wet-proofing			
Anchor	Mangroves (Méndez-Alonzo et al., 2015)	Flexible interconnected structural elements and anchoring systems within permeable barriers to stabilise structures and moderate water flow.	Flexible anchors. Sediment traps that mitigate coastal erosion.
Prevent fungus / bacteria	Plasterer Bees (Ask Nature, 2025)	Apply bio-inspired, water tolerant surface coatings that inhibit microbial growth using life-friendly chemistry.	Bio-plastics. Water resistant wall assemblies.
Protect from microbes / fouling	Long-finned Pilot Whale (Baum et al., 2002)	Use textured, enzyme active surfaces to reduce bio-fouling and maintain surface performance during prolonged water exposure.	Anti bio-fouling surfaces

This rapid bio-brainstorm reveals a range of strategies nature has evolved to manage water inundation. While these strategies have been grouped as flood resilient design responses, in

practice nature rarely relies on a single approach. Instead, organisms combine multiple strategies depending on context, creating redundancy and enhancing resilience. For example, some species elevate themselves and use water-resistant materials. This suggests that buildings may achieve greater adaptive resilience by integrating a combination of flood-resilient strategies.

5. DISCUSSION - FLOOD RESILIENCE STRATEGIES

At the behavioural level, animals relocate to higher ground during floods (elevation), a strategy also used by humans. However, like plants buildings are 'rooted in place' and must rely on structural solutions. Fixed elevation above flood levels using structural supports is a relatively straightforward concept that forms the primary strategy prescribed by Australian regulations. Plants such as mangroves and floodplain trees offer inspiration for lightweight, flexible, and adaptive anchored structures responsive to the dynamics of floodwaters. Another elevation strategy is flotation, achieved through internal air spaces that provide buoyancy, such as the air-filled structures of waterlily pads. In the built environment, this is reflected in the concept of amphibious architecture – floating buildings designed to respond dynamically to fluctuating flood levels (Ameh et al., 2024). While a promising solution, amphibious architecture has practical challenges, including planning restrictions, structural complexity and cost barriers.

In nature, adaptability is more common than total exclusion (dry-proofing), yet some organisms have evolved highly effective strategies to remain dry through surface design and material properties. Notable examples include the superhydrophobic 'lotus effect' and the water shedding properties of cicada wings – both achieved by nano-scale surface architecture. While these principles have informed the development of water repellent coatings, at this time their application to buildings remains limited, particularly at the scale and durability required for flood resilience. Biomimetic waterproof sealants, inspired by organisms such as mussels and sandcastle worms, offer promising solutions for dry-proofing by enabling strong durable adhesion in wet conditions where conventional materials might fail. Dry-proofing a building requires comprehensive sealing of all potential water entry points, such as doors, structural vents and air ventilation openings, similar to how a boat is treated. In Australia, achieving this level of dry-proofing is challenging with typical construction techniques and would require a complete rethink of the building design and construction methods. Avoiding flooding by employing ecosystem level strategies such as levies and dykes, and water sensitive urban design are more practical dry-proofing solutions to protect buildings, neighbourhoods and cities at risk from elevated water levels.

Wet-proofing tolerates occasional inundation while minimising damage, emulating how natural ecosystem adapt to periodic inundation flooding. This strategy deliberately allows water to flow through a building, reducing structural stress. For example, passive flood vents could be designed to activate in response to rising water levels, similar to how pinecones open and close using passive material movements that respond to moisture. Australian regulations restrict the use of wet-proofing to non-habitable spaces, significantly limiting its application and creating dependence on other strategies. Many plants adapt to flooding by layering hydrophobic materials to protect their core from water – a principle that could inform the specification of flood tolerant finishes and materials for habitable areas. True hydrophobic materials are rare, but some common building materials, like masonry, can absorb and release water without lasting damage. Crucially, it is not just individual materials but complete construction systems that must withstand flooding without causing long-term damage or mould growth. Vulnerable elements, such as electrical systems will

still require elevation or dry-proofing in small areas. While elevation and dry-proofing strategies are found in nature, natural systems often utilise wet-proofing to accommodate temporary flooding. For buildings, this is a valuable insight, as immoveable structures will inevitably experience water ingress during flood events.

6. CONCLUSIONS

In line with climate change projections, Australian houses are increasingly vulnerable to flooding, which now causes more damage than any other disaster. At the building scale, current Australian building regulations remain simplistic and limit the adoption of innovative flood resilience solutions. Nature offers inspiring strategies to inform biomimetic solutions for flooding. Among these, plant-inspired strategies offer valuable insights for buildings, which like plants are fixed in place during floods. Strategies such as anchored flotation, structural resistance to hydrostatic forces, and the use of hydrophobic materials suggest how buildings might better withstand temporary inundation and recovery without lasting damage. These approaches remain under-utilized in Australian housing due to regulatory barriers. However, modest adaptations of the regulations such as permitting wet-proofing in habitable spaces, specifying water-resistant materials, incorporating openings to manage water flow, and elevating services, could enable the practical application of these biomimetic strategies and encourage further innovation. Further research is needed to explore international examples of wet-proofing and to test their suitability for the Australian context.

SUMMARY
As the impacts of climate change become more evident, maintaining healthy indoor air quality (IAQ) and preventing overheating are becoming increasingly critical. Canadian buildings, traditionally designed to retain heat, now face challenges due to more frequent and intense heatwaves. Older social housing stock, in particular, lacks adequate IAQ monitoring and management with insufficient data on indoor conditions. This study examines indoor conditions in selected social housing units in Western Canada. Using Internet of Things (IoT) sensors, we monitored IAQ in 20 social housing dwellings. Findings indicate a tendency for these units to overheat, often exceeding comfort thresholds, even with moderate outdoor temperatures. It was shown that sole reliance on weather observations and forecasts can misclassify indoor overheating and its effects. To address this, an automated predictive model was developed to forecast indoor temperatures 24 hours in advance, acting as an early warning system for building managers to efficiently respond to potential overheating events.

Keywords: Indoor overheating, social housing, mitigation strategy, predictive modeling

1. INTRODUCTION

Overheating and prolonged periods of hot weather can have a significant impact on increasing mortality and morbidity. Studies have demonstrated a significant increase in mortality due to heat stress in various Canadian cities (Jandaghian and Akbari 2018, Boudreault *et al.* 2024). Occupants of social housing dwellings are among the most vulnerable to extreme heat (Morey *et al.* 2020). However, there has been limited research on these buildings within the Canadian context. (Laouadi *et al.* 2023) developed an approach that combines the building simulation and bioheat models to generate health-based limit criteria for overheating in long-term care homes. They calibrated their building simulation models using indoor temperature and humidity measurements, allowing the method to predict overheating risks consistent with overall thermal comfort during extreme heat events, in contrast to the comfort-based methods. (Wang et al. 2020) conducted a series of field measurements and simulation studies to assess the overheating risks in vulnerable buildings in Montreal, Canada.

Despite the limited research on social houses, several studies have shown that the impacts of heatwaves in Canada are profound and far-reaching and they are linked to excess mortality and illness caused by elevated indoor temperatures (Khan et al. 2024). Therefore, it is crucial to better understand the indoor conditions in the vulnerable Canadian built environment. Understanding how indoor conditions vary during heatwaves is essential for mitigating the potential impacts of overheating on occupants' wellbeing. Regardless of the overheating mitigation strategy, advanced warning of impending indoor heat exposure risks is critical to minimize future heat-related health risks (Gustin et al. 2020). An early warning of high indoor temperatures can help ensure that healthcare staff and resources are fully prepared for hot weather periods that might impact health. This is particularly relevant for large portfolios of social housing, where prioritizing resources is essential during heatwaves. Therefore, the main focus of this work is to examine the variability of indoor heat exposure in selected vulnerable buildings located in Western Canada and develop an indoor temperature forecasting platform to mitigate the effects of indoor overheating on social housing occupants.

2. METHODOLOGY

2.1. DATASET

We measured indoor conditions in 20 dwellings across three different buildings, all serving as social housing and constructed around the 1970s. Unlike newly built social housing units, these older buildings have demonstrated vulnerability to recent extreme heat events in Western Canada and therefore, were selected for this study. The details of the monitored buildings and dwellings are provided in Table 1. The data collection began in June 2024 and contained until September 15, 2024. All monitored dwellings are studio units, consisting of a single living area used both during the day and at night. None of the units are equipped with a mechanical cooling system. We installed sensors at the thermostat height in locations shielded from direct solar radiation. These sensors recorded indoor temperature and relative humidity at 30-minute intervals. Data was transferred via LoRaWAN technology, to allow for near real-time uploads to a central cloud database. Additionally, hourly weather forecast data was retrieved from the nearest weather station using the Environment and Climate Change Canada (Government of Canada 2024) portal.

Table 1. Characteristics of the monitored buildings

Building	Number of dwellings in building	Monitored dwellings floor	Orientation
A	4	2	North-South
B	8	2 and 5	East-West
C	8	2 and 7	East-West

2.2. INDOOR OVERHEATING ASSESSMENT CRITERIA

The critical review by (Rahif et al. 2021) analyzed the overheating evaluation methods for residential buildings and examined five European national building codes. They found that most standards recommend static comfort models for air-conditioned buildings and adaptive comfort models for non-air-conditioned ones. In Canada, there is a growing focus on addressing indoor overheating in both national and provincial building codes. Notably, the British Columbia Building Code recently introduced a new provision to minimizing the risks to health and safety due to overheating in dwelling units (BC Government 2024). This provision advises that each dwelling unit should have a living space capable of maintaining an indoor design temperature of no more than 26°C. Although more comprehensive overheating criteria can provide valuable insights into the effects of indoor conditions on the occupants, in this work, we adopted the British Columbia Building Code's overheating provision. While this provision is primarily recommended for newly constructed dwellings, it is formulated to mitigate the dangers of indoor overheating and, therefore, may be employed to evaluate heat exposure risks in existing buildings. Comparing indoor conditions in existing buildings against this provision offers insights into the performance of the current social housing units and helps identifying required retrofit measures to achieve the recommended safe indoor conditions. Furthermore, using this criterion ensures the results are comparable to other studies and can be easily reproduced.

3. RESULTS AND DISCUSSION

3.1. INDOOR CONDITIONS VARIATION WITH BUILDING CHARACTERISTICS

The investigated dwellings in each building are located on different floor levels with various orientations (see Table 1), but are equal in size, floor plan and window to wall ratio. Consequently, this section focuses on analyzing the building characteristics related to floor level and orientation.

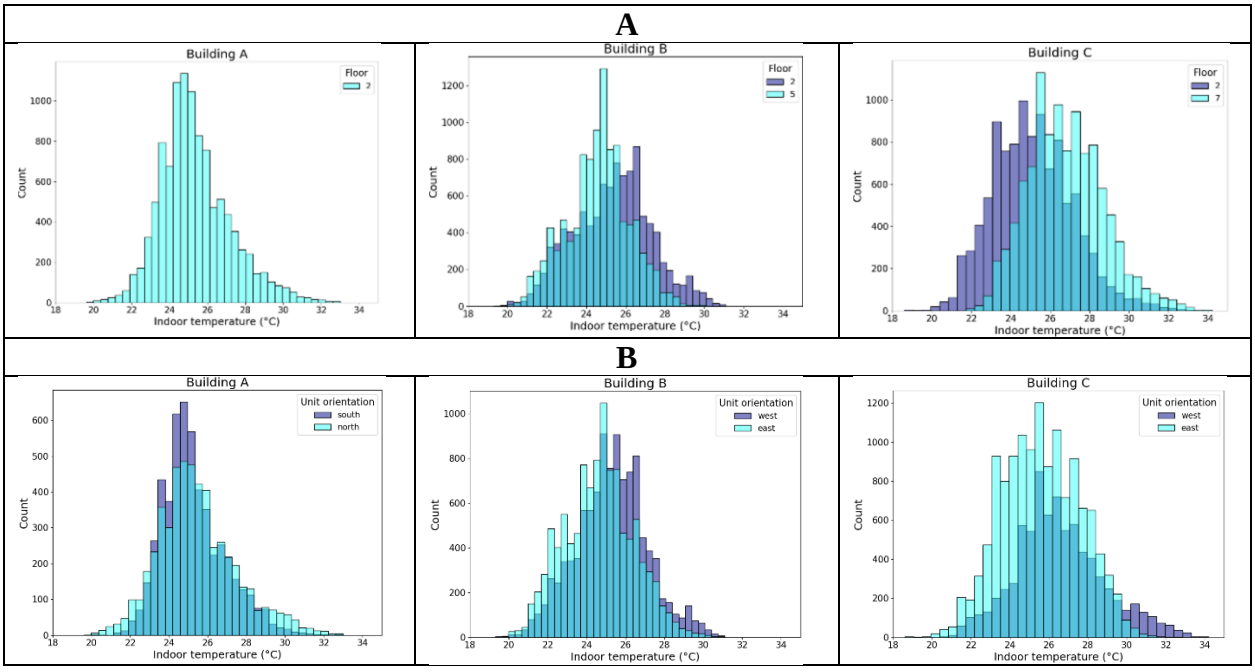

Figure 1. Distribution of hourly indoor temperature measurements with floor level

We aim to investigate whether a basic characteristic, such as orientation, can help pre-determine potentially more vulnerable dwellings within a building. Figure 1A shows the distribution of the indoor temperature for dwellings on different floor levels. The indoor temperatures on the upper floor tend to be higher in Building C, however, this pattern is not observed in Building B. As shown in Figure 1B, west-facing dwellings in Buildings B and C experienced a higher indoor temperature, likely due to increased solar gain in west facing dwellings. In contrast, Building A showed no significant difference in indoor temperatures between north- and south-facing dwellings. Overall, basic dwelling characteristics, such as the floor level or orientation, influence indoor temperature inconsistently. Similar patterns were reported by (Walikewitz *et al.* 2018), suggesting that indoor temperatures are strongly affected by other factors, such as occupant behaviour and outdoor conditions.

3.2. INDOOR TEMPERATURE VARIATION WITH OUTDOOR CONDITIONS

Heat exposure of a population is often estimated using outdoor temperature values. In this section, we examine whether outdoor conditions can reliably indicate the risk of indoor overheating in buildings housing vulnerable occupants. In Canada, humidex rating is used to inform the public about uncomfortable heat and humidity conditions (CCOHS 2024).

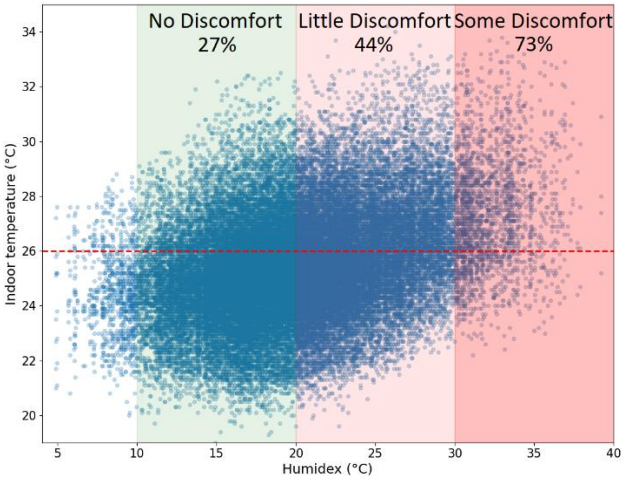

Figure 2. Variation of indoor temperature with outdoor humidex values. Outdoor humidex range descriptions used by Environment Canada are shown. In contrast, percentage values show the fraction of hourly indoor temperatures above 26^{o}C in each range.

Humidex combines temperature and humidity, measured at weather stations, to reflect the perceived temperature. Figure 2 shows the variation in measured indoor temperatures across all dwellings relative to outdoor humidex values. The humidex threshold values are sourced from (CCOHS 2024), and the 26^{o}C indoor temperature threshold from BC Building Code is also displayed. Although, as expected, there is a correlation between indoor and outdoor humidex values, elevated indoor temperatures (i.e., above 26°C) can frequently happen even when outdoor conditions are classified as “no discomfort” or “little discomfort”. This finding underscores the limitations of using outdoor conditions alone to assess the risk of indoor overheating. To better

understand indoor conditions in the studied dwellings, Figure 3 shows the percentage of time during which the indoor temperature exceeded the maximum temperature limit recommended by the BC Building Code. This figure highlights significance discrepancies between dwelling units, even within the same building. As Figure 1 suggests, this variance may primarily be attributed to occupants' behavior and unmeasured mitigation strategies, such as using blinds or opening windows.

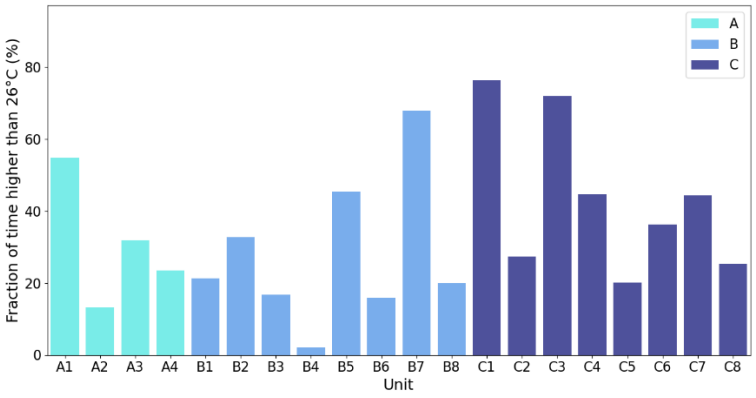

Figure 3. Fraction of time with indoor temperature higher than 26°C for each dwelling

Furthermore, the high indoor temperatures may occur even during relatively mild outdoor conditions, as shown in Figure 2. This emphasizes the need for both short-term and long-term mitigation strategies that prioritize indoor conditions rather than relying solely on weather forecasts.

4. INDOOR TEMPERATURE FORECASTING

An early warning of high indoor temperatures, powered by a forecasting model, may serve as a short-term mitigation strategy. It can help ensure that healthcare staff and resources are prepared for hot weather periods. The development of dwelling-specific forecasting models offers an opportunity to tailor results to the behavioural patterns and vulnerability of the occupants. A practical real-time forecasting framework should leverage low-cost sensors, easily obtainable exogenous data and automated predictive procedures, while generating reasonably accurate results.

4.1. MODEL PARAMETERS

In this work, we used battery-operated IoT sensors to minimize the intrusiveness of the system. All dwelling sensors in a building were connected to a single gateway, which utilized a cellular connection to transfer the measured data to a cloud platform in near real-time. Our ultimate objective is to extend the forecasting framework to a large portfolio of social housing settings. Due to cost constraints, onsite measurement of outdoor conditions is not feasible. Instead, we obtained

hourly temperature and humidity forecasts from Environment Canada (Government of Canada 2024). Solar radiation and wind speed forecasts are not reported at many weather stations. Although these are available from other sources, using the minimum amount of exogenous data can help to cost-effectively scale up the framework across geographically dispersed buildings portfolios. Therefore, we explored the possibility of developing the forecast models using only one exogenous datapoint, namely outdoor temperature obtained from the nearest weather station.

Prediction errors typically increase as the forecasting horizon lengthens. However, a longer forecast horizon is advantageous as it allows for better planning for forecasted indoor heat exposure events. After consulting with the portfolio managers, we determined that a 24-hour forecast horizon may provide a trade-off between maintaining reasonable accuracy and ensuring adequate response time to potential indoor overheating risk.

For large-scale implementation, the models should be designed to be both building- and dwelling-agnostic, incorporating an automated, near-optimal model selection procedure for each dwelling. To this end, we used a sliding window autoregressive model with exogenous parameters, varying lags and training lengths. The procedure for near-optimal model selection and the associated parameters are presented in Figure 4.

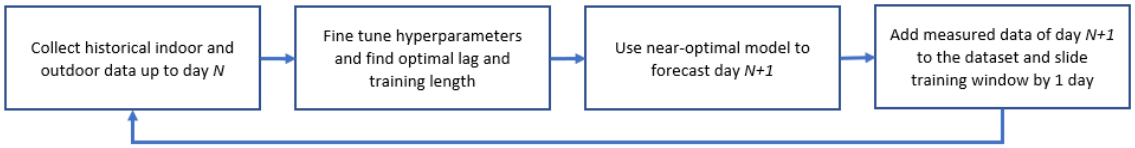

Figure 4. Model development procedure

To forecast indoor temperature for day *N+1*, namely the forecast day, the model was trained and optimized using the data from the hourly historical dataset up to day *N*. We used combinations of model hyperparameters, lags and training lengths to identify the optimized model. We used hour of day, day of week, and hourly outdoor temperature as features. We tested four different training lengths, i.e., 168, 336, 504 and 672 hours to find the optimized model. The combination that leads to the minimum mean absolute error (MAE) was selected to forecast the indoor temperature for day *N+1*. We used a recursive prediction method where an hourly forecasted temperature was fed forward to the next timestep. Training the models every 24 hours with varying training lengths and lags enabled a more flexible framework. This flexibility helps the model to better respond to gradual changes in outdoor conditions and occupants' behaviour patterns within each dwelling. We used XGBoost (Chen and Guestrin 2016) as the base model and implemented the fine-tuning process with Optuna (Akiba et al. 2019). XGBoost, as a decision tree-based method, provides a non-linear regression capability similar to neural networks while being easier to train and less prone to overfitting (McElfresh et al. 2023). The procedure was implemented in Python.

We evaluated the performance of the forecasting approaches using five randomly selected days, referred to as test days. The test days were consistent across all 20 dwellings. For each test day, the near-optimal model was found and then used to forecast the indoor temperature starting at 12

am. Figure 5 shows the MAE for each dwelling, comparing the same-day (day *N*) and test day (day *N+1*) prediction results. As expected, the same-day errors are lower with an average MAE of 0.4°C. The average next-day MAE is consistently below 0.7°C for all dwellings. While this level of accuracy may not suffice for applications such as predictive control, it offers valuable insights into overheating risks. This is particularly noteworthy given the minimal requirement for exogenous data and the dwelling-agnostic nature of the forecasting approach.

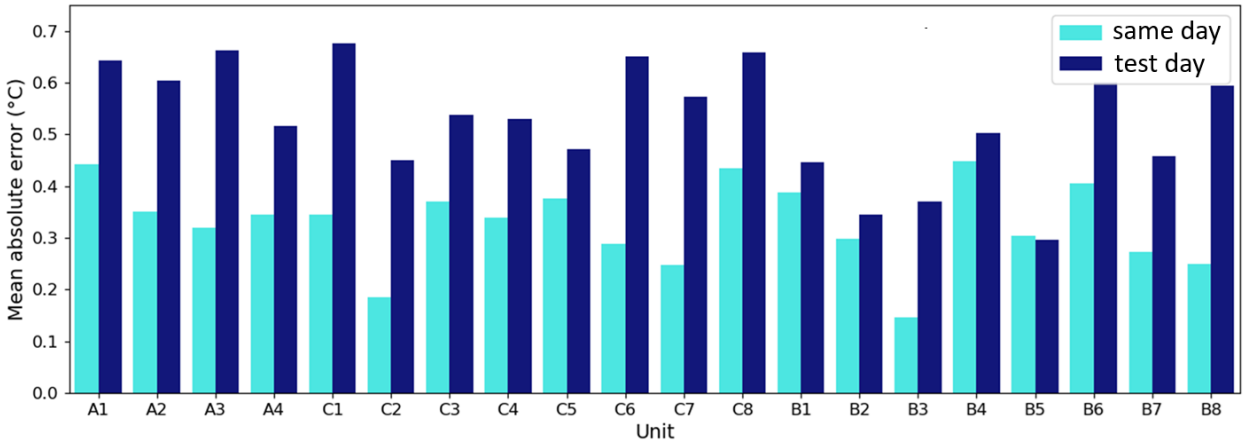

Figure 5. Prediction error for each dwelling

5. CONCLUSIONS

Measurements from 20 social housing dwellings in Western Canada confirm that outdoor conditions are an unreliable indicator of excessive heat exposure risks in occupied homes. Currently, heat alerts rely solely on weather forecasts. However, our assessment indicates that elevated indoor temperatures can occur even during relatively mild outdoor conditions. These findings and similar findings from previous studies underscore a flaw in the existing public weather alerts. This issue is particularly important in the context of social housing due to the potential vulnerability of both the buildings and their occupants. As a short-term mitigation strategy, we developed an automated indoor temperature forecasting framework that uses only publicly available weather forecast data. This framework identifies where, when, and to what extent occupants of individual dwellings might experience overheating. It provides portfolio managers with actionable insights and enables them to effectively prioritize resources during overheating events.

Overall, this work demonstrates that the current heat alerts are not sufficient in responding to the increasing risk of indoor overheating in Canada. The proposed forecasting platform can facilitate the development of a cost-effective and computationally efficient heat alert system. Such systems would inform social housing management about impending heat-related health risks, allowing for timely and individually targeted mitigations. This approach could reduce the heat-related morbidity and mortality among vulnerable occupants and support a coordinated response during extreme heat events.

Acknowledgements

BC Housing develops, manages, and administers a wide range social housing across the province of British Columbia. In all new buildings, BC Housing requires active cooling systems and air filtration systems be installed. However, many buildings in our portfolio are decades old and were built for a cooler climate than what British Columbians are more recently experiencing due to climate change. BC Housing is taking steps to address these challenges through retrofit measures, and installing portable air conditioning units, where possible. BC Housing also provides emergency cooling and clean air items that are distributed to housing operators as needed, during periods of extreme heat. In 2023/24, BC Housing updated our Extreme Heat and Wildfire Smoke Action Plan. This document provides an overview of key priority areas, short and long-term actions, and timelines to ensure that BC Housing, as an organization, is prepared to support people living in social housing and our partners during extreme heat and wildfire smoke events.

This paper is being carried out as a part of the R&D project at the National Research Council of Canada (NRC) under the Climate Resilient Build Environment (CRBE) Initiative.

A comparison of energy use among modular and site-built multifamily buildings in the U.S.

K.R. Grosskopf, Ph.D. [1]

[1]*University of Nebraska, Lincoln, USA, kevin.grosskopf@unl.edu*

SUMMARY
Prefabrication in a controlled, factory setting may improve the energy performance of modular buildings compared to traditional site-built buildings. This research provides energy performance data on 48 modular and 158 site-built multifamily buildings in the U.S. Results suggest that the performance of energy measures in modular multifamily construction meets or exceeds the performance of energy measures in site-built construction. Although few differences were observed between the types of materials and equipment used in either modular or site-built multifamily construction, the installation quality of energy measures in modular multifamily construction appeared to be better when compared to site-built construction. Findings also suggest that the post-occupancy energy use of modular multifamily buildings (113.6kWh/m^2/yr) was comparable to site-built buildings (112.9kWh/m^2/yr). However, since two-thirds of the modular projects studied were affordable housing, dwelling units were smaller (51.9m^2) compared to market rate site-built units (76.9m^2). When normalized for ~30% higher occupant density, modular buildings had significantly better energy efficiency compared to site-built buildings.

Keywords: buildings, energy, modular, multifamily.

1. INTRODUCTION

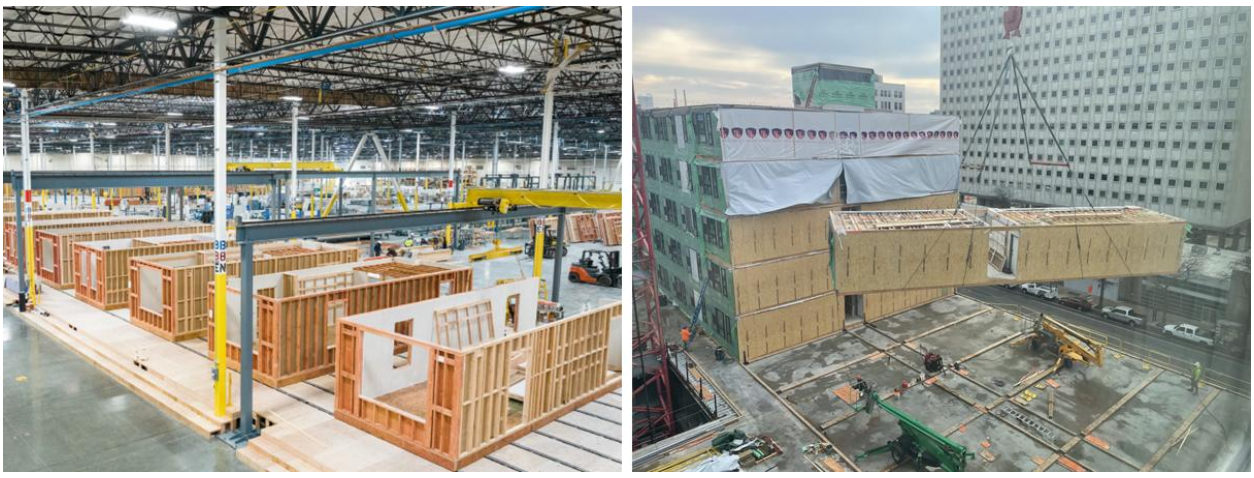

Figure 1. Modular factory (left) and work site (right)**.**

Modular construction consists of building components prefabricated offsite in a manufacturing facility. These components are then transported and assembled onsite (Figure 1). Since both offsite and onsite work occur simultaneously, opportunities exist to shorten construction schedules and speed income generation, particularly for projects with repetitive building units such as apartments and hotels. Modular construction may also reduce costs while improving building performance.

2. METHODS

Multifamily buildings selected for this study were located in four urban areas of the U.S. (Los Angeles, San Francisco, Philadelphia and Seattle) representing two temperate climate zones. Buildings averaged 6 stories, 13,000m^2 and 144 units each. Data was first collected on energy-related material and equipment systems for a total of 25 modular and 30 site-built multifamily buildings under construction. Data collection for each building began with a design document review followed by factory and construction site inspections. In addition, post-occupancy energy use data was collected on another 23 modular and 128 site-built multifamily buildings completed between 2013-2022 in the same urban areas.

3. RESULTS AND DISCUSSION

3.1. Energy Systems

In climate zone 3 (Los Angeles and San Francisco), the average energy efficiency of modular material and equipment systems exceeded most energy code requirements (Figure 2). The exception was thermal transmittance (U) for exterior walls. Similarly, the energy efficiency of modular material and equipment systems exceed the energy efficiency of site-built systems in CZ3 except window solar heat gain coefficient (SHGC).

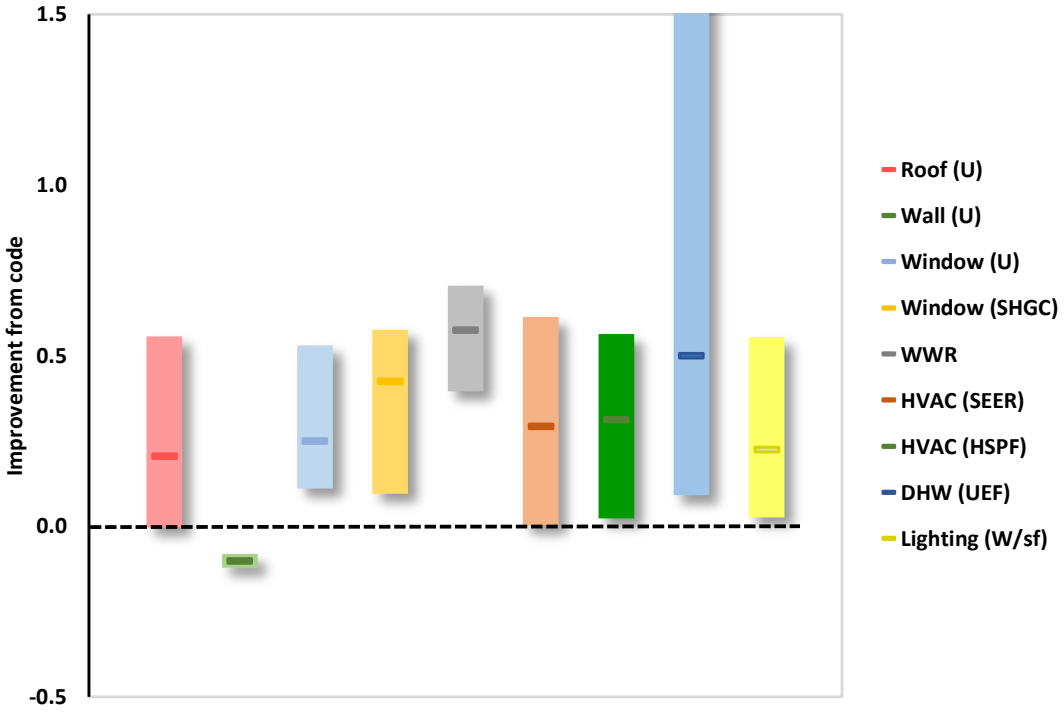

Figure 2. Design improvement from code, U.S. climate zone 3 (Los Angeles and San Francisco).

In climate zone 4 (Philadelphia and Seattle), the average energy efficiency of modular material and equipment systems exceeded all energy code requirements (Figure 3). One modular building failed to meet code requirements for maximum window-to-wall ratio (WWR). The energy efficiency of modular material and equipment systems, however, did *not* exceed the energy efficiency of site-built systems in CZ4 except thermal transmittance for roofs and exterior walls.

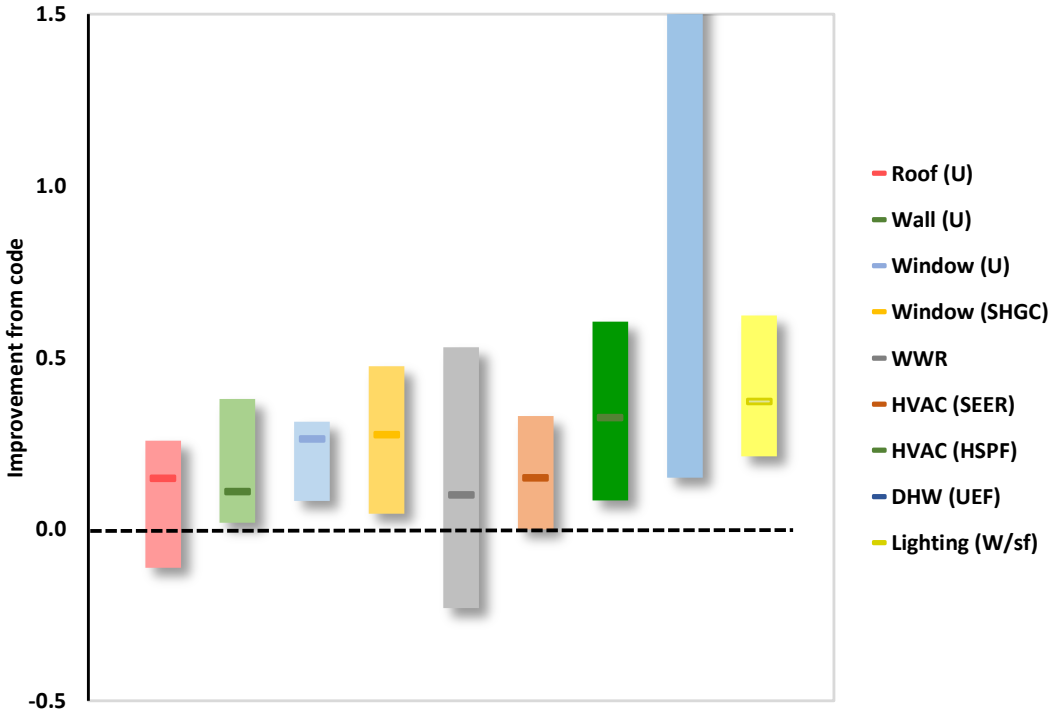

Figure 3. Design improvement from code, U.S. climate zone 4 (Philadelphia and Seattle).

Overall, few differences were observed between the types of materials and equipment used in either modular or site-built multifamily construction. However, the installation quality of insulation, air barrier and other building envelope measures in modular multifamily construction appeared to be better when compared to site-built construction.

3.2. Energy Use

For buildings with at least 1-year of post-occupancy energy use data, the energy use intensity (EUI) of modular multifamily buildings (113.6kWh/m^2/yr) was comparable to site-built buildings (112.9kWh/m^2/yr). However, since two-thirds of the modular projects studied were affordable housing, dwelling units were smaller (51.9m^2) on average compared to market rate site-built units (76.9m^2). When normalized for ~30% higher occupant density and other factors, modular multifamily buildings had higher U.S. Department of Energy (DOE) *Energy Star* scores compared to site-built buildings. The *Energy Star* score represents the energy efficiency percentile of a building in relation to similar buildings in the U.S.

Table 1. Post-occupancy energy performance of modular and site-built multifamily buildings.

	Modular			Site-Built		
Location	Number of Buildings	EUI (kWh/m^2/yr)	Energy Star Score	Number of Buildings	EUI (kWh/m^2/yr)	Energy Star Score
Los Angeles	6	122.7	58	25	112.0	76
San Francisco	9	122.4	91	64	104.1	86
Philadelphia	3	111.7	87	19	146.1	63
Seattle	5	88.3	98	20	100.9	93
Total	23	113.6	86	128	112.9	81

4. CONCLUSIONS

Unlike site-built construction, modular construction relies on a permanent factory workforce under a central point of control. As a result, modular construction may be able to maintain higher levels of quality control when compared to site-built construction. This may explain why modular multifamily construction, when normalized for higher occupant density and other factors, appears to have better energy efficiency compared to site-built construction despite using similar materials and equipment.

Modular projects in this study were completed 30% faster on average when compared to site-built construction. Due to shorter construction schedules, modular projects achieved an average 5% cost savings. Growth for modular multifamily construction in the U.S. is being realized in the Northeast and along the West Coast where roughly one-third of the population lives in multifamily housing as a result of the ongoing housing affordability crisis.

SUMMARY
This research aims to maximize acceptable indoor daylighting levels by optimizing glazing Visible Transmittance (VT) parameter across multi-sectional curtain wall facades. A north-facing, side-lit office in Sydney, Australia, serves as the case study, where optimization is performed using the Brute Force algorithm via Grasshopper's Colibri plugin. Daylight performance is assessed with Ladybug Tools and the Radiance engine based on the well-lit area (D_L) metric where it is between 320 to 800 lux for three visible transmittance values in daylight, view, and spandrel sections (VT_D, VT_V, VT_S). The proposed multi-sectional optimization $(VT_{MSO}, Scenario\ A)$ achieves a 21% improvement in the well-lit area (D_L), outperforming alternative approaches with 8%, 13%, 14.5%, and 16% enhancement for spandrel $(VT_{SSO}, Scenario\ D)$, daylight $(VT_{DSO}, Scenario\ B)$, view $(VT_{VSO}, Scenario\ C)$, and uniformly optimized VT $(VT_{UO}, Scenario\ E)$, respectively, with specific VT values in each section and provided well-lit area (D_L), offering design guidelines for sustainable daylighting practices.

Keywords: Indoor daylighting, Multi-Sectional curtain wall facades, Glazing visible transmittance (VT), Brute force optimization.

1. INTRODUCTION

Daylight is a crucial factor in enhancing occupant well-being by supporting circadian rhythm regulation(Lockley, 2010), productivity, and satisfaction in workspaces(Haynes, 2008), fostering healing process in medical environments(Joarder, 2011), boosting academic performance and contributing to better learning outcomes(Irnawaty et al., 2019), reducing lighting energy consumption in buildings (Bodart & De Herde, 2002). However, high-rise buildings with curtain wall facades, a common construction type in today's world, often face challenges with uneven indoor daylight distribution, particularly in deep side-lit spaces where facade daylight performance is critical and constitutes a substantial portion of the design layout (Government, 2022). In such space, near glazed facades, excessive daylight creates high-intensity illuminance (lux) (over-lit zones), while the back of rooms experiences insufficient daylight illuminance (lux), as daylight typically extends only up to twice the window height (Beltrán, 2020). To address the challenge of

difficulty in balancing indoor daylight penetration and uniformity in such space, a key primarily parameter in effective daylight design and solutions for curtain wall facades is glazing Visible Transmittance (VT) which controls daylight transmission through glazing (Chen et al., 2019; Gündoğdu & Kunduraci, 2019).

1. 1 Literature Gap and Aim

Previous research highlight the critical role of VT, in optimizing indoor daylight illuminance in such space (Hosseini et al., 2018; Singh et al., 2022; Singh et al., 2016). However, applying a single daylight solution or VT value across the entire facade does not ensure uniform distribution across the entire space, highlighting the importance of using specific daylight controls for the daylighting and view sections of the facade, as each section serves a distinct role in optimizing indoor lighting (Aiziewood, 1993; Lim et al., 2012; Tan et al., 2023). Daylighting section typically refers to windows above 2 meters, though this can vary based on room size and facade design but should not be less than 0.75 meters, enhancing light levels in deeper spaces. View section typically refers to window between task area and daylighting glazing, balancing daylight, shading, and outdoor views near task areas, if appropriate daylight controls are utilized(Elkhatieb, 2017). The significance of both glazing Visible Transmittance (VT) and the separation strategy in improving indoor daylight illuminance levels inspired the concept behind this research, which remains to be relatively unexplored in the existing literature. A purpose-driven method to evaluate different VT values in the daylight (upper(D)), view (middle(V)), and spandrel (lower(S)) sections to ensure optimal indoor daylight distribution, is rarely addressed in current studies. Existing approaches typically focus on daylight penetration or glare reduction but often neglect uniformity and the optimal distribution of light across the entire space, relying on simplistic applications such as clear glass above and tinted or shaded glass below without robust optimization tools (Aiziewood, 1993; Hashemi, 2014; Lim et al., 2012; Tan et al., 2023). Therefore, this research is going to address the gap and:

- Proposing a new three-variable optimization method to maximize the acceptable indoor daylight level (well-lit area) in side-lit spaces. The optimization simultaneously focuses on Visible Transmittance (VT) values across the three horizontal sections—daylight (VT_D), view (VT_V), and spandrel (VT_S) —of multi-sectional curtain wall facade (VT_{MSO}).
- Comparing the effectiveness of the proposed approach with other four alternative approaches: daylight (VT_{DSO}), view (VT_{VSO}), spandrel (VT_{SSO}), and uniformly optimized section Visible Transmittance (VT_{UO}).
- Bridging the research gap by providing new insights into optimizing indoor daylight distribution, contributing to both academic knowledge and practical daylighting design, and offering to improve building design and indoor daylighting level.

2. METHODOLOGY

This research outlines the simulation and optimization process, as shown in Figure 1. Following a review of existing gaps and literature, a simulation-based optimization approach is employed using Rhinoceros, Grasshopper, Ladybug, and Honeybee plugins. Rhinoceros is a CAD tool enabling precise 2D and 3D modeling, while Grasshopper facilitates parametric evaluations and algorithm development(Talaei et al., 2021). Ladybug imports Sydney-CBD specific meteorological data based on the Energy Plus weather dataset (EPW format). Meanwhile, the Honeybee plugin connects to Radiance**,** a validated lighting simulation engine employing backward ray tracing for daylight analysis (Reinhart, 2019). Validation studies confirm their precision within ±10%

compared to CIE Test Cases (Reinhart, 2019). Also, a single brute force optimization algorithm using the Colibri plugin in Grasshopper is perform, systematically evaluating all possible VT combinations for the three horizontal curtain wall sections. The analysis focuses on a grid-based daylight illuminance simulation for north-facing glazing on December 21 at 12:00 noon—representing the highest sun altitude and daylight level in the Southern Hemisphere during the summer solstice. The average solar radiation in this month is around 6000 lux, the highest compared to other months of the year. During daytime hours (9 AM to 4 PM), the highest average daylight illuminance is recorded at 8501 lux on December 21st, with a peak at 12 PM. At this peak, direct sunlight contributes 992 lux, while diffuse skylight accounts for 119 lux. Given the time and location, the sky condition in Sydney at 12:00 PM on December 21 is likely to correspond to the "CIE Standard Clear Sky" model. Therefore, for precise modeling or simulation purposes, the ε (epsilon) and δ (delta) values—based on the ISO 15469 standard—are approximately 0.351 and 0.161, respectively. This is ideal for assessing indoor daylight performance under challenging conditions, representing the peak risk of uneven indoor daylight distribution and highest daylight level. According to Eq.1, current research aims to maximize the percentage of the area achieving illuminance between 320 lux and 800 lux ($\text{Well} - \text{lit Area}$), referred to as the D_L metric, by optimizing three VT variables VT_D, VT_V, VT_S through five optimization approaches, as outlined in Figure 1. Where $l \leq VT_D, VT_V, VT_S \leq u$ with $l \; and \; u$ are the lower and upper bounds of the variables ([0.20,0.90] with 0.10 increments).

$$\max\ (\text{Well} - \text{lit Area}) = \max\ (F(VT_D, VT_V, VT_S)) \qquad \text{Eq.1}$$

The case study depicted in Figure 2 examines deep side-lit office layouts, which are common in modern design practices and widely used in high-rise buildings, particularly in Australia. Given the significance of visual comfort, productivity, and health for employees (Government, 2022), there is a strong need for targeted solutions to enhance daylight performance in such environments. Due to the emphasis on daylighting in Australian sustainability policies and rating tools such as NABERS and Green Star, Australia is considered as case study location (Diesendorf & Diesendorf, 2007; Hall, 2010). Among Australia's diverse climate zones, Sydney falls within Climate Zone 5 (Humid Subtropical, Cfa), which represents a significant portion of high-rise buildings across the country, making it a relevant choice for assessing daylight performance under typical climate conditions. Moreover, despite the benefits of ample sunlight and typical CBD office designs in Sydney, current Australian building codes provide limited guidance specific guidance on optimizing VT values for indoor daylight distribution in offices (Board, 2022). While the Australian Glass and Window Association (AGWA) and the Australian Building Codes Board's facade performance calculator offer energy efficiency guidance, they provide less attention to indoor daylight uniformity through appropriate VT. The case study is a large rectangular side-lit office space with an indoor area of 50 m², representative of multi-user offices in large Australian commercial buildings with a window-to-wall ratio (WWR) of 95% on the north-facing wall (5 m × 3 m). The space has a length of 10 m, chosen to align with typical daylighting needs in open-plan offices. Additionally, this configuration represents a perimeter-occupied zone within a large-plate (>30 m) multistory office building, a common layout in contemporary commercial architecture. Moreover, Australian standards (Standard Australia: Sydney, 2006) for office interiors tasks are applied, setting the work plane height at 0.70 m for daylight grids and using the illuminance thresholds including 320 lux- routing office tasks, reading, writing, typing, and inquiry desks and 800 lux-very difficult tasks with very small details and threshold for quality of daylight.

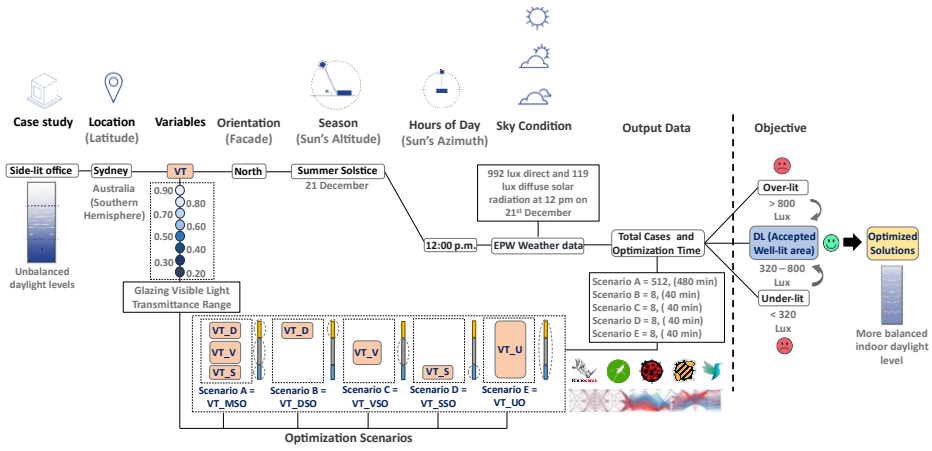

Figure 1. The overall research methodology framework.

3. RESULTS AND DISCUSSION

According to Figure 3 for Scenario A, Multi-Sectional Optimization of Visible Transmittance (VT_{MSO}), the top graph uses a parallel coordinates plot to visualize the range of design solutions and the relationships between visible transmittance values (VT_D, VT_V, VT_S) and the well-lit area (D_L) metric. Where $l \leq VT_D, VT_V, VT_S \leq u$ with $l \; and \; u$ are the lower and upper bounds of the variables ([0.20,0.90] with 0.10 increments). Red lines indicate lower-performing solutions, while blue lines represent higher-performing ones, with a gradient illustrating the optimization quality. This visualization reveals how variations in visible transmittance values influence daylight performance and highlights interdependencies among the sections. The bottom graph shows the progression of well-lit area as a function of the 512 visible transmittance (VT) combinations explored. The well-lit area (D_L) ranges from approximately 22% to a maximum of 46%, demonstrating the algorithm's ability to incrementally enhance daylight performance. The "Base

Case," achieving a well-lit area of 38%, serves as a benchmark. Optimized solutions surpass this benchmark, achieving well-lit area values between 40% and 46%, representing improvements of 2% to 21%. Notably, 155 solutions outperform the Base Case, with 23 solutions achieving the highest well-lit area values (44.5% to 46%). These top-performing solutions, highlighted in the right graph, form clusters that exhibit consistent performance and reflect a 17% to 21% improvement over the Base Case, emphasizing the robustness of the optimization process. The highest-performing designs include configurations reflects 21% improvement in well-lit area (D_L) metric with visible transmittance combinations for daylight, view, and spandrel sections, including VT_D.0.60, VT_V.0.80, VT_S.0.50, and VT_D.0.60, VT_V.0.90, VT_S.0.20. These solutions. The results indicate that the optimization approach effectively identifies design solutions that enhance indoor daylight performance. The horizontal bands in the right graph underscore the consistency of top-performing designs, suggesting flexibility in achieving optimal outcomes. To assess practical application, these results are compared with other scenarios, highlighting the advantages of simultaneous multi-sectional optimization.

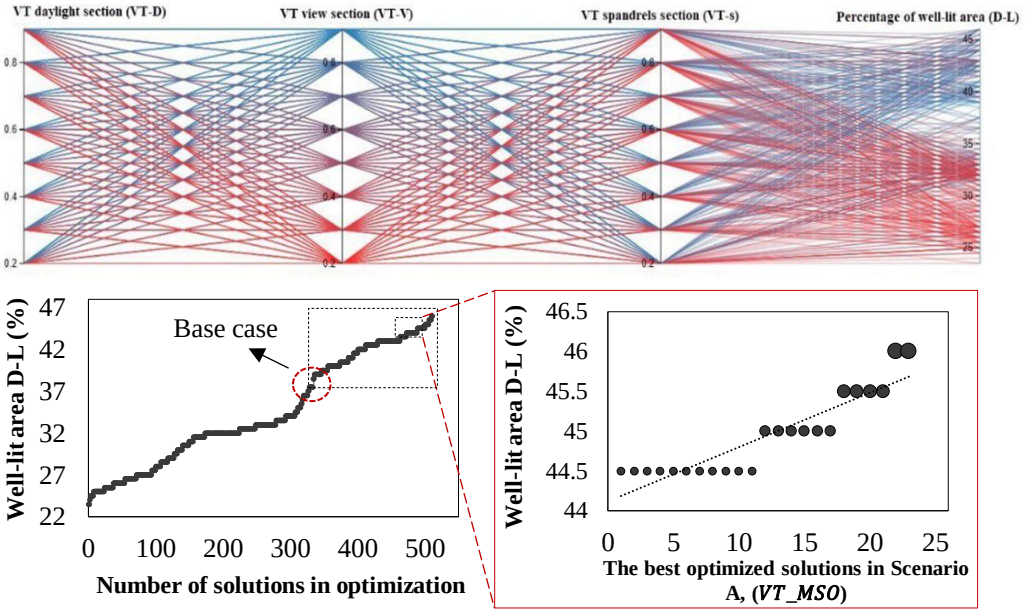

Figure 3. All possible solutions and the best optimized ones in multi sectional optimization (Scenario A, (VT_{MSO})) and provided well-lit area (%) (D_L).

Based to Figure 4, in Scenario B, Daylight Section-Optimized Visible Transmittance (VT_DSO), optimization results show a 13% improvement in the well-lit area (D_L) metric. Well-lit areas increase from 38% (base case) to 43%, with the optimal visible transmittance for daylight section (VT_D) being 0.20. Where $l \leq VT_D \leq u$ with $l\ and\ u$ are the lower and upper bounds of the variables ([0.20,0.90] with 0.10 increments) and $VT_V, VT_S\ are\ fixed\ at$ 0.90. The results indicate that reducing visible transmittance in the daylight section enhances indoor daylight uniformity. The steady increase in Well-lit areas, without significant fluctuations, underscores the critical role of the daylight section in achieving balanced daylight distribution. In Scenario D, Spandrel Section-Optimized Visible Transmittance (VT_SSO), Where $l \leq VT_S \leq u$ with $l\ and\ u$ are the lower and upper bounds of the variables ([0.20,0.90] with 0.10 increments) and $VT_D, VT_V\ are\ fixed\ at$ 0.90, the improvement in Well-lit areas is more modest at 8%, with well-

lit areas ranging from 38% to 41%. The optimal visible transmittance for daylight section (VT_S) is 0.20, indicating that reducing spandrel visible transmittance (VT) improves daylight distribution but to a lesser extent than Scenario B. Scenario C, View Section-Optimized Visible Transmittance (VT_VSO), shows the most significant improvement among single-section scenarios. Where $l \leq VT_V \leq u$ with $l\ and\ u$ are the lower and upper bounds of the variables ([0.20,0.90] with 0.10 increments) and $VT_D, VT_S\ are\ fixed\ at$ 0.90. Well-lit areas increase from 32% to 43.50%, representing a 14.5% improvement. This metric peaks at 43.5% with a visible transmittance for the view section (VT_V) of 0.50 but declines as visible transmittance (VT) decreases further to 0.20. This suggests that mid-range visible transmittance (VT) values for the view section result in optimal daylight performance, while overly low VT reduces its effectiveness. Scenario E, Uniformly Optimized Visible Transmittance (VT_UO) that applies a single, uniform VT value across all sections to ensure consistency in light transmission, Where $l \leq VT_D + VT_V + VT_S \leq u$ with $l\ and\ u$ are the lower and upper bounds of the variables ([0.20,0.90] with 0.10 increments), achieves well-lit areas ranging from 25% to 44%, with a 16% improvement at a uniform visible transmittance of 0.70.

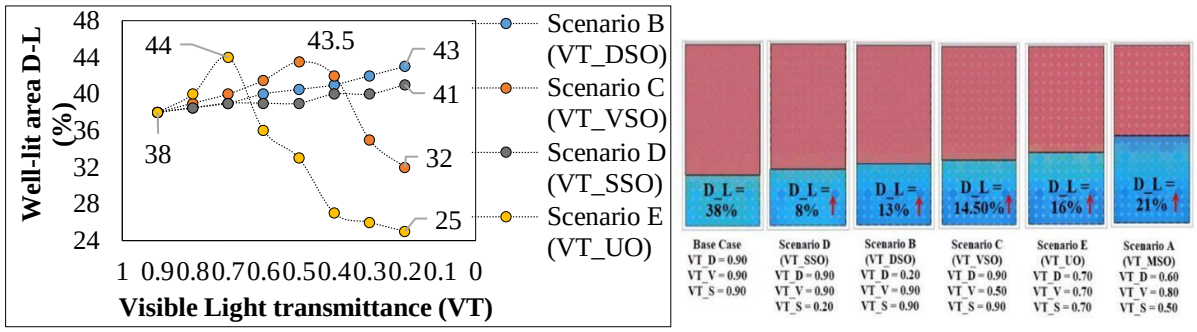

Figure 4. Comparison of five optimized solutions for providing the well-lit area in the north-facing facade on December 21 at 12 p.m.

Although performance fluctuates similarly to Scenario C, Scenario E spans a wider Well-lit area (D_L) range (25% to 44%) compared to Scenario C (32% to 43.5%). The results reveal a nonlinear relationship between visible transmittance (VT) and well-lit area (D_L), with diminishing returns or declines in performance at higher visible transmittance (VT) values in some scenarios. Notably, Scenario A (VT_{MSO}), which simultaneously optimizes all three visible transmittance variables, achieves the highest and most consistent $\text{Well} - \text{lit area}\ (D_L)$ outcomes. This highlights the effectiveness of multi-sectional optimization in balancing visible light transmittance across the daylight, view, and spandrel sections to improve indoor daylight distribution. The figure 4 further illustrates the comparative improvement in daylight performance across all optimization scenarios relative to the base case, with Scenario A emerging as the most robust solution for achieving uniform and well-lit indoor environments. In addition, the figure demonstrates design configurations that yield less favorable outcomes based on the selected performance metric are Lower-performing solutions based on their well-lit area **(**D_L), which is the metric visualized in the color bar. Solutions with lower D_L values achieve less daylight coverage across the space, indicating reduced daylight performance. The figure also, presents the distribution of daylight within the case study, with well-lit areas shown in blue and inadequately lit areas in red in all five optimization scenarios.

4. CONCLUSION

This research introduces a new optimization method for Visible Light Transmittance (VT) across three distinct horizontal sections of multi-sectional curtain wall facades. Using advance simulation tools— a Brute Force optimization algorithm through Grasshopper's Colibri plugin, supported by Ladybug Tools (LBTs) and the Radiance engine— this research addresses the challenge of achieving uniform indoor daylight distribution in side-lit spaces—common in high-rise buildings. A north-facing office in Sydney, Australia, serves as the case study, exploring an issue not thoroughly investigated in previous studies. The research evaluates the concept of assigning distinct VT values to each horizontal section —daylight (VT_D) , view (VT_V), and spandrel (VT_S) – as three variables within a VT range of 0.20 to 0.90. The evaluation focuses on the well-lit area percentage, defined by the D_L metric, for a case study conducted on 21 December at 12 noon. It also compares the effectiveness of the proposed multi-sectional optimization approach ($VT_{MSO}, Scenario\ A$) with alternatives including daylight section optimized ($VT_{DSO}, Secnario\ B$), view section optimized ($VT_{VSO}, Scenario\ C$), spandrel section optimized ($VT_{SSO}, Scenario\ D$), and uniformly optimized VT ($VT_{UO}, Scenario\ E$). Although, the research has some limitations that open directions for future work, such as adapting the methodology to different climates, facade geometries, types, orientations, and building categories. Future studies could also extend the analysis to additional hours and days throughout the year and integrate dynamic facade systems or smart technologies. Moreover, employing more advanced optimization methods, such as multi-objective optimization, and incorporating additional metrics for glare, thermal, or energy performance—along with real-world case studies or sensitivity analyses—could enhance the robustness and credibility of the findings. Overall, key findings reveal that:

- The proposed multi-sectional optimization (VT_{DSO} , Scenario A) achieved up to a 21% improvement in well-lit area (D_L metric) with VT combinations including VT_U = 0.60, VT_V = 0.80, VT_S = 0.50, and VT_U = 0.60, VT_V = 0.90, VT_S = 0.20, compared to the base case (D_L= 0.38%), highlighting the effectiveness of sectional optimization and adjusting VT values for individual sections in enhancing daylight penetration and uniformity.
- Optimizing VT for individual sections shows that spandrel section optimized ($VT_{SSO}, Scenario\ D$), daylight section optimized ($VT_{DSO}, Scenario\ B$), view section optimized ($VT_{VSO}, Scenario\ C$) , and uniformly optimized VT ($VT_{UO}, Scenario\ E$), achieve improvement of 8%, 13%, 14.5%, and 16% , respectively, in well-lit area (D_L metric), placing them in the subsequent choices.
- Considering VT_S = 0.20 in Scenario D, VT_D = 0.20 in Scenario B , VT_V = 0.50 in Scenario C, and VT_U = 0.70 in Scenario E, with the other two VT values kept at 0.90, represent the best optimized solutions, leading to the highest D_L value.
- The extension of this research has the potential to provide architectural design guidelines for related areas of building design and codes, optimizing VT values for enhanced daylight performance and aligning with sustainability rating tools such as NABERS and GREEN STAR.

ABSTRACT

Evaluating the potential benefits of moss-based vertical greening systems on the Indoor Thermal Autonomy and Energy demand of residential buildings located in various Canadian cities of differing climate was the intent of this study. Moss is considered as a useful nature-based solution given its low maintenance requirements, high resilience, and potential as a sustainable alternative to conventional green facades and "living walls". Simulations were conducted using typical residential archetypes derived from databases available from Natural Resources Canada (NRCan) and the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE). These archetypes represent buildings constructed in 1980 and 2020 and are modeled for three Canadian cities: Montreal, Toronto, and Vancouver. Building geometries were developed in Rhino3D-Grasshopper®, and the analysis incorporated both historical and future projected weather data to assess the impacts of the integration of moss on building energy consumption and thermal comfort under current and future climate scenarios. The results indicate that moss provides insulation benefits, reducing heating energy consumption; however, it also retains heat in summer, slightly increasing cooling demand. Energy savings are more noticeable in older buildings and colder climates, such as Toronto and Montreal, but become negligible in newer buildings and milder climates like Vancouver, especially under future weather conditions. Additionally, moss-based systems have a minimal effect on indoor overheating. Therefore, their effectiveness depends on climate-specific applications, and they may be best utilized alongside other passive design strategies.

Keywords: Vegetation, Energy, Thermal comfort.

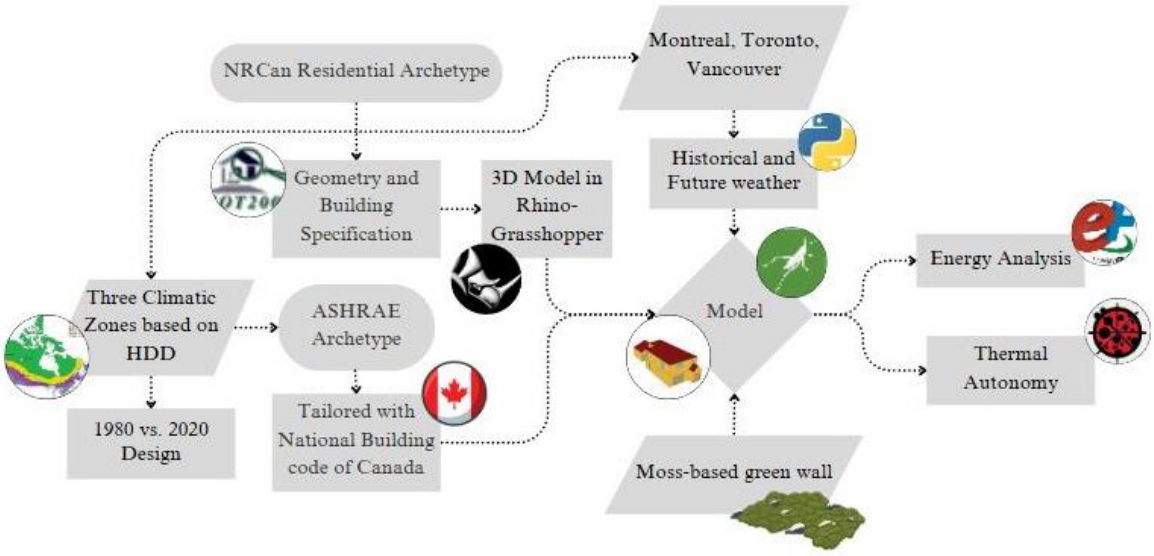

Figure 1. Graphical Abstract

1. Introduction

his study explores the use of moss-covered vertical surfaces as a sustainable design strategy to improve energy efficiency and thermal comfort in residential buildings. Moss is highlighted for its resilience, low maintenance, and adaptability, making it suitable for urban sustainability efforts. The research models moss application on NRCAN archetype buildings in three Canadian cities, comparing 1980 and 2020 construction standards. It includes a literature review on green walls and moss species, outlines the modeling methodology, and analyzes energy use and Indoor Thermal Autonomy (ITA). The findings aim to guide sustainable building practices in Canada.

2. Literature Review

Vegetation on building façades has been demonstrated to significantly reduce energy demand for heating and cooling, while also offering additional benefits such as improved air quality and urban biodiversity [1]. Using simulation and experimental mix research, *Moore et al.* showed that a green wall can provide thermal resistance comparable to a 2.5 cm layer of expanded polystyrene insulation. This highlights the potential of green walls as an insulating solution that contributes to energy efficiency in building design [2]. Also, Green walls can contribute to Urban Heat Island (UHI) Mitigation [3]. *Iaria et al.* found that increasing the coverage and leaf area index (LAI) of green roofs, living walls, and green façades significantly boosts their Urban Heat Island (UHI) mitigation potential. LAI increases from 1.5 to 3 greatly enhanced UHI reduction—by 70% for green roofs and 90% for living walls. Green roofs' effectiveness declines with taller buildings, becoming negligible above 40 m, while living walls and façades perform better up to 20 m. The study highlights the need to optimize coverage, LAI, and consider building height for effective UHI mitigation [4]. Green walls, also known as living walls or vertical gardens, are created using a variety of plant species that are suited to vertical growth, thrive in low-maintenance settings, and contribute to aesthetic and environmental benefits like insulation, air purification, and biodiversity support. Table 1 presents the thermal properties of each type of vegetation that can be incorporated into a thermal model. Common vegetation types used for green walls include (Figure 2):

1) Ivy is a popular green wall plant for its fast growth, surface adhesion, and adaptability to light, providing year-round greenery in mild climates. In colder regions, it may lose leaves or suffer winter damage. Ivy also improves air quality by capturing dust and pollutants, acting as a "particle sink," especially in high-traffic urban areas [5]. Additionally, Ivy canopies help regulate wall surface microclimates, reducing risks of frost and salt damage, which aids in preserving building materials in five sites across a range of climatic settings within England [6]. Studies in Manchester show that ivy-covered walls can raise external temperatures in late winter, reducing energy loss by 8%. Nighttime temperatures increase by 1.4°C, while daytime temperatures drop by 1.7°C due to shading. However, on warmer days, ivy may slightly reduce passive solar heat gain. Overall, evergreen walls like ivy can enhance energy efficiency and lower heating costs [7].

2) Virginia Creeper is valued for its fast growth and vibrant appearance, offering extensive facade coverage. As a deciduous plant, it provides summer shading that reduces cooling demand and allows winter solar gain to lower heating needs. This dual seasonal benefit makes it especially effective for thermally retrofitting poorly insulated buildings [8]. A comparative analysis of its thermal performance relative to English Ivy was conducted under controlled laboratory conditions, with experimental results validating its efficacy [9].

Figure 2. English Ivy (left) [8], Virginia Creeper (middle) [9], and Wisteria frutescens (right) [10].

3) Rosa setigera and Wisteria frutescens are ideal for green façades due to their lush growth and ability to reduce solar heat gain. While studies on climbing roses are limited, Wisteria performs well on sunlit west or south walls, improving thermal comfort. It can lower wall surface temperatures by up to 9°C and reduce heat flux by 22.3 W/m² in summer and 8 W/m² in winter, making it an effective, low-cost option for enhancing thermal performance in affordable housing [10].

2.1. Mosses

Bryophytes are a group of non-vascular plants that include mosses, liverworts, and hornworts. They are characterized by their simple structures and lack of true vascular tissues, which are typically found in higher plants. This means they rely on diffusion and osmosis to transport water and nutrients, limiting their size and growth to moist environments [11]. osses have existed for over 450 million years and are often overlooked due to their simple structure. Sphagnum, a genus of about 380 species, is a key ecological engineer and one of the oldest moss clades. Found in peatlands, which cover 3% of Earth's surface, Sphagnum stores about 30% of global soil carbon—twice as much as all forests—making it vital for carbon cycling and climate regulation [12].

2.1.1. Sphagnum moss

Sphagnum Palustre is commonly used in green walls for its excellent moisture retention and adaptability to humidity, supporting other plant growth and thriving in shaded, indoor settings. However, it is less suitable for sunny exterior walls and may negatively affect wall durability and moisture performance [11].

Figure 3. Sphagnum Fallax (Left) is typically found in moist, acidic environments such as bogs, fens, and wet heathlands. Sphagnum Palustre (right), also known as marsh moss, is commonly found in wetter environments, particularly in marshes, swamps, and around the edges of ponds [12]**.**

2.1.2. Hypnum Moss (Hypnum Cupressiforme)

Known for its ability to grow on a variety of surfaces, including stone and wood, this moss is suitable for vertical gardens (Figure 4). It can tolerate partial shade and does well in moist environments, making it a low-maintenance option for urban green walls[11].

Figure 4. Hypnum Moss (Hypnum Cupressiforme) Photo by Claire Halpin [11].

2.1.3. Sheet Moss (Hypnum imponens)

It forms a dense carpet of green that is highly effective for vertical surfaces. Sheet moss is often used in moss walls and vertical gardens for its aesthetic appeal and ability to cover large areas uniformly. Sheet Moss (Hypnum imponens): Often used for vertical green walls due to its lush, uniform appearance and ability to grow on various substrates [11].

Figure 5. Hypnum imponens, Photo by Sharon Pilington [11].

Figure 6 shows a real case for the Moss-based vertical wall The polyurethane sheet is securely attached to the building's wall, maintaining a gap that allows for monitoring the irrigation and fertilization system, which is divided into zones at different heights. This system consists of a layered network of pipes with emitters, supplied by a pump. Irrigation occurs vertically in multiple layers, using gravity to moisten the wool and distribute water to the plants, with the entire process being automated. To prevent moisture-related issues, proper ventilation and drainage must be ensured within the gap.

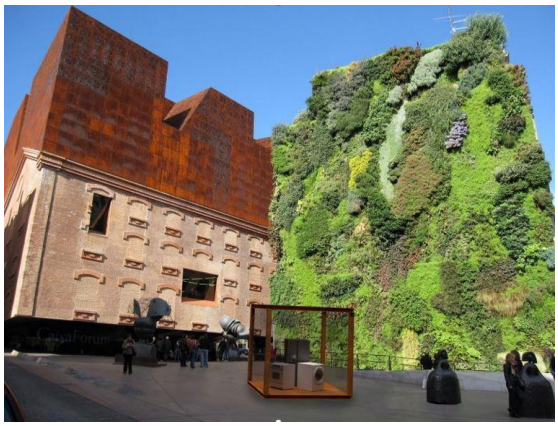

Figure 6. Caixa Forum Madrid, Patrick Blanc's Le Mur Vegetal System [13].

3. Methodology

Archetype data on geometry and thermal features is crucial for quick energy modeling of homes, covering dimensions, envelope, systems, and ventilation. Metered energy use offers a baseline, while age and climate-specific defaults aid thermal predictions. NRCan's "11 archetypes" were developed from 6,000 Energy Guide records using averaging techniques [14]. These archetypes, representing attached and detached residential buildings, are used for modeling and analyzing the feasibility and impact of building codes. In this study, Archetype 7, with the total gross floor area of 375 m^2—representing a two-story detached house without a basement—is modeled (Figure 7) [15]. The minimum insulation requirements, aligned with the Canadian climate, are evaluated for two construction years, 1980 and 2020, reflecting the National Building Code of Canada versions 7 and 15, respectively. The analysis is conducted for three cities—Montreal, Toronto, and Vancouver—each representing distinct climate zones in Canada. By analyzing the modeled archetype under different insulation standards and climate zones, the study can also assess the impact of vertical moss-based walls, on energy efficiency and thermal behavior. This evaluation helps determine the potential benefits of integrating sustainable and nature-based solutions into

modern building designs, particularly in the context of evolving building codes and climate-specific requirements.

Figure 7. NRCan Archetype 7, representing a two-story detached house without a basement.

The analysis was conducted using the Rhino Grasshopper simulation tool, which utilized the EnergyPlus module for energy analysis and the Ladybug plugin for thermal comfort evaluation [16]. The study incorporated National Building code of Canada insulation requirements and the characteristics of a vertical moss-based wall, modeled as an external additional layer to the wall assembly. Detailed specifications for the insulation requirements and the moss-based wall are provided in Table 1 and Table 2, respectively. The moss-based wall was modeled as an external layer added to the default building envelope. A stomatal resistance of 300 s/m was assumed, and the soil reflectivity and emissivity were set at 0.3 and 0.9, respectively.

Table 1. Minimum Insulation Requirements (NBC).

No.	Code	Year	Zone 4		Zone 5		Zone 6		Description
			Heating Degree Days (HDD)<3000		3000<HDD<4000		4000<HDD<5000		
			Vancouver (HDD=2825)		Toronto (HDD=3520)		Montreal (HDD=4200)		
			Minimum R SI (m^2K/W)		Minimum R SI (m^2K/W)		Minimum R SI (m^2K/W)		
			Wall	Roof	Wall	Roof	Wall	Roof	
1	NBC (7th Edition)	1977	1.47	1.43	1.60	1.57	1.73	1.71	Refers to The ACNBC Residential Standards 1977 (based on economic considerations)
2	NBC (15th Edition)	2020	2.78	4.67	3.08	4.67	3.08	4.67	Buildings without Heat-Recovery Ventilator

50	0.95	0.2	20	0.5	1500	0.06	[17], [18], [19], [20]

Historical and projected future weather files for energy analysis were used in this study. Historical data is sourced from the Canadian Weather Year for Energy Calculation (CWEC) dataset, created by the Meteorological Service of Canada (MSC). The CWEC dataset uses the Typical Meteorological Year (TMY), selecting twelve representative months from 15 to 30 years of hourly data to form a synthetic year reflecting average weather conditions [21]. These files are widely used in building performance evaluations and align with the National Building Code of Canada. For future projections, this study uses the Representative Concentration Pathway (RCP) 8.5 scenario, which predicts a 3.5°C temperature rise due to high greenhouse gas emissions. RCP 8.5 assumes high population growth, slow income growth, and limited technological advancements, leading to increased energy demand and GHG emissions without climate policies [21]. [22]

4. Results and Discussion

4.1. Energy demand

Table 3 show the heating and cooling demand for different scenarios.Table 3. Cooling and Heating demand for the different scenarios.

Construction Year	Weather file (TMY)	Building envelope	Energy Demand KWh/m^2	Montreal	Toronto	Vancouver
1980	Historical	Default	Heating	339.0	323.4	195.1
			Cooling	13.7	13.7	3.0
1980	Historical	Moss Wall	Heating	323.6	305.6	183.3
			Cooling	13.5	13.4	3.0
1980	Future RCP 8.5	Default	Heating	231.5	192.3	104.9
			Cooling	58.3	58.3	14.1
1980	Future RCP 8.6	Moss Wall	Heating	220.8	181.3	99.1
			Cooling	60.2	59.1	14.7
2020	Historical	Default	Heating	264.5	251.2	154.4
			Cooling	8.9	8.6	1.3
2020	Historical	Moss Wall	Heating	257.7	243.4	148.7
			Cooling	8.9	8.6	1.3
2020	Future RCP 8.5	Default	Heating	178.8	147.7	80.7
			Cooling	47.0	47.3	11.6
2020	Future RCP 8.5	Moss Wall	Heating	174.1	142.9	78.1
			Cooling	48.3	48.1	12.0

Buildings constructed in 2020 consistently consume less energy for both heating and cooling compared to those built in 1980 as the newer buildings are more energy-efficient, likely due to improved insulation, better construction materials. Also, Future weather files predict higher cooling energy consumption and lower heating energy consumption compared to historical data. This aligns with climate change projections, where warmer temperatures reduce heating demand but increase cooling demand. Montreal has the highest heating energy consumption due to cold winters. Cooling energy consumption is relatively low, Toronto has the moderate heating and

cooling energy consumption, and Vancouver has the Lowest heating and cooling energy consumption due to its mild climate.

Moss walls improve building energy efficiency by reducing heating demand, especially in colder climates, while having minimal impact on cooling. For 1980 buildings, heating demand drops by up to 6% under historical weather and up to 5.7% under future RCP 8.5 scenarios. Cooling demand remains largely unchanged or slightly increases. For 2020 constructions, heating reductions are smaller (2.6–3.7%), with no significant cooling effect. Overall, moss walls are most effective for enhancing heating performance in older, less insulated buildings.

4.2. **Indoor Thermal Autonomy**

To further evaluate the benefits of moss-based vegetation, its impact on thermal autonomy was analyzed for a 1980-built structure in Montreal under RCP 8.5 future weather conditions, representing a 3.5°C temperature increase due to global warming. The operative temperature data in the southwest room, which receives the most sunlight and is considered the hottest space, is used for the analysis (Figure 8). Indoor Thermal autonomy (ITA) measures the proportion of hours throughout the year during which indoor operative temperatures (equation 1) fall within a comfortable range, typically defined between 18°C (64.4°F) and 25°C (77°F) [22]. Operative temperature averages air and mean radiant temperatures to accurately reflect how building elements impact thermal comfort. For Indoor Thermal Autonomy (ITA) evaluation, buildings are simulated in "free running" mode without active systems or occupancy, assessing how many hours annually (out of 8,760) the indoor operative temperature stays within a comfort range [23].

$$t_o = \frac{(h_r t_{mr} + h_c t_{a)}}{h_r + h_c} \qquad (1)$$

t_o = operative temperature (°C)

h_c = convective heat transfer coefficient (W/m²·K)

h_r = linear radiative heat transfer coefficient (W/m²·K)

t_a= air temperature (°C)

t_{mr}= mean radiant temperature (°C)

Overly hot conditions increased from 31.9% to 32.0% of the year (+0.1%), thermal autonomy decreased from 17.7% to 17.6% (-0.1%), and overly cold conditions decreased from 50.4% to 50.3% (-0.1%) (Table 4). These results indicate that the moss-based wall has a negligible impact on ITA, with a slight trade-off between increased heat retention in warmer periods and improved insulation in colder conditions.

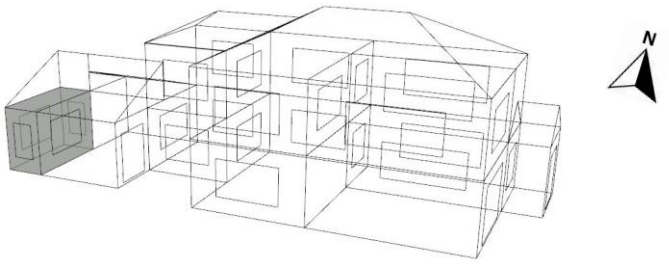

Figure 8. The operative temperature data were recorded from an indoor sensor located in the southwest room, which receives the most sunlight and is considered the hottest space, ensuring the maximum potential impact is captured.

Table 4. Indoor Thermal Autonomy status for a house located in Montreal in Future climate with default and Moss-based green wall.

Condition	Default Envelope	Moss-Based wall
Overly Hot (Temp>25 °C)	31.9%	32.0%
Thermal Autonomy (18<Temp<25 °C)	17.7%	17.6%
Overly Cold (Temp<18 °C)	50.4%	50.3%
Total Hour of the year (8760)	100%	100%

5. Conclusions

The findings suggest that while moss walls offer some insulation benefits by reducing heating energy consumption, their tendency to retain heat in summer leads to a slight increase in cooling demand. Energy savings are more pronounced in older buildings and colder climates, such as Toronto and Montreal, but become negligible in newer buildings and milder climates like Vancouver, particularly under future weather conditions. As global temperatures rise, the reduced heating demand and increased cooling needs may limit the effectiveness of moss walls as a passive energy-saving strategy.

One of the key benefits of green walls (including moss walls) is their ability to reduce cooling loads through shading and evaporative cooling. With minimal shading, the moss wall's ability to lower indoor temperatures during summer would be limited, potentially resulting in higher indoor operative temperatures. Future studies should explore strategies to reduce moss walls' slight summer cooling drawbacks, address real-world challenges like maintenance and regulatory integration, and clarify moss's advantages over conventional green walls in Canada. Additionally, assessing whether the modest energy savings justify the investment compared to other passive measures and examining policy and design implications for moss wall adoption in Canadian buildings is recommended.

SUMMARY
This study evaluates the effectiveness of cool roofs and green roofs as climate adaptative summer comfort control strategies for a case study building in Brussels and Madrid under current and future climate scenarios. Using EnergyPlus simulations, the study compares these strategies with standard roofs in terms of thermal comfort and operative temperature. Key findings show that both cool and green roofs can significantly improve thermal comfort in the case study building compared to the traditional roof covering, both in terms of the number of unmet hours and the extent to which comfort limits are exceeded. The cool roof option finish is shown to generally perform better in Brussels, while green roofs show greater adaptability to higher temperatures, excelling in the Madrid climate. In both locations, both strategies significantly reduce unmet comfort hours during the current summer, with a slight decrease in effectiveness projected for future summers. Their benefits are most notable during temperature peaks and heat waves. However, these strategies come with certain limitations, such as a potential winter penalty. As climates continue to shift and winters grow milder, adapting rooftop mitigation strategies to these evolving conditions offers the potential for more balanced and optimal performance year-round.

Keywords: rooftops, thermal comfort, climate

1. INTRODUCTION

In the context of climate change, regions traditionally associated with heating requirements, such as Belgium, are increasingly encountering the challenge of cooling during the summer months and frequent heatwaves. This transition is particularly evident in urban areas, which are more susceptible to global warming and extreme temperatures due to the urban heat island effect (Wouters et al., 2017). Roofs, as the most exposed building surfaces, play a crucial role in mitigating climate extremes and improving thermal performance. Recent research has underscored the importance of adaptive roof strategies (D'Agostino et al., 2024), particularly for cool and green roofs, as promising solutions. Cool roofs reflect more sunlight and absorb less heat than traditional roofs owing to their high solar reflectance and thermal emittance. Green roofs can be either extensive or intensive, with extensive roofs being lightweight and low maintenance, whereas intensive roofs support diverse plants and recreational use. Despite extensive research on these individual rooftop mitigation strategies (Zinzi and Agnoli 2012; Bozonnet, Doya, and Allard 2011; Li and Yeung 2014; Cirrincione, Marvuglia, and Scaccianoce 2021), research gaps remain, particularly regarding long-term performance under future climate scenarios and limited data on cool and green roofs in moderate climates, such as Belgium.

The main aims of this study were threefold: First, it sought to address the knowledge gap through simulation-based assessments of green and cool roofs in current and future climate scenarios. Second, the study aims to provide a direct comparison of different rooftop mitigation strategies. Finally, it intends to offer comprehensive guidance to support informed decision making for future renovation projects in moderate climates in Western Europe.

3. METHODOLOGY

3.1 Research design

A case study building in Brussels, "Co-working office La Lustrerie," was selected to compare the current rooftop configuration with cool roof (CR) and green roof (GR) strategies. A post-occupancy survey evaluated summer comfort in the existing condition, featuring a traditional black bitumen roof, revealing severe overheating often described as "unbearable." To analyse these problems, a digital twin of the building was created using actual usage data, consumption profiles, material specifications, and details from building plans and site visits. This model was enriched with insights from user surveys and effectively replicated overheating problems, thereby reinforcing its relevance. Using the EcoRoof model and roof surface absorption properties in EnergyPlus, this study simulates and compares green, cool, and traditional roof finishes for summertime thermal comfort. The comparison spans 2024, 2050, and 2080 for Belgium and Madrid, reflecting the shifting climate zones. Lessons from Madrid's strategies can inform solutions for Brussels while assessing the future effectiveness of these approaches in Madrid.

3.2 Roofing strategies

3.2.1 Standard roofing

Reference scenarios were needed to evaluate and compare the performance of the cool and green roofs. A flat roof with a traditional construction setup was used consisting of a black bituminous roof membrane, an insulation layer with variable thickness - (0.0001 cm), 5 cm, 10 cm and 15 cm - and a roof slab in light-weight concrete. Both mitigation strategies are implemented on this roofing typology.

3.2.2 Cool roofs

For the implementation of the cool roof, the black bituminous roofing membrane is changed to a cool roof layer. This layer is made of a highly reflective coating designed to minimize solar absorption and maximize thermal emittance. Below this layer, the conventional roof layers follow as before. Properties of the standard roof and the changed cool roof layer are given in Table 1.

Table 1. Layers and used parameters of conventional flat and pitched roof

Layers	Thickness (m)	Density (kg/m³)	Conductivity (W/mK)	Specific heat (J/kgK)	Thermal absorptance (-)	Solar absorptance (-)	Visible absorptance (-)
Cool roof / Roofing membrane	0.01	40	0.1	1400	0.95	0.15	0.15
	0.01	1120	0.16	1460	0.9	0.65	0.65
Insulation	~	43	0.03	1210	0.9	0.7	0.7
Light-weight concrete	0.15	1280	0.53	840	0.9	0.8	0.8

3.2.3 Green roofs

To implement the green roof, an additional green roof layer is added to the standard roof. The

parameters are divided into two parts: vegetation (Table 2) and soil (Table 3). The minimum stomatal resistance indicates the evapotranspiration rate of the plants. Soil parameters include saturation content (moisture at full saturation), residual content (dry matter) and initial moisture content at the start of the simulation.

Table 2. Used parameters for the green roof vegetation layer

Layer	Height of plants (m)	Leaf Area Index (-)	Leaf reflectivity (-)	Leaf emissivity (-)	Minimum stomatal resistance (m/s)
Vegetation	0.05	5	0.25	0.95	180

Table 3. Used parameters for the green roof soil layer

Layer	Thickness (m)	Density of dry soil (kg/m³)	Conductivity of dry soil (W/mK)	Specific heat of dry soil (J/kgK)	Saturation content (-)	Residual content (-)	Initial content (-)
Soil	0.10	1100	0.35	1200	0.5	0.1	0.5

3.3 Adaptive comfort model

To assess thermal comfort, an adaptive comfort model is used, which is based on the principle that individuals adapt to their environment. An adaptive model is used because the idea around "comfort" will change in the future, in extreme situations we will need to adapt more than in other situations. As a result, the indoor comfort temperature is not fixed but varies depending on the running average of the outdoor air temperature. The model (CEN 15251) is divided into three categories: Category I represents a high comfort level for sensitive occupants, such as those in hospitals, elderly care facilities, and nurseries; Category II reflects normal comfort expectations for most buildings, including offices and homes; and Category III applies to moderate comfort expectations, typically for existing buildings or less demanding environments. Since the building in question is an office, Category II is selected. The adaptive comfort model in CEN Standard EN15251 has been shown to be an effective approach for evaluating thermal comfort in naturally ventilated buildings across various climates and regions (Sánchez-García et al., 2018).

3.4 Climate scenarios

This study examines two types of climate: Belgium's moderate maritime climate and the more extreme Mediterranean climate, using Brussels and Madrid as reference cities. Belgium has an average annual temperature of 10°C, while Brussels ranges from ~0°C in January to 22°C in July (Climatestotavel.com, 2024a). Madrid's climate is characterized by mild winters (6.3°C in January) and hot summers (26°C on average, peaking at 40°C) (Climatestotavel.com, 2024b). Simulations use EnergyPlus Weather (EPW) files for typical years, derived from 18 years of hourly data. Future scenarios for 2050 and 2080 use IPCC-based climate-adjusted EPW files (Jentsch et al., 2012).

4. RESULTS

4.1 Thermal comfort summer

4.1.1 Unmet hours

Unmet hours were calculated for the summer period from June 21 to September 21. As explained in Chapter 3.3, for comfort class II these occur when the operative temperature exceeds the comfort

temperature by ±3°C. Hours are only counted when people are present in the building —, this corresponds to full days during working hours on weekdays and partial occupancy on Saturdays. The 93-day period leads to 1042 hours. Figure 1 shows results for the current climate, 2050, and 2080. Standard roofs show the highest number of unmet hours, with a significant increase by 2080. Both rooftop mitigation strategies demonstrate fewer unmet hours compared to the standard roof. However, this still results in uncomfortable summer indoor conditions for approximately 40% of the time. The simulation assumes no active air conditioning and closed windows. On a yearly basis, the percentage would decrease with winter comfort controls, but additional measures like the planned renovation as explained before are needed to keep the building comfortable.

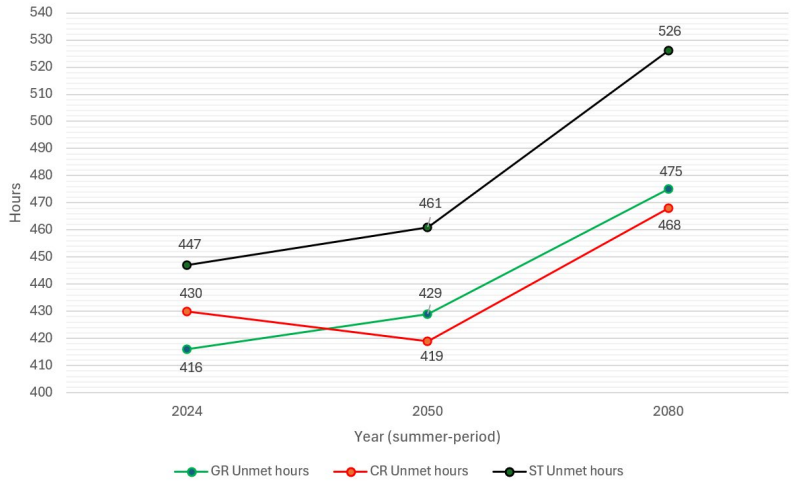

Figure 1. Unmet hours for summer season.

4.1.2 Temperature balance July

To thoroughly examine thermal performance strategies during hot spells, simulated temperatures were assessed throughout July. These included the external dry bulb temperature, the internal radiant surface temperature of the roof, the external surface temperature of the roof, the mean operative temperature of the space, and the mean air temperature (dry bulb) of the space. These simulation results were requested for the case study building in both Brussels and Madrid for the years 2024, 2050, and 2080. Figures 2 and 3 display these findings, although only 2024 and 2080 are shown since 2050 was very similar to 2080, but with smaller variations. The results presented all pertain to the scenario with an insulation thickness of 5 cm. While the operative temperature alone would suffice to compare the different strategies, the additional temperatures reported provide a deeper insight into the thermal response of each strategy. Trend lines are employed to facilitate a more straightforward evaluation of the hourly temperatures, making it easier to compare the strategies.

Overall, the results for cool roofs and green roofs are quite similar. Green roofs lower indoor air temperatures by just over 0.5°C compared to standard roofs, while cool roofs achieve a reduction of nearly 1°C. The differences are more noticeable during high temperature peaks than during cooler periods. Specifically, the internal radiant temperature of the cool roof in the case study is almost 2°C lower than that of the standard roof. Similar findings were reported by (Xing and Jones,

2019) , where a green roof reduced indoor air temperatures by 2.5°C compared to a bare aluminum roof during a heatwave event in the UK. Other research from Italy found that during the summer, cool roofs can decrease the indoor operative air temperature by more than 3°C (Pisello, Cotana, and Rossi, 2014). The external surface temperature offers additional insights, showing the consistency of these mitigation strategies. It rises steadily with outdoor air temperature but does not exhibit significant fluctuations. For conventional roofs, the external surface temperature surpasses 40°C during peak times (with a trend line around 33°C) and falls below the operative temperature during cooler periods. This pattern suggests strong solar radiation during peak times and limited sunlight during cooler periods. The external surface temperature of the mitigation strategies also underscores their effectiveness, remaining below the operative temperature and demonstrating the cooling effect of evapotranspiration in green roofs and the material properties of cool roofs. Similar findings were reported by Pisello et al., where cool roofs reduced the average external roof surface temperature by more than 10°C (Pisello, Cotana, and Rossi, 2014).

The elevated operative temperature is not due to a hot external roof surface but rather higher internal air temperatures, likely caused by the building's large windows, which allow significant solar gain. In the simulations, the windows remain closed, but opening them in reality could help cool the indoor air while the mitigation strategies manage the roof's thermal performance. In future climate scenarios, these effects are observed but amplified, with larger differences. Green roofs become more effective as their external surface temperature aligns more closely with the outdoor air temperature, while that of cool roofs increases. This is because cool roofs reflect solar radiation, which remains unchanged in future scenarios, while the general outdoor temperature and ambient heat rise. Green roofs better mitigate these effects. In Madrid, where temperatures are generally higher, green roofs outperform cool roofs even in the 2024 climate. Green roofs slightly lower the operative temperature and significantly reduce the external surface temperature compared to cool roofs, highlighting their advantage in hotter conditions. This advantage assumes a permanently active irrigation system for the green roof, as it is a fixed parameter in the simulations.

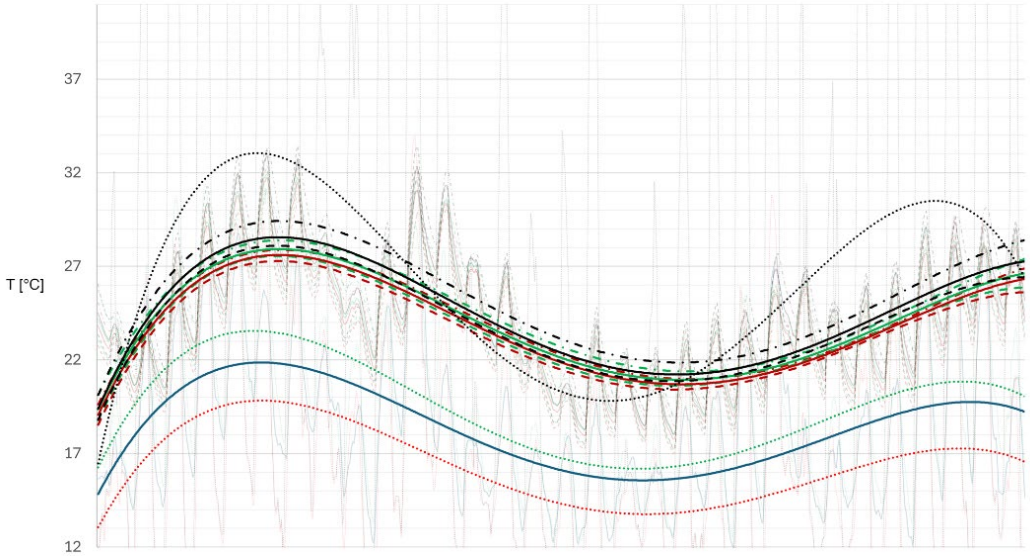

Figure 2. Thermal performance July, Brussels 2024.

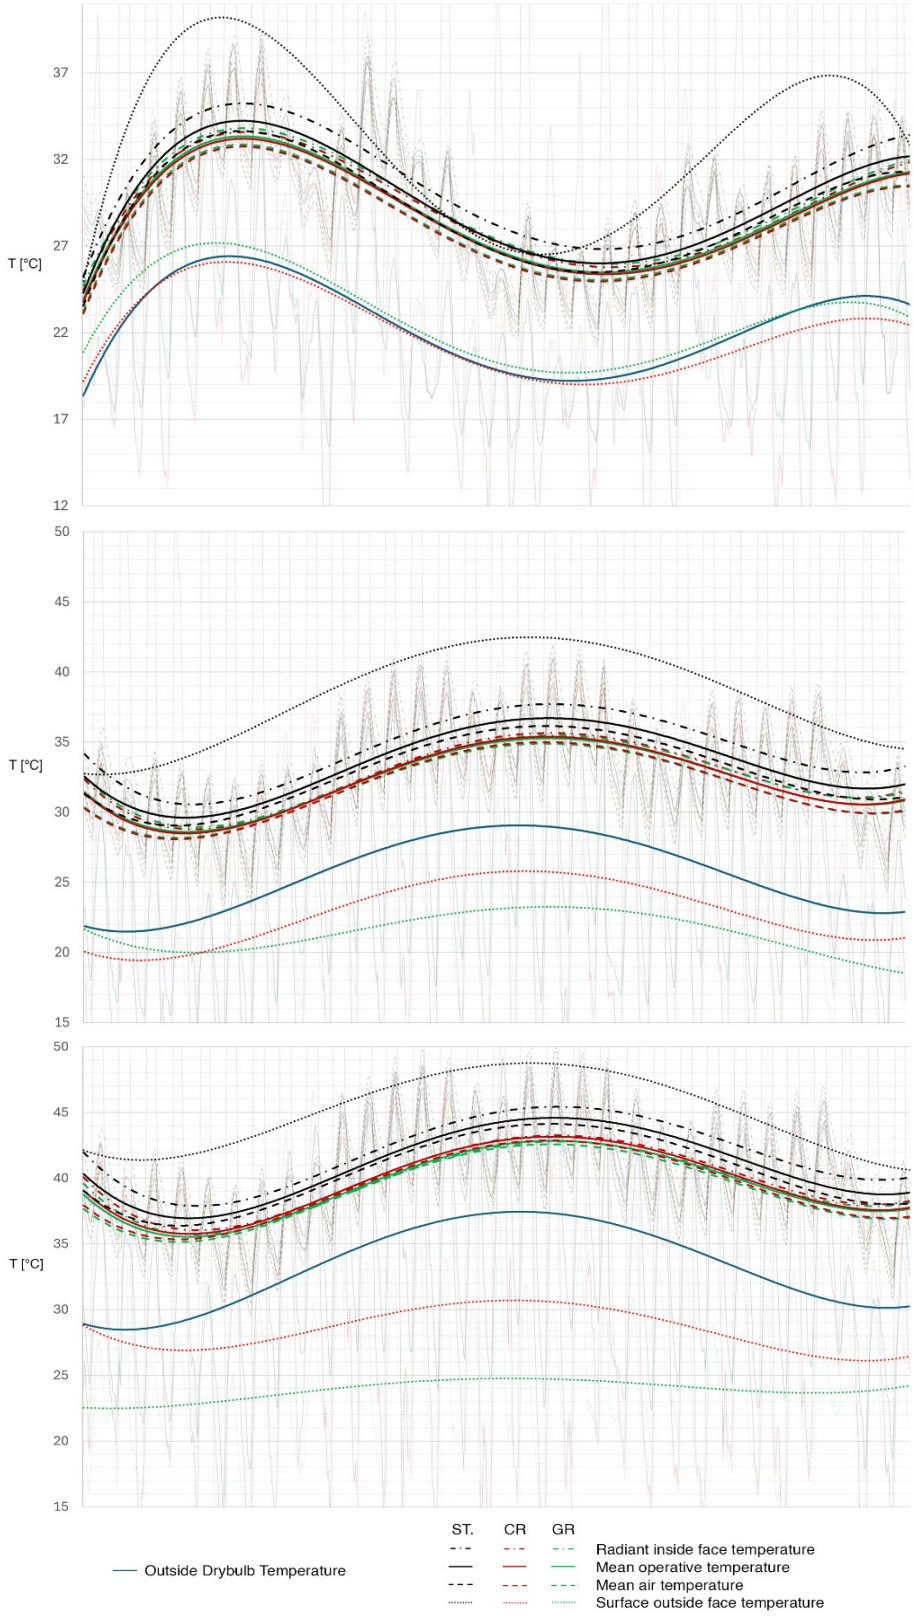

Figure 3. Thermal performance July. Top: Brussels 2080, middle: Madrid 2024, bottom: Madrid 2080.

4.5 Heatwave performance

In this study, a heatwave is defined as at least five consecutive days with maximum temperatures of 25°C or more, including three days over 30°C. This period was analysed to understand daily temperature trends. Figure 4 shows temperature peaks around 2 pm over five days. Similar to the monthly chart, nighttime outdoor temperatures drop, but rooftop mitigation strategies show a smaller decrease. Standard roof radiant temperatures vary more during the day, the mitigation strategies show more equilibrium between radiant and operative temperatures. At noon, operative temperatures exceed radiant ones, but the reverse occurs at night, suggesting high operative temperatures are influenced by elements like windows, while roof temperatures remain stable. Data from the standard roof supports this, as operative temperatures never exceed radiant ones, highlighting the effect of traditional roofing materials during peaks. These conclusions are backed by the research of (Di Giuseppe and D'Orazio, 2014) on green and cool roofs in a Nearly Zero Energy Building. Findings confirm that high albedo materials with a low U-value have limited internal comfort effectiveness, suggesting the building's U-value in this study is not low, as the cool roof outperforms the green roof during heatwaves.

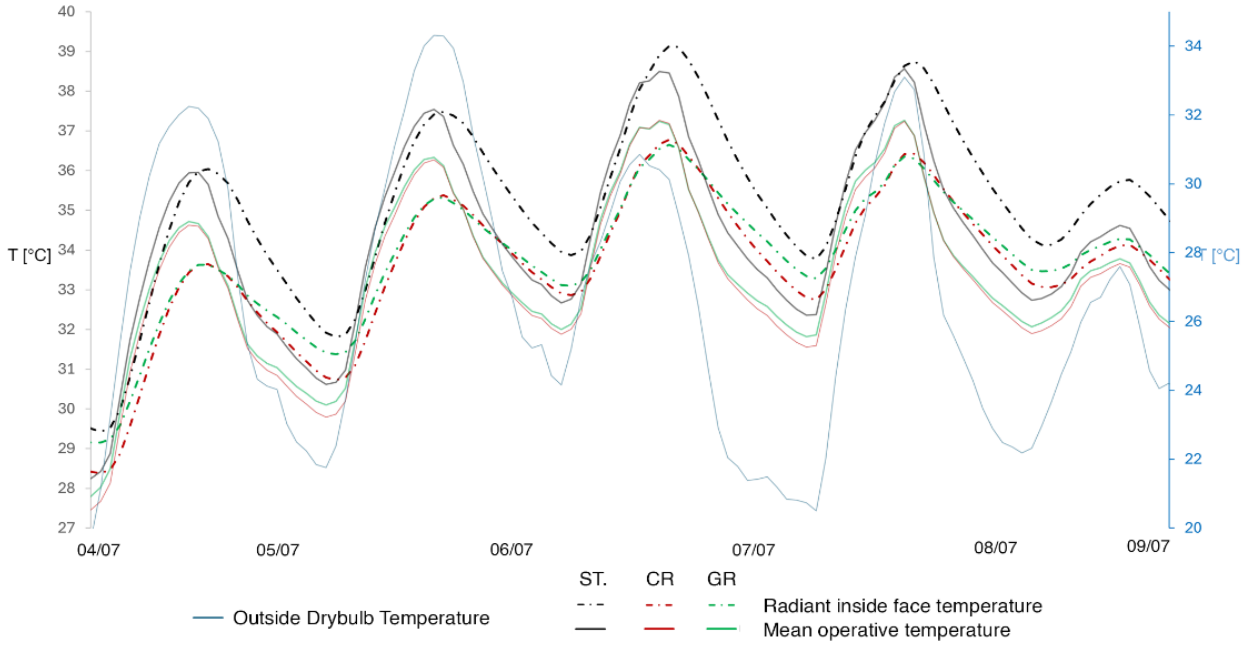

Figure 4. Heatwave performance

5. CONCLUSION

This research highlighted the effectiveness of cool and green roofs in Brussels and Madrid under current and future climate scenarios. Both roof types enhanced thermal performance compared to standard roofs, with cool roofs proving most effective in Brussels, while green roofs excel in hotter climates like Madrid. In future climate scenarios, as temperatures shift northward, green roofs were projected to offer better thermal comfort in Brussels. However, it is important to note that the case study building used in this research did not represent a typical structure for Madrid's hotter climate, given its large windows and lack of external shading. In such cases, mitigation strategies alone are insufficient to maintain comfort during extreme heat. Simple measures, such as adding daytime

shading and utilizing natural night ventilation, could significantly improve thermal comfort. Further studies are needed to assess the thermal performance of these mitigation strategies in buildings with diverse typologies in both climates. Additionally, research should investigate other factors, including cost, energy performance, stormwater management, and environmental impacts such as biodiversity. Finally, future studies should explore the potential of combining multiple strategies across various roof types to reduce the urban heat island effect and enhance both building and environmental comfort.

ACKNOWLEDGEMENTS

This work builds on the Master's thesis conducted by Sanae Chaga at the Vrije Universiteit Brussel. The case study and parts of the methodology - including the use of an EnergyPlus script and material parameter specifications - have been adopted from the original research.

SUMMARY
This study examines the impact of potted tree configurations on $PM_{2.5}$ concentrations from air traffic emissions near Schiphol Airport. Air quality sensors collected data between 2022 and 2024 at a field lab 5 km from the Kaagbaan runway. ENVI-met simulations were first validated and calibrated using ground-truth measurements under stable meteorological conditions, followed by simulations of $PM_{2.5}$ concentrations across six tree configurations in the field lab. The *'V7_End_Dense'* configuration achieved the greatest $PM_{2.5}$ reduction, while *'V2_Dispersed'* and *'V3_Double_Row'* showed moderate effects. In contrast, *'V4_Exposed,' 'V5_Exposed_Dense,'* and *'V6_Gate_Dense'* unexpectedly hindered reduction, highlighting the complex interactions between wind corridors, tree layouts, and built environments. The findings emphasise the need for long-term ENVI-met validation against real measurements, as seasonal variations were not captured in short-term analyses. Despite limitations, the study provides practical guidance for urban designers, highlighting the nuanced role of green infrastructure in mitigating aircraft-induced air pollution and emphasising the complexity of wind and pollution dynamics in urban environments.

Keywords: $PM_{2.5}$, aircraft emission, urban morphology, urban green infrastructure, tree configuration

1. INTRODUCTION

Particulate matter ($PM_{2.5}$) is widely recognised as a major contributor to illnesses such as heart disease, respiratory infections, and chronic lung disease, causing approximately 4 million deaths worldwide (Thangavel et al., 2022). Schiphol Airport, one of the busiest airports in the country, exposes nearby residents to elevated pollutant concentrations from air traffic, increasing health risks (RIVM, 2019). Research shows that linear green infrastructure positively impacts $PM_{2.5}$ concentrations (Jeong et al., 2023a); However, studies on the effects of different tree configurations on air pollution, especially $PM_{2.5}$, remain insufficient compared to research in other domains such as urban heat, noise, and glare pollution (Lugten et al, 2024, Wuite et al, 2023). From a planning perspective, it is crucial to explore how trees mitigate air traffic-related pollution and identify the most effective tree configurations for filtering $PM_{2.5}$, benefiting residents exposed to air traffic pollution. To address this, the Urban Comfort Lab (UCLab) at AMS Institute established a field lab in Hoofddorp, located less than 1 km from Schiphol Airport's Kaagbaan runway. Between 2022 and 2024, the lab collected empirical data on sound pressure levels, air quality, meteorological conditions, and flight activity. These data form the foundation for ongoing and future research in a semi-controlled lab environment, aimed at evaluating the pollution mitigation effects of urban greenery. The lab findings are intended to address real-world challenges related to climate and built environments.

According to Dellaert and Hulskotte (2017), air pollutant emissions from civil aviation including PM have increased significantly in recent years in the Netherlands. Green infrastructure, such as trees, can help reduce urban $PM_{2.5}$ concentrations (Isaifan & Baldauf, 2019b). Jeong et al. (2023b) examined the impact of urban street trees on $PM_{2.5}$ concentrations and found that reductions depend on tree presence and planting structure. Notably, areas with multi-layered planting structures (e.g., shrubs, arbours) experienced greater reductions. Similarly, Wu et al. (2021) assessed three road green belt configurations and found that combinations of arbour and shrub species performed best in reducing PM concentrations from road traffic.

Although studies on tree impacts on air pollution and $PM_{2.5}$ are limited, existing research suggests trees can mitigate pollutant concentrations by capturing particles or reducing secondary pollutant formation (Isaifan & Baldauf, 2019a). Chen et al. (2017) investigated different abilities of tree species to capture $PM_{2.5}$ after rainfall and identified species with high PM-capturing potential in urban areas. Liu et al. (2022) used ENVI-met (a numerical modelling tool) to analyse how tree height influences $PM_{2.5}$ concentrations near roads and found that the optimal height depends on street canyon openness. Traffic-related PM emissions can also be affected by trees, evidenced by Popek et al. (2022) who studied PM accumulation in urban forests and identified key influencing factors, including crown width, leaf area density, and seasonality.

While existing studies explore tree characteristics (e.g., height, crown width) and their effects on PM emissions from road traffic, very rare research has examined PM emissions from air traffic or their correlation with tree configurations (e.g., tree layout). This gap is likely due to the lack of long-term aircraft pollution measurements beneath tree canopies at street level, as well as the confounding effects of urban heat islands (UHI) from diverse anthropogenic activities. This paper examines aircraft emissions and three key factors influencing simulation accuracy: area geometry (e.g., courtyards, tree configurations), pollutant sources (e.g., air traffic volume, emission position), and meteorological conditions affecting dispersion.

2. MATERIALS & METHODS

2.1 Data

ENVI-met is a 3D modeling software for microclimates and pollutant dispersion, but its accuracy in simulating particulate matter (PM) remains uncertain. Despite significant model limitations, some studies suggest it performs well in modeling PM10 dispersion in urban street canyons (Hofman & Samson, 2014; Paas & Schneider, 2016). Therefore, we assess the validity of ENVI-met in simulating $PM_{2.5}$ concentrations before evaluating intervention strategies.

Figure 2. ENVI-met model (left); Courtyard 2 double-row tree (middle); Courtyard 1 without vegetation (right)

The raw weather files were retrieved from the KNMI weather services and morphed with UHI effects to force the boundary conditions of the ENVI-met model. The simulation period was set to September 2023 to ensure a comprehensive comparison with measured $PM_{2.5}$ concentrations, as this month had the highest recorded levels and the most complete dataset for the double-row tree configuration. Double row in courtyard 2 was chosen to be the tree configuration for validation and courtyard 1 was kept bare comprising a geometry with a slanted roof during simulation period. The layout of courtyards and double row tree configuration are shown in Figure 2.

Historical meteorological data for September 2023 was retrieved from the KNMI database and linked to a weather mast at Schiphol Airport. The dataset includes cloud cover, wind direction, wind speed, air temperature, relative humidity, and precipitation. Meteorological conditions from 6am on 14 Sep 2023 to the same hour on 17 Sep 2023 were extracted to adjust boundary conditions for validation, calibration, and simulation in ENVI-met. Using measured hourly flight data, hourly $PM_{2.5}$ emissions from air traffic at Kaagbaan were calculated and implemented as a line source emission in ENVI-met, following the equation (1) by Smulders (2022).

$$Line\ source\ \left[\frac{\mu g}{m*s}\right] = \frac{N*E*1000[\frac{\mu g}{mg}]}{d} \quad (1)$$

Where

N: number of hourly flights
E: PM emissions (mg/s) per flight
d: average distance between fights (m), 4167m

2.2 Simulation constraints

Over the past three years (2021–2024), the UCLab collected air pollution and meteorological data at a high temporal resolution (10-minute intervals). To ensure representative longitudinal analysis, specific criteria were applied: periods with relatively high $PM_{2.5}$ concentrations were selected for simulation validation. Precipitation-free conditions were prioritized to avoid biases from wetting losses and splashing effects, as the Nanenos partector 2 (<30% error), BC Carbon (<25% error), and NodeMCU sensors V3 (<10% voltage-dependent error) have limited correction capabilities (Bezantakos et al, 2024; Naneos Particle Solutions GmbH, 2022). Wind direction was restricted to northeast–southwest, aligning with in-situ measurements identifying Kaagbaan runway as the primary pollution source, with emissions dispersing southwest (Thielen et al., 2024a). Wind speeds at roof level (10m) were kept below 3 m/s, as higher speeds negatively correlate with $PM_{2.5}$ concentrations (Wang & Ogawa, 2015; Thielen et al., 2024b). Relative humidity was capped at 85% to maintain sensor accuracy and avoid misreading water particles as PM (Casari & Po, 2023). Finally, ENVI-met simulations were extended to 72 hours to ensure model convergence.

2.3 Validation and calibration protocols

ENVI-met validations and calibrations were iteratively conducted to assess atmospheric stability, verifying pollutant source presence, wind conditions, and courtyard materials. Validation was performed at a single point in the courtyard due to limited apparatus availability, selected based on PM sensor locations (Figure 3). Two citizen sensors were positioned at (29, 36) in Courtyard 1 and (29, 44) in Courtyard 2, both 1.5m above ground. Measured and simulated $PM_{2.5}$ concentrations were compared across multiple calibration rounds, with results presented as time series data and discrepancies quantified using Root Mean Square Error (RMSE). Due to instability,

a constant wind direction (averaged over 72 hours) was maintained to approximate real-world conditions. Sensitivity tests included pollution source height (1-18m), configuration (line vs. surface source), and emission intensity normalization (divided by number of different heights, in this paper they are 18 for the wide surface or 36 for the narrow one) when transitioning from line to tilted surface sources. Once the calibrated scenario best aligned with measurements, it was applied as the boundary condition in ENVI-met for the follow-up simulations with different trees interventions.

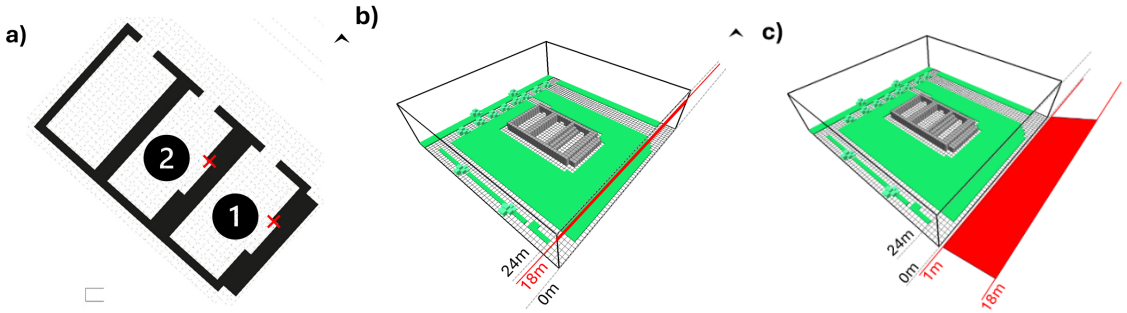

Figure 3. a) Positions of citizen sensors (red crosses) in Courtyard 1 and 2, b) Pollutant source as a line at 18m, and c) Pollutant source as a tilted plane, consisting of 18-line sources ranging from the height of 1m to 18m

2.4 Tree configuration

All seven configurations, including the baseline 'Bare' scenario (no vegetation) were selected from the tree configuration log (Figure 4) and tested in ENVI-met to assess their impact on air pollution.

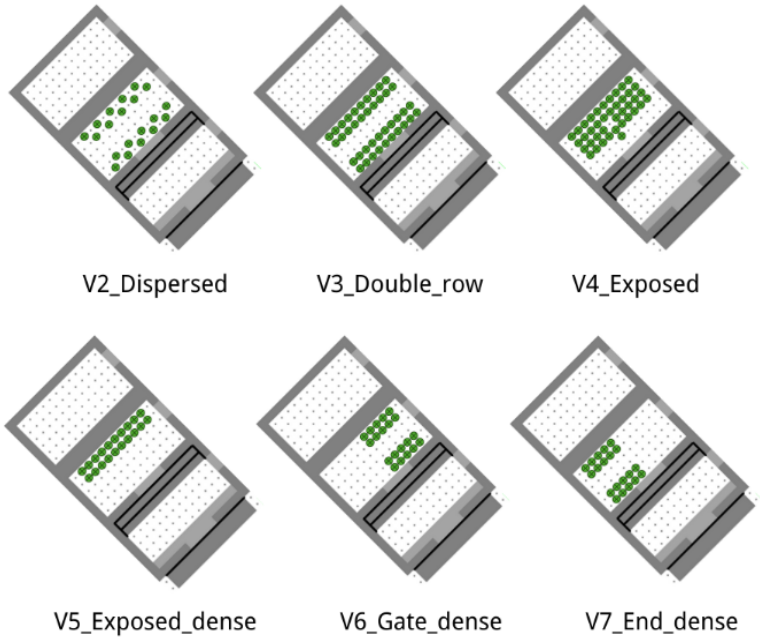

Figure 4. Tree configuration log in Courtyard 2, UCLab, from 2023 to 2024. V3 was used for validation.

3. RESULTS

3.1. Validation and calibrations

The RMSE results indicate that the modified pollution source aligns most closely with the measured data (Figure 5). Figure 6 illustrates PM diffusion in the Y-Z section under the modified pollution source, featuring a line-to-surface source with 18 steps at uniformly spaced heights.

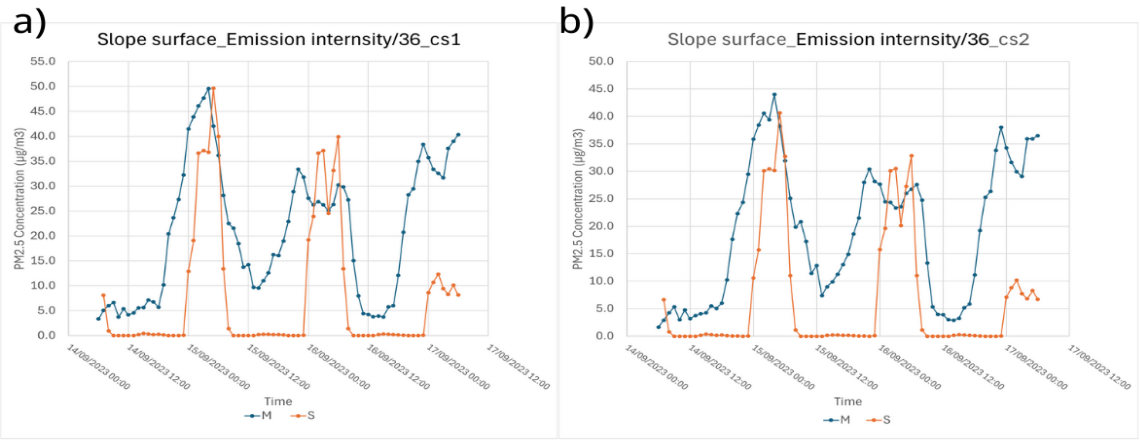

Figure 5. Temporal validations comparing simulated $PM_{2.5}$ concentrations with measured data in a) Courtyard 1 and b) Courtyard 2 (blue line: measurements, orange line: simulation).

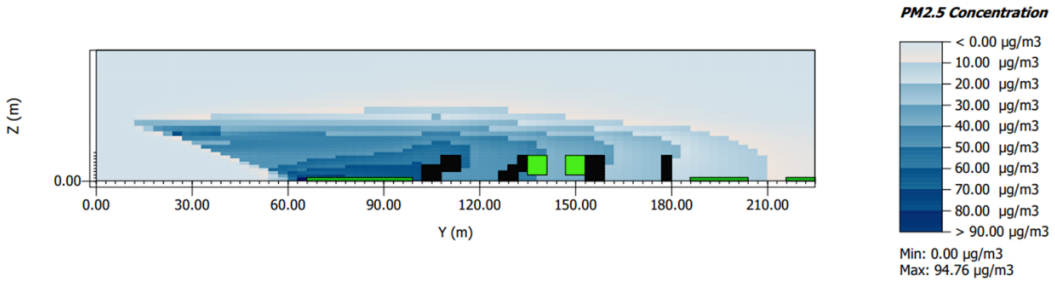

Figure 6. Y-Z section of PM concentration with Pollutant source as a tilted plane

3.2. $PM_{2.5}$ patterns with different tree configurations

Courtyard 2 (trees courtyard) was meshed and divided into 78 grids, and the absolute PM concentration difference for each grid was calculated. Figure 7 illustrates the intra-courtyard $PM_{2.5}$ concentration at 6am and the difference with other five tree variants. The *V7 End Dense* and *V3 Double Row* configurations demonstrated the most significant $PM_{2.5}$ reductions compared to other layouts. The largest reductions occurred at the end side and upper left side of Courtyard 2, while $PM_{2.5}$ concentrations increased near the gate side.

Figure 8 presents the descriptive statistics of absolute PM concentration differences for each tree configuration, supported by a Kruskal-Wallis test. The negative average absolute difference in PM

concentration between *V3 Double Row* and *B1 Bare Ground* indicates that the double-row configuration effectively reduces $PM_{2.5}$ concentrations in Courtyard 2. In contrast, the positive average absolute difference for *V4 Exposed* suggests an increase in PM concentration compared to the baseline. Among configurations with 20 trees, *V2 Dispersed* and *V7 End Dense* contributed to PM reduction, with the greatest decrease under *V7 End Dense*. Conversely, *V5 Exposed Dense* and *V6 Gate Dense* led to increased PM concentrations in Courtyard 2.

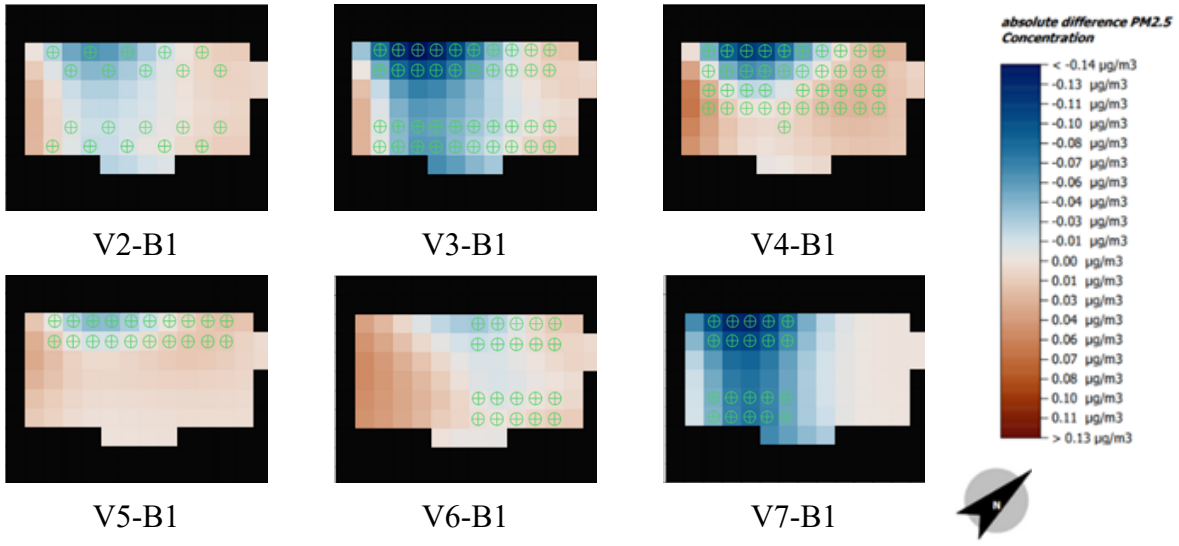

Figure 7. Absolute difference of PM concentration in grids of courtyard 2 (tree courtyard) at 6am.

	V2_B1	V3_B1	V4_B1	V5_B1	V6_B1	V7_B1
Mean	-0.00548	-0.02913	0.004863	0.007234	0.010225	-0.03678
STD	0.018442	0.038209	0.033129	0.012244	0.019581	0.03509

Figure 8. Descriptive statistics of the absolute PM concentration difference at 6:00 AM for each tree variant (V) compared to the baseline (B). Orange represents variants with 40 trees, and blue denotes those with 20 trees.

4. DISCUSSIONS & CONCLUSIONS

This study demonstrates that under controlled conditions—constant wind direction (averaged over the simulation period), a pollutant source modelled as a tilted plane (1 m to 18 m high), and emission intensity scaled to 1/36 of the initial value—ENVI-met performs well in simulating $PM_{2.5}$ over a 72-hour period in September compared to real measurements. Among the six configurations tested, the *End-Dense* layout had the most significant impact in reducing $PM_{2.5}$ concentrations in courtyard spaces affected by air traffic pollution. For urban planners, these findings highlight the importance of considering both pollutant dispersion patterns and site-specific wind conditions when designing tree layouts. Dense tree clusters in strategic locations, such as pollutant accumulation zones, can effectively reduce $PM_{2.5}$ concentrations, while uniform tree distribution may help prevent wind corridors that allow unfiltered pollutant flow. We recommend that tree configurations should balance air pollution mitigation with acoustic and thermal effects, adopting a multidimensional approach to enhance overall urban comfort. Future research should incorporate additional pollutant sources, particle size interactions, and long-term simulations to improve the accuracy and applicability of $PM_{2.5}$ reduction strategies in diverse urban environments.

ACKNOWLEDGEMENTS

The research is funded by the municipality of Haarlemmermeer, the Dutch ministry for infrastructure and water management, the Dutch ministry for housing and domestic affairs, Stichting leefomgeving Schiphol, and the AMS institute for advanced metropolitan solutions. T. Li would like to express his gratitude to the Urban Comfort Lab team for their support. Special thanks to M. Lugten for organising weekly meetings and providing feedback, Z. Peng for guidance on ENVI-met modelling and proofreading, G. Wuite for support on data analysis, and H. Zheng for expertise on air quality. He also extends his appreciation to B. Thielen for onboarding assistance and valuable suggestions on the research topic on urban air quality.

SUMMARY
Urbanization leads to the loss of green spaces, which results in ecosystem degradation and diminishes the quality of life for residents. Consequently, urban areas are facing significant challenges related to human well-being and ecosystem health. Incorporating ecological principles into the design process at various scales (from buildings to the urban scale) can greatly improve ecological sustainability, reducing environmental degradation, and enhancing comfort and livability conditions for humans. The ECOLOPES project developed an innovative design approach, along with related methods and tools, to incorporate ecological processes and objectives into the design of building envelopes. This contribution presents the interdisciplinary design process and some of the computational components developed, outlining the implications and future perspectives.

Keywords: Urban greenery, ecology, optimization, microclimate

EXTENDED ABSTRACT

Urbanization is regarded as one of the most transformative processes, significantly altering ecosystems' biotic and abiotic characteristics and substantially impacting biodiversity and ecosystem services. Several studies highlight the crucial role of green spaces within cities in supporting biodiversity and enhancing human well-being, thanks to ecosystem services provision (Sadler et al. 2010). Conversely, evidence indicates that higher population density facilitates the development of compact, low-carbon cities, which help preserve habitats at the edges of expanding urban areas while promoting walkable and more livable environments (McDonald et al., 2023).

The ECOLOPES design approach aims at introducing ecological knowledge and related data into the architectural design process (Weisser et al. 2023). To do this, we integrate the ecological requirements and ecological consequences into the architectural design process. This was achieved by modifying the standard architectural design process (Figure 1). Importantly, the general workflow of building design is not changed, but enriched to include the requirements of plants, animals and other living organisms, i.e. non-human inhabitants, as highlighted in Figure 1. One important advance in the ECOLOPES project is that the use of Key Performance Indicators (KPIs) that address the needs of human, and of other species, aligning design development with the dual objectives of designing for humans as well as for other inhabitants such as plants (Selvan et al. 2023). The selection and assessment of appropriate KPIs have proven effective in aligning design development with the dual objectives, which depend largely on the ecological knowledge and data

that designers acquire at the outset.

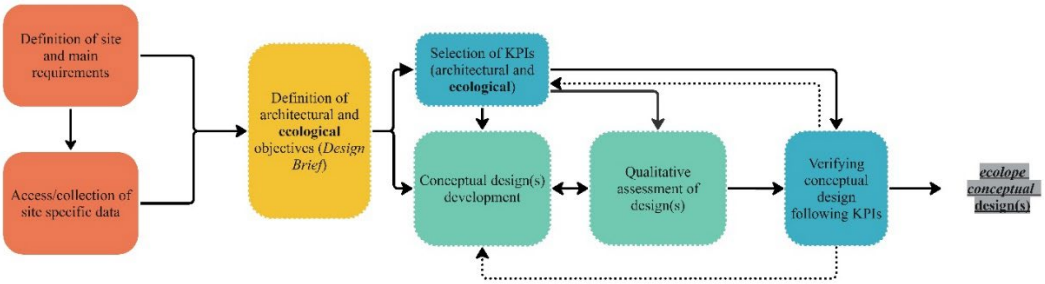

Figure 1. ECOLOPES simplified design workflow (based on Weisser et al., 2023).

The design workflow was tested by master students at the Technical University of Munich, in order to identify the potential and the limitations of the ECOLOPES approach. We will now briefly describe some of the components developed within the ECOLOPES project to support the design process. A case study in the city of Munich (Neuperlach district, in the South-East area of the city) is finally presented to show how a design proposal can be developed following the envisioned design process.

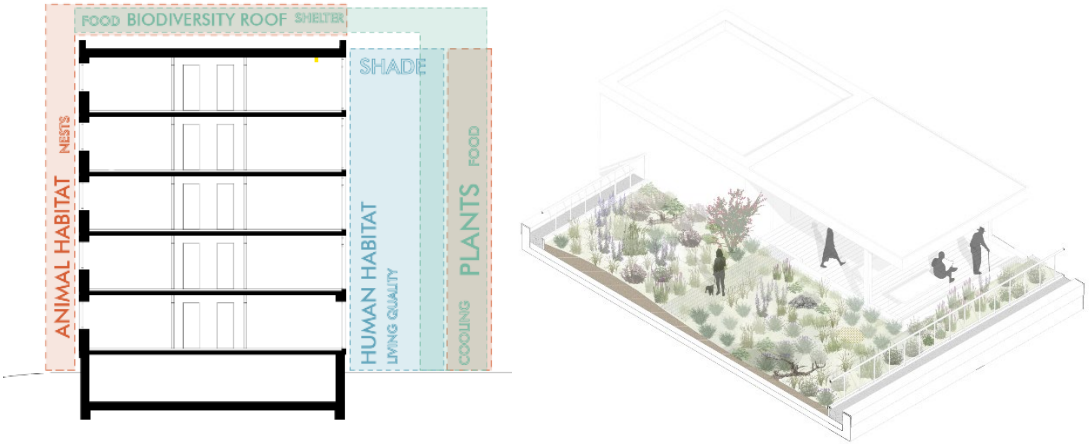
To address the needs of the plants and animals, it became clear that it would be necessary to integrate into the design workflow the interactions between the building, humans, and the other inhabitants (Grobman et al. 2023). This is because the way a building is designed will affect where plants and animals can live. Conversely, plants and animals will modify the building (environmental) conditions, through processes such as colonization, extinction and succession. In this context, interactions and the further development of the site are highly relevant. For this reason, ECOLOPES has started to develop a **plant-animal-soil model** that can simulate the development of the plant and animal community based on soil conditions, and the mutual feedback between the building, plants and animals. In order to deal with the enormous variety of organisms, the project chose to summarize plant and animal species in plant and animal functional groups (Weisser et al. 2023). The model will evolve in complexity over time. At present, buildings affect plants mainly by the shading they exert on plants, and by the depth of soil on various surfaces. The geometry of the building affects the locomotion of animals and the number of resources, for example, the amount of plant biomass, affects what animals can occur on or next to the building, and what their home range is.

Another component is the **optimization** and evaluation of *ecolopes* design alternatives, based on a hybrid multi-criteria decision-making (MCDM) (Selvan et al. 2023). In particular, a model was developed to facilitate the refinement of multispecies distribution on an *ecolope* based on inhabitants' objective priorities. The model sequentially employs multi-objective (MODM) and multi-attribute decision-making (MADM) to streamline the computation of key performance indicators, such as Soil volume, Solar Radiation, Local PFGs richness, Structural Connectivity, informed by ecological knowledge for architectural design decision-making. The resulting ranked alternatives can be represented geometrically, through a catalogue format, and numerically, through dataframes describing the overall performances of the alternative pool and the abiotic and biotic metadata of each cell per alternative.

The assessment of ecological building envelopes' **impact on microclimate** can then be implemented through the integration of Plant Functional Groups (PFGs) features into a computational-fluid-dynamics (CFD) simulation approach, allowing a stronger connection between ecological and environmental performances. Based on geometrical features of PFGs, such as crown diameter and plant height, the group of plants can be modelled in the 3D CAD

environment and their capacity to provide shading calculated. The integration of this component into the design process serves as a starting point for including the quantification of the environmental performance of the envelope, in addition to ecological performance, with the aim of supporting the ecosystem while also enhancing livability in urban areas (Mosca et al., 2025). Eventually, the interactions between the building and the inhabitants will be encapsulated in an ontology. The **Ontologies** provide knowledge representation for reasoning and can be queried by the designer and aid rule-based processes (Pruski & Hensel, 2022). The initial design consists of (1) the *translational* process and (2) the *generative* process. In the former the designer analyses, correlates, and spatially locates architectural and ecological requirements contained in a design brief, taking into consideration relevant constraints. This process involves a knowledge graph that is queried by the designer to support decision making concerning spatially locating architectural and ecological elements in the CAD environment. The spatially located elements in the CAD environment and datasets in the ECOLOPES Voxel Model, are input for the *generative* design process in which rule-based generative processes are aided by ontologies, resulting in variations of spatial organization and surface geometry in urban and building scales. Design outputs of the initial design stage are 3D geometry in Rhinoceros 3D, datasets in the ECOLOPES Voxel Model, and ontological output.

Case study: The proposed approach has been applied by an interdisciplinary team of architects and landscape architects, supported by ecological experts, to renovate building façades in Munich as a case study. The project focused on the 3D transitional space beyond the building envelope proposing refurbishment strategies to address two key challenges: wildlife damage to the building envelope and excessive heat on the south-facing balconies. Computational tools optimized soil distribution in the gabion walls and balcony sizes, while plant selection for the southern façade was based on sun exposure analysis. Vegetation will completely envelop the structure, improving air quality, reducing the urban heat island effect, and serving as a model for sustainable urban architecture. Figure 2 shows the application of the design workflow on the real case study described and the proposed design outcomes.



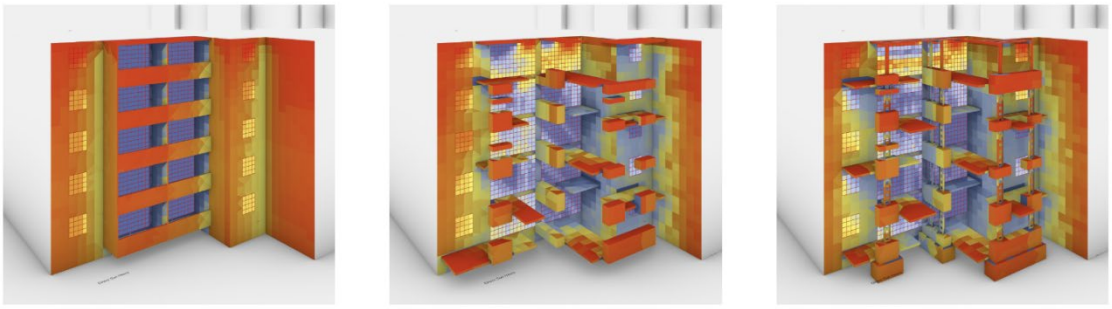


Figure 2. ECOLOPES case study concept and visualization. Top: concept and floor plan; bottom: façade surface temperatures from current state to design project, high (red) to low (blue) (credit: Lukas Meisner, Nairi Koulakezian, Nicklas Neubauer, Lewin Schmid).

Summary and future perspectives: The ECOLOPES approach can lead to integrating the interactions between the building, humans, and the other inhabitants in the design process. This establishes foundational frameworks for future advancements at multiple scales, such as environmental integration within urban infrastructure and architectural elements for the building envelope, multispecies components for animals and plants. Furthermore, considerations arise regarding the maintenance needs of multispecies habitats and their integration into existing building maintenance protocols. Additionally, the interplay between humans, animals, and plants—particularly human responses to the introduction of animals into urban environments—requires careful consideration and understanding of its broader implications.

ACKNOWLEDGEMENTS

The presented work summarizes part of the results achieved within the ECOLOPES research project, funded within the EU H2020 FET-OPEN program (grant agreement number 964414, https://ecolopes.org/). All the ECOLOPES partners and members are thanked for their fundamental contribution.

Modelling control schemes of a desalination battery for electrolysis and trigeneration designed for ships at seaports

Himanshu Dehra

Monarchy of Concordia, Wellstar Beacon Labs, Faridabad, India, anshu_dehra@hotmail.com

ABSTRACT

The objective of this study is to present a generalized scheme for simultaneously achieving: i) desalination with a rechargeable seawater battery using Na metal redox flow cell system; ii) electrolysis of water for hydrogen production in a separate electrochemical cell; iii) trigeneration for heat, cooling and electric power using direct-current generator's engine utilizing hydrogen blend as fuel. Sodium metal-based battery systems have recently attracted increasing research interest due to the abundant resources of the raw materials with use of seawater and sodium related compounds as the positive and negative electrodes. The extra stream of freshwater is utilized in the electrolysers for generation of hydrogen as a blended fuel for marine engines. Considering the thermal processes with the utilization of heat recovery, this study proposes a novel auxiliary trigeneration system for ships based on the waste heat of its engine to produce electricity, cooling, and freshwater. The system consists of a regenerative organic Rankine cycle with R600 working fluid, a lithium-bromide/water single-effect absorption chiller, and a sodium metal-based desalination battery unit. The integrated control scheme of the full system configuration with a redox flow battery is summarized both from the ship's micro grid and energy storage sides. The control technology of the redox flow sodium metal seawater battery energy storage system is also briefly outlined.

Keywords: Desalination Battery, Electrochemical Cell, HVAC.

1.0 INTRODUCTION

An electrochemical reactor or cell is a device that can generate electrical energy from the chemical reactions occurring in it, or use the electrical energy supplied to it to facilitate chemical reactions in it (Haverkort, 2024). These devices can convert chemical energy into electrical energy, or vice versa. In the electrochemical flow reactor, there are combined features for processes of electrochemistry and flow chemistry, example is a parallel-plate industrial electrolyser for generation of hydrogen from electrolysis of water (Rajora et al., 2022). Figure 1 presents a simple tank cell based electrochemical flow reactor.

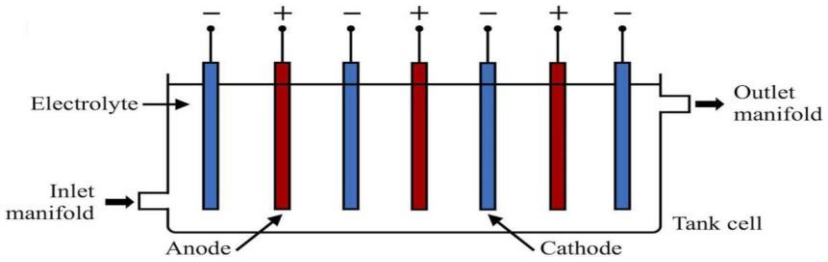

Figure 1. Electrochemical flow reactor

The Seawater battery with desalination (SWB-D) process, which is an electrochemical redox flow reactor, has been experimentally tested only in a steady-state (or batch) at the laboratory scale mode so far, so there was not much consideration for limiting factors such as the diffusion of ions and conductivity of influent solution. In the current scenario, the continuous flow cell of SWB-D process is tested at the laboratory scale in South Korea and Italy (see Figure 2) (Son, et al, 2022; Barelli et al, 2023). To compare SWB-D technology with other seawater desalination technologies, the development of a continuous process such as a flow-cell, which is exclusively designed for ships to eventually fully commercialize the technology must be investigated. The schematic of a generalized redox flow battery is presented in Figure 3, whilst the generalized design parameters for the electrochemical flow reactor are presented in Figure 4.

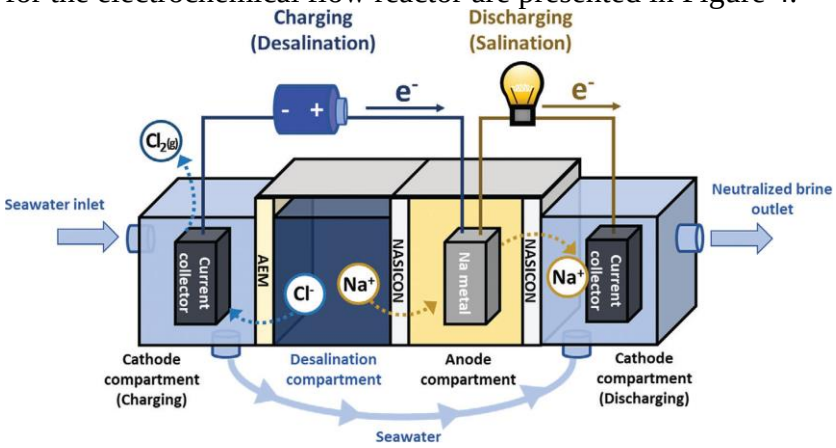

Figure 2. Schematic illustration of the SWB-D system (Son, et al, 2022)

2.0 PERFORMANCE INDICATORS

Performance indicators of a good electrochemical flow reactor include (see Figure 4):
m, Mass transfer coefficient for 2D electrode;
k_mA_e, Volumetric Mass transfer coefficient for 3D electrode;
X_A, Fractional conversion of reactant;
STY, The space time yield of an electrosynthesis cell;
NSV, The normalized space velocity of environmental treatment cell.

Hydraulics parameters include:
Q, Volumetric flow rate of electrolyte, cm3/s; v, Mean linear flow velocity past the electrode surface, cm/s; P, Pressure, Pa; Re, Renard's number

Requirements of good flow cell:
- High productivity
- Good mass transport
- Good temperature control
- Low electrical resistance
- Ease of operation
- Safety in operation
- Ability to deal with gaseous products and reactants
- Minimum cost

3.0 OBJECTIVES AND PROCESS FLOW DESCRIPTION

The objectives of this study are summarized as follows:

a) The objective of this study is to present integrated process flow scheme for simultaneously achieving (Dehra, 2024) (see Figure 5): i) desalination with a rechargeable seawater battery using Na metal redox cell system; ii) electrolysis of water for hydrogen production in a separate electrochemical cell; iii) trigeneration for heat, cooling and electric power using direct-current generator's engine utilizing hydrogen blend as fuel. The integrated control scheme of the full system configuration with a redox flow battery is summarized both from the ship's micro grid and energy storage sides.

b) The control technology of the redox flow battery energy storage system is also briefly outlined.

Once this energy technology is developed, it will be utilized in the ship's power plant for improving its energy efficiency. Sodium metal-based battery systems have recently attracted increasing research interest due to the abundant resources of the raw materials with use of seawater and sodium related compounds as the positive and negative electrodes. Upon charge, Na+ ions are reduced in the anodic compartment, which needs to be closed, (i.e., isolated from seawater via a solid electrolyte layer enabling the flow of Na+ ions only) while several oxidation reactions can

take place at the positive electrode, such as the oxidation of hydroxide anions (OH-) resulting in the oxygen evolution reaction and that of chloride ions (Cl-) resulting in the formation of chlorine. Herein, the sodium seawater battery technology considered employs sodium-biphenyl (Na-BP) as the anolyte (Kim et al., 2022). Seawater battery cells utilizing biphenyl have demonstrated high energy efficiency, exceeding 80%, which is higher than lead-acid batteries and vanadium redox flow batteries. The use of sodium metal seawater system as large-scale, stationary, rechargeable batteries, these cells can also be utilized for production of sodium metal from seawater via the extraction of sodium produced at the negative electrode. An important by-product of the sodium metal production (i.e., the charging phase) via seawater cells is chlorine (Cl2). This is a precious reactant chemical heavily used by the chemical industry, which commercializes many chlorine-containing compounds. The potential use of sodium production via seawater cells is desalination, by a modification of this system for producing freshwater. The extra stream of freshwater is utilized in the electrolysers for generation of hydrogen as a blended fuel for marine engines.

Considering the thermal processes with the utilization of heat recovery, this study proposes a novel auxiliary trigeneration system for ships based on the waste heat of its engine to produce electricity, cooling, and freshwater. The system consists of a regenerative organic Rankine cycle with R600 working fluid, a lithium-bromide/water single-effect absorption chiller, and a sodium metal-based desalination battery unit. A multi-heat recovery technique is implemented in this conceptual design framework, having a well-organized waste recovery system with three subsystems (Cao et al, 2022).

Firstly, using the heat-based energy of the hot exhaust gases of the ship's engine, the Rankine cycle is inducted via a high recovery vapor generator. By conveying heat, the combustion gases are purged out of the system. The Rankine cycle uses the R600 organic working fluid (Jiménez-García et al., 2023). The R600 organic working fluid enters pump in the form of saturated liquid and is directed towards the vapor generator and receives heat from the combustion gases leaving the ship's engine. Thereafter, it enters the turbine where it is expanded, and a share is drawn out of it and sent back to the open feed heater. After producing mechanical work energy which is converted to electrical power by a direct-current (DC) electrical generator. The rest of the stream is conveyed to a generator of single-effect absorption refrigeration cycle. By transfer action, the heat enters a condenser to turn into saturated liquid and is then sent to the feed heater via another pump, together with the turbine's exit, and this cycle is repeated. In the absorption refrigeration cycle that utilizes water (H2O) as the refrigerant and lithium bromide (LiBr) as the absorbent, the weak solution leaves the absorber and is pumped to the heat exchanger. The preheated weak solution enters the refrigeration cycle's generator.

The Direct-Current (DC) generator distribution system has been proposed in this research, as a replacement for the alternating-current (AC) power distribution system for ships with electric propulsion. The biggest potential with DC generator for fuel savings lies in the ease with which energy storage devices, such as batteries or super capacitors, can be easily added to the DC system. Energy storage will help the marine engines level out load variations from the thrusters and other large loads. DC distribution system allows for new ways of thinking regarding operational optimization. The system is flexible and can combine different energy sources such as engines, turbines, and fuel cells. This means that there is the potential to implement an energy management system that considers varying fuel prices and the availability of different fuels (ABB, 2011).

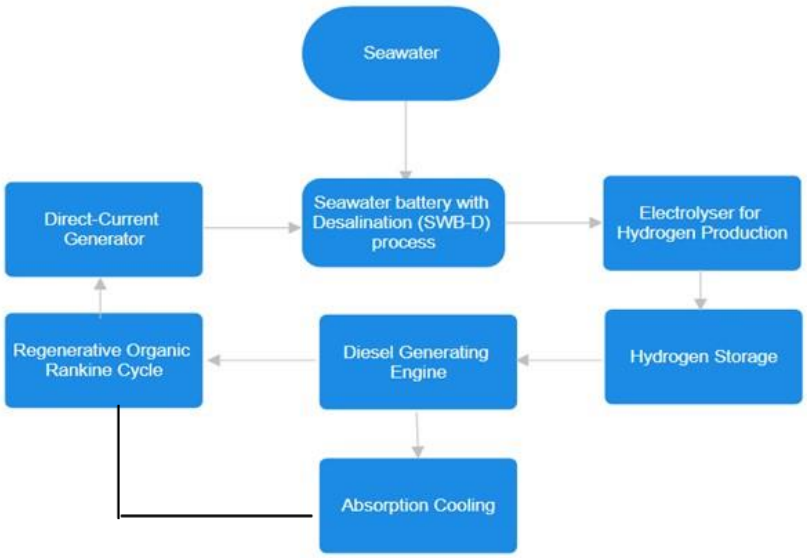

Figure 5: Process Flow Diagram of a Desalination Battery for Electrolysis and Trigeneration

3.1 On the Advantages of Sodium Metal Batteries

Sodium ion batteries have advantages of rich resources, low-cost, high-energy conversion efficiency, long cycle life, and low maintenance cost, which have been regarded as a promising energy storage technology. But due to their relatively low energy density compared with the commercialized lithium–ion batteries still impede their application for power systems. Anode–free rechargeable sodium–metal batteries (AFSMBs) pose a solution to boost energy density and tackle the safety problems of metal batteries. Combination of electrolyte, interface, and current collector strategies will eventually bring the AFSMBs closer to high energy and long–life AFSMBs for energy storage systems or power batteries. The strategies such as electrolyte optimization, interfacial chemistry engineering, and current collector modification, are also expected to be utilized for better understanding of anode-free rechargeable sodium-metal batteries (Ni et al., 2022). Sodium batteries demonstrate exceptional performance stability and capacity retention across a wide temperature spectrum. This unique characteristic positions them as a highly promising technology for various applications in extreme environments. As research progresses and costs continue to decline, sodium batteries are poised to play a transformative role in the future of electric vehicles, energy storage systems, and renewable energy integration.

3.2 Quantifying Performance: Capacity Retention Rate

The capacity retention rate is a vital indicator of how well a battery holds its original capacity under varying temperatures. Sodium batteries shine in this aspect too, exhibiting remarkable stability across a wide range of -40°C to 80°C.

- **Low-Temperature Capacity Retention:** Even at -40°C, sodium batteries can retain over 70% of their capacity. This is a testament to their optimized design and the use of low-temperature-friendly electrolytes. These features allow sodium batteries to deliver high energy output and efficient charge-discharge cycles even in extreme cold.
- **High-Temperature Capacity Retention:** Similarly, under scorching temperatures of 80°C, sodium batteries retain over 80% of their capacity. This impressive feat is a result of their inherent high-temperature stability and the effectiveness of their thermal management systems. By keeping the internal temperature low despite the external heat, these systems

ensure continued performance stability.

3.3 Modelling Control Schemes

Here are some important pointers to consider when modelling and controlling a sodium metal based redox flow battery (RFB):

- **Electrolyte**: The electrolyte concentration and capacity can be changed to alter the energy storage capacity of the battery.
- **Reactor size**: The output power of the battery can be changed by adjusting the size of the reactor.
- **Charging and discharging**: The charging and discharging efficiencies of the RFB increase as the power increases.
- **Pump loss**: The pump loss is relatively constant, so the charging and discharging efficiencies of a RFB increase as the power increases.
- **Charging power**: When the charging power is less than 9% of the rated power, the charging efficiency is considered zero. This is because the charging power is not enough to start the pump operation.
- **State of charge**: There are techniques to estimate the state of charge of a RFB.
- **Control strategies**: There are main control strategies for RFB systems.

A RFB system consists of three main components: the electrolyte, the cell stack, and the balance of plant (BOP). A Power Conversion System (PCS) is a device for bidirectional conversion of electrical energy connected between the battery system and the grid and/or load. This device should have charge and discharge functions, active and reactive power control functions and off-line switching functions. The PCS device enables the grid to work in both types of ships whether it is Direct-Current or Alternating-Current based electrical distribution system.

A "PCS Parallel System" refers to a system where multiple Power Conversion Systems (PCS) operate in parallel, meaning they are connected to share the load and work simultaneously, typically used in large-scale energy storage applications to efficiently manage the flow of electricity between the grid and battery storage units by combining the power output from several PCS units (Liu et al. 2023).

3.3.1 Key points about PCS Parallel Systems:

- **Function:** Each PCS acts as a converter, transforming DC power from the battery bank into AC power for the grid, and vice versa, allowing for bidirectional energy flow. In case the ship distribution system is based on DC power the PCS parallel system is based on DC-DC converter.
- **Redundancy:** By having multiple PCS units operating in parallel, the system can maintain power output even if one PCS fails, enhancing reliability.
- **Scalability:** This design allows for easy expansion of the energy storage capacity by simply adding more PCS units as needed.
- **Load Balancing:** The control system within the parallel PCS network can distribute the load evenly across all operating units, optimizing performance and extending lifespan.

3.3.2 Applications of PCS Parallel Power Systems:

- **Renewable Energy Integration:** To manage fluctuations in power generation from solar or wind farms at seaports coastal zones by storing excess energy in batteries and feeding it back to the grid when needed.

- **Microgrids:** To provide reliable power supply to the ship's localized area by combining distributed generation sources with Na metal seawater battery redox cell storage.

3.3.2 Important Design Considerations for PCS Parallel Systems

- **Synchronization:** Ensuring all PCS units are precisely synchronized to maintain stable power quality and avoid grid disturbances.
- **Control System Design:** Developing a robust control system to manage power sharing, fault detection, and protection mechanisms across the parallel PCS units. In a DC microgrid, such as in the ship "droop control" is a decentralized control strategy that enables multiple distributed power sources (like batteries or solar inverters) to automatically share load based on their available power. This is achieved by adjusting their output voltage slightly according to their current output, effectively acting like a virtual resistance to achieve balanced current sharing without the need for complex communication between devices. Essentially, the more current a source is supplying, the slightly lower its output voltage becomes, encouraging other sources to contribute more power to the grid. A droop control mode considering power cost, discusses the real-time relationship between the operation efficiency and control parameters by introducing bus voltage reference value, and realizes real time adjustment of droop coefficient of electric-hydrogen hybrid energy storage system (see Figure 6).

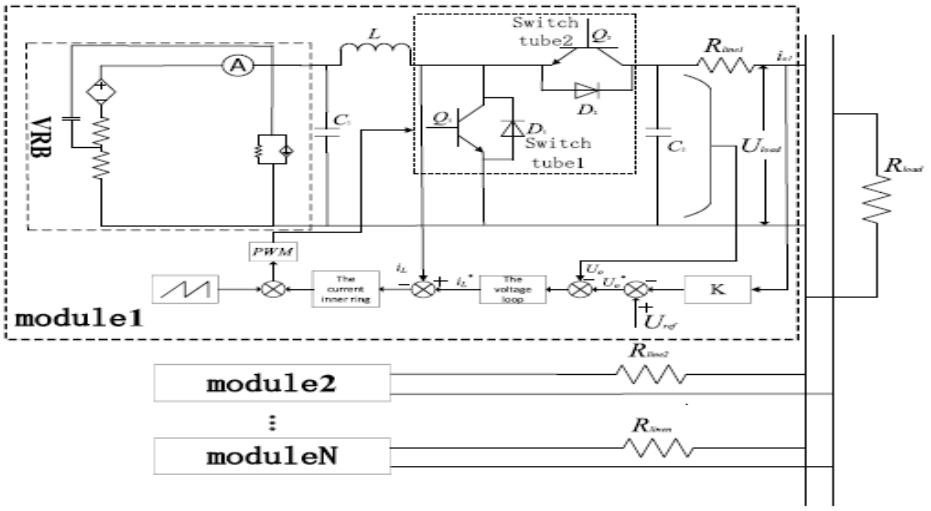

Figure 6. Droop Control Topology (Liu et al. 2023)

4. CONCLUSION AND FUTURE RECOMMENDATIONS

The paper presented a brief description of Seawater Battery with Desalination (SWB-D) system for electrolysis and trigeneration designed for ships at seaports. Currently, the shipping industry is facing many challenges for improving the fuel's energy efficiency. The ship power plant's energy efficiency can be improved and many strategies for decarbonization can be utilized (Barone et al., 2023). The proposed research is aiming at developing tools in COMSOL software and developing a Python code and linking it to the Arduino Cloud (for Python) (Rajora et al., 2022; Zheng 2023). These tools will be useful for modelling, simulation, and real-time control (for MIMO Control System problems such as Model-Predictive Control).

The modelling phase of this project comprises of the following i) model for Sodium Metal based

Redox Flow Desalination Battery; ii) model for the Electrolyser; iii) model for DC Electric Power from DG Engines/Gas Turbine Sets with hydrogen blend as fuel; iv) model for Absorption Cooling based on heat recovery from engine exhaust; vi) overall Mass & Energy Balance Model for calculating the energy-efficiency.

In general, the outcome of the study will be useful in: i) optimum utilization of earth's natural resources and switching from carbon economy to hydrogen economy; ii) modelling of systems through observer design with tipping point for GHG emissions and setpoint air temperature for multiple inputs and multiple outputs approach and considering the nature's abundant wealth of natural resources with transitioning through electrochemical energy conversion and storage through sodium batteries while switching from carbon economy to hydrogen economy.

The potential challenges related to practical shipboard implementation such as spatial constraints, system scalability, integration complexities, and maintenance requirements would be tested with complete full-scale experimental prototype exclusively designed with integrated control scheme for ships so as to guide future research for real-world applications.

SUMMARY
Canada's Pan-Canadian Framework aims to reduce GHG emissions by 40-45% by 2030 and achieve net zero emissions by 2050, with retrofitting existing buildings for energy efficiency being crucial to meet these targets. While prior literature reviews address energy efficiency optimization or Life Cycle Assessment (LCA) in isolation, the systematic decoupling of these domains has led to fragmented frameworks that fail to resolve the inherent tension between short-term energy savings and long-term lifecycle consequences. This study presents a systematic literature review on building energy retrofit optimization, focusing on integrating LCA for net-zero energy buildings. It explores optimization models, algorithms, tools, simulation software, and lifecycle considerations, highlighting gaps for future research. These gaps include uncertainties in simulation inputs, underrepresentation of non-residential buildings, neglect of social aspects, limited post-intervention monitoring, neglect of embodied energy, underutilization of LCA tools, lack of comprehensive life cycle inventory databases, exclusion of full life cycle phases, and the need for integrated approaches at the district scale.

Keywords: Building energy retrofit, Optimization, Life cycle assessment (LCA), Net zero energy buildings (NZBE)

1. INTRODUCTION

Buildings account for about 30% of worldwide energy use and greenhouse gas emissions (“World Energy Outlook 2024 – Analysis - IEA,” n.d.). In Canada, this challenge is amplified by an aging building stock: over 50% of residential buildings are older than 30 years, with 20% exceeding 50 years (“Residential Housing Stock and Floor Space | Natural Resources Canada,” n.d.). These aging structures often lack modern energy efficiency measures, contributing disproportionately to the sector’s carbon footprint. To address this, Canada has committed to an 80% reduction in carbon emissions by 2050 compared to 2005 levels, a target demanding urgent, scalable retrofitting strategies (“Government of Canada sets ambitious GHG reduction targets for federal operations - Canada.ca,” n.d.). While conventional retrofits focus on operational energy savings, achieving life-cycle net-zero energy (NZBE) requires a paradigm shift. As defined by the U.K. Green Building Council, true NZBE necessitates balancing both operational and embodied energy impacts over a building’s lifespan, ensuring net-zero emissions across all lifecycle phases (“2019: Net Zero Carbon Buildings: A Framework Definition | UKGBC,” n.d.). Additionally, retrofits inherently involve balancing upfront investments against long-term environmental, economic, and social benefits (Mostafazadeh et al., 2023). These interdependencies necessitate robust optimization frameworks to systematically evaluate trade-offs and identify Pareto-optimal solutions.

While existing literature reviews have investigated optimization methods for retrofitting existing buildings (Hashempour et al., 2020), genetic algorithm-based retrofit optimization approaches (Costa-Carrapiço et al., 2020), optimization of low-energy buildings (Longo et al., 2019), and building envelope optimization (Kheiri, 2018) and life cycle assessment (LCA) in buildings (Amini Toosi et al., 2020; Dahiya and Laishram, 2024; Li et al., 2020), a critical disconnect persists between energy optimization and LCA frameworks. This fragmentation has led to retrofit strategies prioritize short-term operational efficiency while neglecting embodied carbon impacts. Most existing frameworks fail to holistically integrate energy retrofit optimization with LCA methodologies, resulting in suboptimal solutions that hinder progress toward Net-Zero Energy Buildings (NZEB). This oversight underscores a pressing need for a unified approach that bridges energy performance optimization with lifecycle sustainability.

This study provides the first systematic synthesis of energy retrofit optimization and LCA studies to bridge this foundational gap to achieve NZBE. Unlike previous fragmented reviews, this work:

- Synthesizes critical components, objective functions, optimization models, algorithms, and tools, while explicitly linking them to lifecycle considerations.
- Identifies key synergies and trade-offs between operational energy savings and embodied carbon impacts, enabling more robust, future-proof retrofit strategies.
- Proposes a novel research agenda to advance integrated optimization-LCA frameworks, offering actionable insights for policymakers, engineers, and sustainability practitioners.

By harmonizing these currently siloed domains, this study not only fills a major methodological gap but also its findings are poised to reshape retrofit practices by ensuring that energy efficiency gains do not come at the expense of long-term environmental burdens.

2. METHODOLOGY

This systematic literature review follows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines to ensure methodological rigor and transparency (Moher et al., 2009). The search strategy was executed on the Scopus database on 9th January 2025. Titles, abstracts, and keywords were searched using the following query, which yielded 47 results:
(building* AND energy AND (retrofit* OR refurbishment OR rehabilitation OR renovation OR "existing building*") AND optimi* AND (lca OR "life cycle" OR life-cycle OR lifecycle OR embodied) AND (nzeb OR zeb OR "net-zero energy" OR "zero energy" OR "nearly zero energy"))

The screening process followed a sequential three-step approach to refine the results. First, 13 records were excluded during the initial screening phase due to non-English language, review articles, book chapters, or ineligible document types. Subsequently, title and abstract screening assessed relevance to the integration of optimization, retrofits, LCA, and NZBE principles, excluding 9 studies with insufficient focus on these themes. Finally, a full-text review evaluated methodological alignment with the study's scope, eliminating 6 articles. This process resulted in a final set of 19 articles for in-depth analysis.

3. RESULTS AND DISCUSSION

Table 1 presents a detailed summary of key aspects evaluated and discussed in the final screened papers.

3.1. Typology and building function

Studies on energy retrofit optimization are broadly categorized by building type: residential and non-residential (commercial, educational, industrial, office, and special-function buildings like

hospitals or hotels). Residential buildings dominate the literature, reflecting their substantial share (~70%) of global building energy consumption ("World Energy Outlook 2024 – Analysis - IEA," n.d.). Non-residential retrofits, crucial for sectoral decarbonization, are underrepresented in research (~30% of studies), likely due to operational complexity, and challenges in minimizing retrofit disruptions (Dadras and Kavgic, 2022; Munguba et al., 2024; Rabani et al., 2020).

3.2. Objective functions

Objective functions define the goals of optimization models and are critical for identifying optimal retrofit strategies. In building energy retrofit studies, objective functions are typically categorized into three domains: environmental, economic, and social, each reflecting distinct and often conflicting priorities in decision-making (Citadini de Oliveira et al., 2024).

Environmental objectives focus on reducing the environmental impact of buildings, primarily by minimizing energy consumption and greenhouse gas emissions. These objectives are critical for aligning retrofit projects with global sustainability goals, such as achieving net-zero energy buildings or meeting climate targets. The most frequently employed environmental objective functions, used in about 90% of studies, focus on minimizing energy consumption metrics such as primary energy consumption, total energy demand, and heating or cooling demand (Ismaeil and Sobaih, 2023; Las-Heras-Casas et al., 2021). As shown in Table 1, only 16% of studies quantified GHG emissions as core optimization targets (Amani and Kiaee, 2020; Niemelä et al., 2017a; Ruparathna et al., 2017) despite the fact that it is a necessity to achieve true NZBE.

Economic objectives aim to optimize the financial performance of retrofit projects, ensuring cost-effectiveness and maximizing return on investment. By focusing on economic objectives, optimization models can identify retrofit strategies that balance upfront costs with long-term savings, ensuring that projects deliver measurable financial benefits. The most frequently employed economic objective function, used in 63% of studies, is minimizing lifecycle costs using the net present value method (Gremmelspacher et al., 2021; Niemelä et al., 2017b). Additional financial metrics, including initial investment or payback period, are occasionally calculated as auxiliary metrics (Lohse et al., 2016; Naves et al., 2021; Wu et al., 2021).

Social objectives, such as thermal comfort, visual comfort, and indoor air quality, address occupant well-being and societal benefits. However, only 10% of the reviewed studies have addressed social objectives, with a sole focus on thermal comfort (Seghier et al., 2022; Zuhaib and Goggins, 2019). For the widespread adoption of NZEBs, it is essential to ensure occupant comfort, as it is a key factor in securing stakeholder support.

3.3. Optimization models and frameworks

Optimization algorithms are essential for solving building energy retrofit problems, with metaheuristic algorithms such as GA and PSO being the most widely adopted, used in 53% of studies, due to their ability to handle complex, non-linear, and multi-modal problems (Ferrara et al., 2019; Lorenzati et al., 2019). Simulation-based optimization integrates building energy simulation tools with optimization algorithms to identify optimal retrofit strategies. This approach leverages detailed building performance simulations to evaluate the impact of different retrofit measures. Building energy simulation tools are used to model the building's energy performance. Optimization algorithms iteratively explore the solution space by running simulations for different

retrofit scenarios. The algorithm identifies the combination of retrofit measures that best meet the defined objectives. One of the key advantages of simulation-based optimization is high fidelity in predicting actual building performance, as it relies on detailed physics-based models (Mirzaei et al., 2020; Shadram et al., 2020; Tavakolan et al., 2022). It is also capable of handling complex, non-linear relationships between variables, making it suitable for evaluating a wide range of retrofit measures. While simulation-based optimization is effective for individual buildings or small portfolios, its reliance on numerous iterative simulations makes it computationally expensive and time-consuming for large-scale or complex problems. Additionally, achieving true NZEBs requires simultaneous optimization of both operational and embodied energy, further increasing computational demands due to the need for separate software tools for each assessment.

Metamodel-based optimization, also known as surrogate model-based optimization, addresses the computational challenges of simulation-based optimization by replacing the detailed simulation model with a simplified, data-driven approximation. In this approach, a metamodel is trained using input-output data generated from a limited number of building energy simulations (Abokersh et al., 2021). The trained metamodel is then used as a surrogate for the simulation tool during the optimization process. The primary advantage of metamodel-based optimization is its computational efficiency, making it faster than simulation-based optimization and suitable for more complex or large-scale problems or when multiple optimization runs are required (Batres et al., 2023; Mostafazadeh et al., 2025). However, as shown in Table 1, only one study (Abokersh et al., 2021) has utilized metamodels, highlighting a critical research gap that needs to be addressed.

3.4. Optimization tools and software

Optimization tools provide the computational framework necessary to integrate building energy simulations, optimization algorithms, and data analysis by automating the iterative process of evaluating multiple retrofit scenarios. These tools can be broadly classified into programming languages and specialized optimization software. Programming languages, such as MATLAB and Python, offer flexibility and customization, enabling users to implement a wide range of optimization algorithms tailored to specific needs (Munguba et al., 2024). On the other hand, specialized optimization tools like GenOpt and jEplus are designed specifically for building energy optimization. They provide user-friendly interfaces and seamless integration with building energy simulation software, making them accessible without extensive programming expertise (Rabani et al., 2020); however, they are less flexible than programming languages. EnergyPlus is the most widely used simulation software for calculating operational energy demand due to its reliability, open-source nature, and text-based framework. However, there is a lack of integration of LCA tools in retrofit optimization frameworks, which are essential for evaluating embodied energy.

3.5. Energy retrofit measures (decision variables)

Energy retrofit measures, serving as decision variables in optimization frameworks, are broadly categorized into passive, active, renewable energy systems, user behavior, and smart building controls (Citadini de Oliveira et al., 2024). Passive measures such as upgrading insulation materials and window glazing properties mainly focus on improving the building envelope to reduce energy demand. These measures minimize heat transfer and air infiltration, thereby lowering heating and cooling loads without reliance on mechanical systems (Rabani et al., 2020). Active measures such as replacing conventional HVAC systems with efficient alternatives and installing advanced lighting controls involve upgrading or retrofitting mechanical and electrical

systems to improve operational efficiency. Such measures optimize energy use dynamically, responding to real-time occupancy patterns and environmental conditions (Lohse et al., 2016). Renewable measures often interact synergistically with passive and active strategies. Renewable energy systems address energy supply by integrating on-site generation technologies to offset non-renewable energy use. As shown in Table 1, solar-based renewable energies, including photovoltaic (PV) panels and solar thermal collectors (SC), are used in 70% of the studies (Ferrara et al., 2019; Lorenzati et al., 2019). Achieving NZBE requires a holistic integration of passive, active, and renewable energy retrofit measures. There is a widely acceptable rationale to build nearly zero energy buildings to reduce the energy demand first and then supply energy from renewable sources ("World Energy Outlook 2024 – Analysis - IEA," n.d.).

3.6. Life cycle assessment

LCA is a critical methodology for evaluating the environmental and economic impacts of building energy retrofits across their entire lifecycle. According to the EN 15978 standard (BS EN 15978, 2011) the life cycle of a building is divided into product stage (material extraction and manufacturing), construction stage, use stage (operational energy and maintenance), and end-of-life stage (demolition and disposal). The most commonly considered system boundary in retrofit studies is operational stage excluding product and end-of-life stages due to data limitations or lower relative impact. Investigated studies relied on Environmental Product Declarations (EPDs) or existing literature to estimate embodied carbon and energy, as conducting full-scale LCAs can be resource-intensive with high levels of uncertainty. The service life span considered in retrofit studies typically ranges from 20 to 30 years, reflecting the expected lifespan of retrofit measures.

The connection between LCA and NZBE is particularly significant, as achieving NZBE requires balancing operational energy reductions with embodied energy impacts. While operational energy dominates traditional building energy use, embodied energy from materials and construction processes becomes increasingly important as operational energy decreases. However, investigated studies focus solely on life cycle cost (LCC) and operational energy, neglecting embodied energy and comprehensive environmental LCA analysis. This oversight can lead to suboptimal retrofit strategies that minimize operational impacts but inadvertently increase embodied carbon, undermining overall sustainability goals. Integrating both operational and embodied energy assessments into retrofit optimization is essential for achieving true NZBE and ensuring that environmental benefits are not offset by upstream impacts.

4. CONCLUSION

This paper systematically reviewed the methodologies and tools for optimizing building energy retrofits, focusing on their role in advancing NZBE objectives. Our analysis explored optimization models, algorithms, and tools that enable the integration of energy performance simulations with retrofit decision-making. We examined energy retrofit measures as critical decision variables and emphasized the importance of LCA in evaluating environmental and economic impacts. The following gaps have been identified in the reviewed studies:

- High uncertainty in simulation model inputs (e.g., retrofit costs, energy prices, emissions, material variability, grid carbon intensity, and model assumptions) remains unresolved.
- Overlooked uncertainties in occupant behavior, maintenance, and replacement scenarios limit real-world applicability.

- Inadequate consideration of future climate projections, energy price fluctuations, system degradation, and evolving energy mixes.
- Limited pre- and post-intervention monitoring undermines confidence in retrofit outcomes, hindering robust conclusions.
- Prioritizing operational energy reduction while neglecting embodied energy and environmental impacts of materials.
- Underutilization of LCA tools, insufficient documentation, and lack of comprehensive life cycle inventory (LCI) databases hinder accurate embodied energy assessment.
- Lack of integration of LCA tools in retrofit optimization frameworks, which are essential for evaluating embodied energy.
- Ignoring end-of-life impacts, and circular economy principles in retrofit optimization.
- Focusing on environmental (LCA) or economic (LCC) dimensions while neglecting social aspects of sustainability.
- Non-residential buildings are underrepresented despite their complex retrofit challenges.
- Scarcity of research on integrated retrofit solutions at the neighborhood or district scale.

SUMMARY
Improving building energy performance is central to reducing energy bills, reducing electricity demand, increasing resiliency and enhancing the health and comfort of building occupants within their communities. In 2025, it is expected that the National Model Building Code of Canada will set operational carbon limits for buildings located in every province using annually averaged emission factors for the electrical grid and natural gas which assumes that the carbon intensity of electrical usage remains constant during the year and is not affected by seasonal and daily variations. Whereas, in reality, emission factors vary during the year, especially in an electrical utility where both fossil fuel and renewable generation assets are used. In this paper, we will compare how the energy demand and operational carbon calculation is affected using annually averaged data versus hourly data for the grid carbon emission factors in an example of an electrified heating dominated mixed-source grid, during a winter peak event.

Keywords: building decarbonization, energy efficiency, grid carbon intensity

2. INTRODUCTION

The recent Pan-Canadian Framework on clean growth and climate change, as developed by the Canadian Government, has set the goal to reduce GHG emissions from 40 to 45% by 2030, as compared to the amount emitted in 2005, and as well, has legislated a commitment to reach net zero emissions by 2050. Globally, operational and embodied emissions of buildings account for 28 and 11 percent of the global emissions (IEA, 2023). Two main components that can transform the construction sector to achieve its environmental targets are energy efficiency and building decarbonization. Although these two terms are often used interchangeably, and are interconnected approaches for achieving sustainability in buildings, there can be distinct and critical differences between them. Achieving energy efficiency in buildings typically involves the implementation of the following measures:

- High performance building envelope: Building envelopes include the exterior walls, foundations, roofs, windows, and doors. Improving the insulation and air sealing of the building envelope can reduce heat losses and the need for heating and cooling of the building.
- High-efficiency equipment: Energy efficient HVAC systems and appliances can directly reduce the energy demand for the same level of service.
- Smart building controls: Advanced control systems that can use the real time and forecasted data to minimize energy demand.
- Lighting design: Maximizing the use of natural light within buildings, and the use of energy efficient fixtures, such as LED lighting and automatic sensors, can reduce the energy demand for lighting.
- Building occupant behaviour: Building occupants can play a very important role by

employing energy saving practices whereby energy is used responsibly. Includes measures such as changing thermostat set point to reduce cooling and heating loads, using a drying line instead of mechanical dryers, and participating in demand response programs with the utility.

Energy efficiency measures have the potential to reduce emissions, contribute to energy security, reduce the operational energy costs and improve the thermal comfort within buildings, and the health of building occupants [IEA, 2023]. Energy efficiency is the key element of plans by the Canadian Government to reduce emissions by up to 45 percent by 2030, and achieve a carbon neutral economy by 2050. Hence, the main approach, as adopted by the relevant committees of the National Building Code of Canada, has focused on energy efficiency, for which five energy tiers have been introduced that represent a reduction in energy use in buildings and residential houses, with an anticipated correlation to operational carbon emissions (Magwood et al., 2020). There is a widely accepted rationale to implementing these changes by first constructing nearly zero-energy buildings to reduce the energy demand, and thereafter, provide energy to these buildings from renewable sources (IEA, 2023).

Decarbonization mainly focuses on reducing or eliminating carbon emissions associated with the construction, maintenance, and operations of a building. In respect to operational carbon emissions, decarbonization focuses on shifting from fossil fuel-based energy sources to cleaner, renewable alternatives. The key pillars of building decarbonization according to the ASHRAE Centre of Excellence for Building Decarbonization are:

- Efficiency measures and building electrification
- Operations and maintenance
- Refrigerants: Low-GWP, minimizing volume, and improving management
- Renewable energy sources (on and off-site) and energy storage
- Building-grid integration and real-time carbon signals
- Embodied carbon
- Decarbonized electrical grid

In addition to these pillars, carbon offsetting technologies have been used to offset the released emissions. Some other energy storage solutions such as batteries and thermal mass storage solutions are also being explored; however, the primary barriers to the uptake of these solutions are their high initial costs and associated embodied carbon [ASHRAE 228, 2023].

Electrification is often used as a decarbonization strategy, especially in Canada where until recently, the electricity grids had a target of net-zero emissions by 2035. This was also coupled with a federal policy push to increase electrification of heating, not necessarily focused on reduction in demand. Additionally, decarbonization potential of electrification is typically determined using annual average emissions factors, with limited studies being completed on the potential effects of sub-annual emissions factors impact on decarbonization potential due to a lack of published data. Lou et al. investigated the potential of five different retrofit energy conservation measures to reduce emissions through modelling of an archetype mid-sized office building using dynamic hourly emission rates for five different climate locations across the U.S. (having correspondingly different grid-mixes and renewable adoption rates). In this paper it was

demonstrated that the impact of different retrofit measures for medium office buildings can vary depending on the climate and grid-mix, with warmer climates more likely to benefit from equipment efficiency and lighting upgrades, whereas, in colder climates, the benefits of retrofitting the building envelope has increasing potential for reducing emissions. St. Jacques et al. (2023) provided an important contribution to understanding the impacts of using hourly emission factors compared to annual emission factors to account for the GHG emissions of several buildings in a number of different cities in Ontario using whole building energy modelling. The authors additionally investigated the impact on building operational GHG emissions if fuel switching, from natural gas heating to a ground source heat pump, was completed. The results of the study demonstrated the importance of accounting for the hourly energy usage (i.e., consumption based hourly emission factors) when calculating emissions for different grid-mixes. It was estimated that, for most locations, the switch to electrified heating would significantly reduce building operational GHG emissions, however limitations in the scale up of electrified heating, that necessitated utility capacity increases, were not considered.

In this paper, focus is on how electrification can be employed as a decarbonization strategy and how reductions of building operational emissions can be leveraged to optimize cross sector emissions in the electricity grid, especially considering the push in Canada towards electrification of heating sources. Electricity sources and emissions factors in different provinces are discussed, as well as how the electricity supply has evolved over the last 30 years, and how energy efficiency measures correlate with carbon reductions. As an example, the importance of using hourly emissions in New Brunswick, Canada, is demonstrated for a province having predominantly electrified heating and a mixed-emission source electricity grid.

2. CANADIAN ELECTRICITY MIXES AND ELECTRIFICATION

According to the IEA buildings NetZero plans, energy efficiency measures and electrification will need to account for roughly 30% and 40% of global direct emissions reductions by 2050, respectively. According to the Canadian Energy Regulator (CER), in 2021, Canada produced 625.7 terawatt-hours (TWh) of electricity. More than half (60%) was generated from hydroelectricity. The remainder was produced from other sources that included nuclear, natural gas, wind, coal, biomass, solar, and petroleum. Canada is also a net exporter of electricity (27.6 TWh in 2023). According to IEA, 2023 report, electricity production has only increased by 3% between 2000-2023, whereas, electricity consumption (demand) per capita has decreased by 16% within the same time. Electricity in buildings is primarily used for heating, cooling, lighting, cooking, and to power devices. Further electrification of end-uses, especially transportation, in conjunction with the decarbonization of electricity generation, is an important pillar of clean energy transitions. The industry sector is the largest consuming sector of electricity (35%) followed closely by residential buildings (33%). It is also worth mentioning that currently, 47% of the residential energy demand is provided by electricity and 44% is from natural gas. Energy efficiency measures recommended by the National Building Code of Canada (NBC) have resulted in an overall 28% decrease in the energy intensity of residential buildings between 2000-2023 [CER, 2023], and they have been proven to be effective despite the increased population and the total square footage of the built environment.

Canada’s electricity grid is regulated at the provincial and territorial levels. There is also a significant variation between the sources of generation and grid type. For all provincial electrical

utilities, the historical electricity use emission factors are available as annual averages from the National GHG Inventory datasets, published on the CER website, as presented in Figure 1. Only two provinces (Ontario and Alberta) have the potential for historical hourly emissions factors to be calculated with public data as they have open electricity markets. Although annualized average emissions are useful to link the energy demand and the associated GHG emission, for mixed grids, that contain high and low carbon generation sources, the uncertainties associated with using them to assess the potential for retrofits to reduce emissions can be significant.

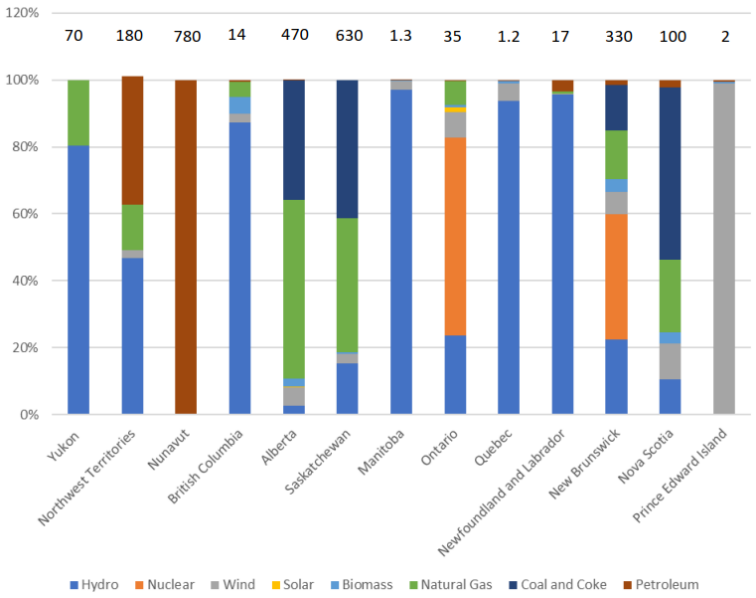

Figure 1. Annual distribution of generation sources per provincial grid and emissions factors (gCO_{2e}/kWh), (CER, 2022)

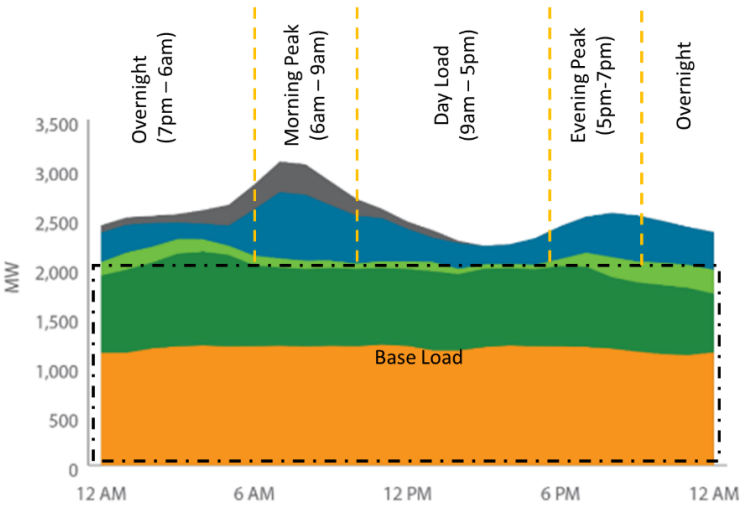
3. RESULTS AND DISCUSSION FOR THE NEW BRUNSWICK ELECTRICITY

Energy demand in Canada (IEA, Canada 2022), is dominated by space heating and accordingly the heating source and the grid mix play very important roles in the GHG emissions of the building sector. As can be seen in Figure 1, the present Canadian energy mix varies across all provinces. Additionally, the source fuel for heating in buildings varies across provinces, with high use of natural gas for heating fuel in provinces like Alberta, Ontario and BC, and high use of electrified heating in Quebec and the Atlantic provinces (NRCan, 2019). In the Atlantic provinces, New Brunswick (NB) provides a unique opportunity to investigate the effects of electrified heating on utility emissions, given NB grid contains a mix of high and low-intensity carbon generation sources (Figure 1) and is predominantly electrified residential heating, with a high penetration of heat pumps. The mix of renewables with fossil fuels and high penetration of electrified heating is representative of the challenges many other utilities will face in the future as electrified heating increases.

Figure 2 (NB Power, 2023) shows an example of how daily energy demand is met with different generation sources for a system peak day in winter. For this example day, two peak demand periods are also shown at 6 to 9 a.m. and 4 to 8 p.m., and are attributed to increased demand from the residential sector (NB Power, 2023). It is important to note this is a representative example and

that the actual allocations of electricity generation and amounts are dependent upon many factors including weather, demand, availability, and market prices and conditions. However, this example figure demonstrates that in a mixed-energy source utility, emissions factors are likely to vary during the day, dependant on which assets are used to meet demand, meaning that there are times during the year where the annual average emission factor is likely to deviate significantly from the hourly factor.



Base Load

1. Wind up to wind capacity factor, then
2. Up to 100% Nuclear, then
3. Up to 30% Coal, then
4. Up to 100% Natural Gas, then
5. Up 70% Coal, then
6. Up to 100% Fuel Oil Reserve

Morning Peak

7. Base Load, then
8. Up to 100% Peaking Hydro, then
9. Up to 100% Peaking Diesel

Day load

7. Base Load, then
8. Up to 50% of Peaking Hydro, then
9. Up to 100% Diesel

Evening Peak

7. Base Load, then
8. Up to 80% of Peaking Hydro, then
9. Up to 100% Diesel

Overnight

7. Base Load, then
8. Up to 30% of Peaking Hydro, then
9. Up to 100% Diesel

Figure 2. NB power winter dispatch example, exhibiting the NB two-peak challenge (NB Power, 2023) and the dispatch category

To compare the potential difference in emissions between hourly and annual factors, one would need the hourly energy source mix, which is not typically publicly available for Canadian utilities. However, the total hourly demand for the NB grid is published. Therefore, for the purposes of demonstrating the comparison between emissions factors in this paper, a winter dispatch sequence was derived from Figure 2, and applied to the published historical total hourly NB demand. In this case, a dispatch sequence consists of determining the order in which power generation assets are used to meet a given demand. With the total demand and dispatch sequence, the total power produced by each asset in a given hour to meet the total demand can be calculated. Thereafter the hourly emissions can be determined by multiplying the power generated in a given hour by a given generator by that generator emissions factor. The electricity emission factor is then determined as the total emissions due to generation in an hour, divided by the total demand in the hour. This is shown in (**1**.

$$GHG_{perMWh_h} = \sum_{i}^{n} \frac{Gen_i EF * MWh_{Gen_i}}{Total\ Demand + Transfers} \quad (1)$$

Where:

GHG_{perMWh_h}	is the hourly emission factor in kg CO_{2eq}/ MWh
Gen_iEF	is the emissions factor for generator 'i' to produce a MWh
MWh_{Gen_i}	is the amount of power produced by Generator i
$Total\ Demand + Transfers$	Total demand in NB, net transfers between other adjacent utility grids.
i	Each generator
n	Number of generation stations used in the given hour

The NB Power generation assets, and corresponding emissions factor associated with each asset to calculate the hourly emissions factor, are provided in Table 1. The emission factors for each asset were calculated from the National GHG Emission Inventory Dataset (ECCC, 2023) for New Brunswick.

Table 1. NB Power grid generation capacity

NB Power Grid Generating Capacity (Total, MW)		**MW**	**Emissions factor (gCO2e/kWh)**
Base Load	**Nuclear Generation**	663	0
	Coal	467	965
	Natural Gas	284	582
	Fuel Oil Reserve	972	1138
Peaking Hydro		668	0
Wind		355	0
Peaking Diesel		525	1138

To determine the power produced by each asset in a given hour, the total demand for each hour was divided into five dispatch sequence categories, depending on time of day, consisting of: base load, morning peak, day load, evening peak, and overnight. The base load was determined as the lowest load during each respective day, and was used to calculate how much each base load. The dispatch sequence for each category is provided in Figure 2**Error! Reference source not found.**.

In addition to the assumptions made for the categories shown in Figure 2**Error! Reference source not found.**, a method to calculate the potential wind generation for each hour was needed. The hourly wind power potential was calculated by multiplying the hourly average windspeed, measured at the closest weather station (scaled to the hub height), by the corresponding turbine power output curve (Wind Power, 2024) for each turbine location and corresponding turbine type (Government of Canada, 2024) in NB. It to supplement fossil fuel generation of the base load. Given the assumptions to incorporate wind power, two utilization factors were used to see the effect of wind on hourly emissions: i. 30% of the available wind power generation; and, ii. 100% of available wind generation. The 30% value was estimated based on the utilization factor quoted in the NB Power Integrated Resource plan (NB Power, 2023). It is important to note that the model results presented in this paper are completely hypothetical, as many assumptions needed to be made to create the dispatch sequence from Figure 2. Hence, the model values should not be taken as accurate for NB Power generation hourly emissions, rather that the intent of the model is to provide an example of considerations needed when estimating the effectiveness of building retrofit scenarios to achieve decarbonization in a province where building heating is predominantly electrified.

Using the dispatch model, the hourly emission factors for each hour in the winter of 2022

(December, January and February) were calculated. The results were then averaged to represent a typical 24-hour day over this period. The results, compared with the published annual emission factor for the NB Grid in 2022 from the CER website, of 330 g CO2eq/kWh, are depicted in **Figure 3**. Winter months are selected due to the higher seasonal electricity demand; one can anticipate that the hourly emissions would be higher that the annually averaged emissions factor. It can be seen that during the high demand times, the annual averaged data underestimates the emissions in comparison to the hourly emissions scenarios. The results show that the energy efficiency measure are more important than one can assume using the annually averaged emissions factors. First, the energy demand reduction can lead into a higher absolute emissions reduction, and second, if they are employed across all the existing buildings through retrofit and new buildings through the National Model Codes, one can anticipate that the hourly emissions factor can also be decreased. It is still recommended that analysis should be done on a case-by-case basis, to ensure that the energy efficiency measures result in decarbonization for other electricity grids.

due the anticipated higher electricity demand and hourly emission factors (). The results were then averaged to represent a typical 24-hour day over this period. The results, compared with the published annual emission factor for the NB Grid in 2022 from the CER website, of 330 g CO2eq/kWh, are shown in **Figure 3**. One can conclude that energy efficiency measures are more important than what one could assume using the annually averaged data only. First since
As one can see the electricity demand is the highest during winter and the absolute value of emissions are expected to be at the highest.

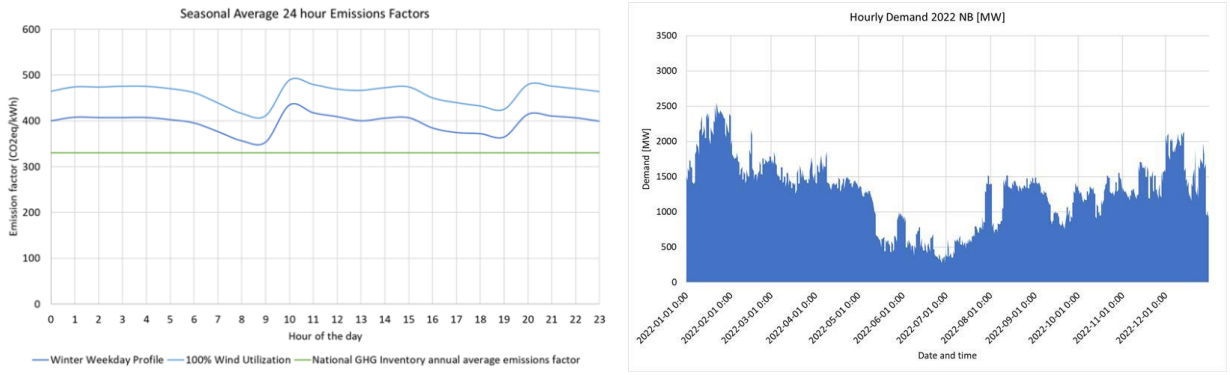


Figure 3: Hourly emission factor for winter compared to annual average (left), hourly demand in 2022 (right)

7. CONCLUSIONS

It has been shown that increasing the energy efficiency of buildings has the potential to lead to several benefits including the reduction of GHG emissions. Although there are many overlaps between energy efficiency and decarbonization, these two concepts do not always represent the same outcome. It is very important to understand their differences and how reductions in operational energy can be translated into building decarbonization. In this paper, the following points were discussed:

- The key differences between energy efficiency in buildings and building decarbonization.
- How the electricity supply has evolved in Canada in the last 33 years.
- The viability of relying on electrification as the main mode of decarbonization considering the capacity issues and electrification in other sectors.

- The importance of using hourly emissions factors versus the annualized average emissions factors when considering energy efficiency measures in buildings.

This paper unfolds new research topics to be explored in the future. It has been shown that a comprehensive study on the electricity supply is needed to further understand plans to meet the increasing electricity demands before suggesting electrification as the primary method for decarbonization. For future work, the balance between the energy demand and supply in different locations in Canada will be assessed and the best path forward to decarbonize the construction sector will be considered in relation to the demand and supply of electricity in the respective provinces.

SUMMARY
Carbon emissions in the construction industry are significant, and bamboo is recognized as an eco-friendly building material. It plays an important role in achieving sustainable development in the construction sector and the carbon peak and carbon neutrality goals. This paper reviews domestic and international research on carbon emissions from bamboo structures, covering three aspects: bamboo carbon emission factors, life-cycle carbon emission calculations, and carbon emission comparisons with other building structures, as well as carbon reduction strategies. It highlights existing issues such as insufficient fundamental data research, inconsistent calculation methods, and insufficient in-depth research on carbon reduction strategies. Future efforts should focus on strengthening fundamental data research, constructing a unified and comprehensive bamboo carbon emission factor database, establishing standards and guidelines, developing carbon emission calculation methods specifically for bamboo structures, and enhancing research on carbon reduction strategies.

Keywords: Bamboo construction, Carbon emission, Life cycle.

1. INTRODUCTION

The global climate crisis is becoming increasingly severe, and high carbon emissions in the construction industry are one of the key contributors to exacerbating this problem. In response to this challenge, China has actively advocated for a green transformation of production and lifestyle in the 14th Five-Year Plan period. The construction sector urgently needs to embrace a green transformation to move towards sustainable development. Bamboo has unique advantages in China: it is abundant, grows rapidly, and its annual output value far exceeds that of wood (Abrahams et al., 2003). Bamboo also has strong carbon sequestration capabilities (Li et al., 2015) and is widely recognized as an eco-friendly building material. Known as "plant steel," bamboo exhibits excellent properties such as light weight, high strength, and high bending flexibility. Its tensile strength is almost equal to that of steel, and its compressive strength is twice that of concrete (Yadav and Mathur, 2021).

Today, more and more scholars are recognizing the tremendous potential of bamboo in fields such as architecture and furniture, believing that it holds significant value for widespread application. As research on bamboo structures continues to deepen, studies on carbon emissions have increasingly captured scholars' attention. However, existing research is relatively fragmented. This paper aims to review the current research progress, providing valuable insights for carbon emission research in the construction industry.

2. RESEARCH METHODS

This study strictly follows the PRISMA guidelines for systematic reviews, clearly defining the search strategy, literature screening process, and inclusion criteria. The search keywords center around *bamboo building, bamboo structures, bamboo materials, carbon emissions, and life cycle,* and are expanded to include related concepts such as *carbon sink* and *low-carbon bamboo architecture* to enhance the comprehensiveness of the literature coverage. Three authoritative databases—Web of Science (Core Collection), China National Knowledge Infrastructure (CNKI), and Wanfang Data—were selected as the primary sources for the literature search.

The inclusion criteria are as follows: the content must focus on carbon emissions in bamboo-structured architecture, covering key themes such as the determination of carbon emission factors, life cycle carbon calculation models, comparative analyses with traditional building materials, and carbon reduction strategies for bamboo structures. Priority is given to literature published within the past ten years (2014 to 2024), although classic theories and key data are considered with some flexibility. Only core journal articles, international conference papers, and authoritative research reports are included; a small number of high-quality dissertations were also included after full-text screening.

The specific literature screening process is as follows: an initial search yielded 769 documents. After a preliminary screening based on titles and abstracts, 141 duplicates were removed, leaving 628 documents. Following a full-text evaluation, 53 documents met the inclusion criteria, and ultimately, 17 highly relevant studies were included in the review.

3. RESEARCH PROGRESS ON CARBON EMISSIONS IN BAMBOO STRUCTURES

Bamboo has a long history of application in the construction industry, and research on its carbon emissions primarily focuses on its carbon sequestration capacity, the environmental friendliness of engineered bamboo, and the carbon footprint of bamboo products. At present, carbon emissions research on bamboo-structured buildings is still in its early stages. Existing studies have made some progress in areas such as bamboo carbon emission factors, life-cycle carbon emissions calculations, and carbon reduction strategies. Many studies compare bamboo-structured buildings with traditional reinforced concrete, steel, and timber structures to demonstrate their advantages in terms of carbon emissions.

3.1. Research on Bamboo Carbon Emission Factors

The bamboo carbon emission factor is a fundamental basis for carbon emission calculations and is crucial for accurately assessing the environmental impact of bamboo-structured buildings. Currently, scholars primarily conduct field investigations of the bamboo production process, considering carbon emissions from various aspects, such as materials and energy consumption, and integrating these factors with bamboo's carbon sequestration characteristics to calculate its carbon emission factor. Zhang et al., (2021) based on an investigation of the bamboo particleboard production process, analyzed the materials and energy inputs involved in manufacturing pretreated bamboo and bamboo particleboard, and, in turn, assessed the carbon emission factors for these materials. Zhang et al., (2023) using the 'Fish Leisure Bamboo Pavilion' at the Yangzhou World Horticultural Expo as a case study, conducted factory surveys to gather data and proposed a calculation method for the carbon emission factor of round bamboo building materials. They

derived the carbon emission factor for round bamboo and pointed out that carbon emissions from the cooking and degumming processes, as well as the hot bending and straightening stages, were particularly high. They suggested that improving energy usage strategies during the production stages could reduce overall emissions.

3.2. Research on Carbon Emission Calculations for Bamboo-Structured Buildings

With the deepening research into life cycle assessment (LCA) theory, researchers have applied it to the carbon emission calculations of different types of bamboo materials or bamboo-structured buildings to comprehensively assess the environmental impact of bamboo structures throughout their entire life cycle. Early studies focused primarily on bamboo building materials or bamboo products. For example, Liu et al., (2024) conducted a life cycle assessment (LCA) on structural glued laminated bamboo (SGLB), focusing on its carbon emissions from raw material extraction to the production stage. They emphasized the advantages of using renewable energy to reduce carbon emission. These studies laid the foundation for the broader application of bamboo materials in construction and provided significant theoretical support and practical references for subsequent environmental impact assessments of bamboo-structured buildings.

In recent years, research on the carbon emissions of various types of bamboo-structured buildings has gained momentum. Chen et al., (2015) divided the entire life cycle of bamboo frame houses in Zizhuyuan Park into stages: raw material acquisition, transportation of building materials, production of building components, and construction. Their analysis revealed that bamboo-structured houses maintain a negative carbon state throughout their life cycle, classifying them as green housing. Zhang et al., (2023), following the "Building Carbon Emission Calculation Standard" (GB/T 51366-2019), divided the life cycle of round bamboo landscape buildings into stages: material production and transportation, operation, construction, and demolition. Using the "Fish Leisure Bamboo Pavilion" at the Yangzhou World Horticultural Expo as a case study, they performed a life cycle carbon emission calculation. Their results showed that carbon emissions during the material production stage accounted for the highest proportion (66.70%) of total emissions. Due to bamboo's carbon sequestration characteristics, total emissions during this stage were negative, achieving a negative carbon design. Zhu et al., (2024) divided the life cycle of bamboo-wood hybrid structures into three phases: materialization, operation, and demolition, and conducted a life cycle carbon emission analysis of a bamboo residential building at Nanjing Forestry University. They found that emissions during the operation phase were the highest, accounting for approximately 89.8% of total life cycle emissions, while bamboo's carbon storage accounted for 8.8%. The results indicated that the materialization phase, particularly the material production stage, was the primary source of carbon emissions. Huang et al., (2024) proposed a carbon emission measurement model for bamboo ribbed houses, dividing the life cycle into five stages: material production, transportation, construction, operation, and demolition. Their case analysis concluded that the operation phase contributed the largest share of carbon emissions, while the material production stage within the materialization phase had the highest proportion.

3.3. Comparative Research on Carbon Emissions of Bamboo-Structured Buildings

Researchers have quantified the carbon emissions of bamboo-structured buildings throughout their life cycles to identify their carbon emission characteristics. By comparing bamboo structures with other types of buildings, they assess the carbon reduction potential of bamboo structures and their advantages in reducing carbon emissions.

Zhu et al., (2024) compared the life cycle carbon emissions of bamboo structures with those of timber, steel, and hybrid bamboo-wood residential buildings. Their results showed that the carbon emissions during the operation phase were the highest for bamboo-structured houses, but the net carbon emissions of different bamboo-wood structures were similar. In contrast, the carbon emissions of steel structures were approximately 89.9% higher than the average carbon emissions of bamboo-wood structures, demonstrating that bamboo-structured buildings have significant energy-saving potential during the operation phase and offer advantages in overall life cycle carbon emissions. Liu et al., (2023) compared the life cycle carbon emissions of rural glued bamboo residential buildings in Ningbo, Zhejiang, with those of reinforced concrete buildings. They found that the life cycle carbon emissions of bamboo-structured buildings were 30.4% lower than those of reinforced concrete buildings, with significant carbon reduction potential in the production and transportation stages. Yu et al., (2011) compared the energy consumption and carbon emissions of bamboo structures with those of brick-concrete buildings. Their findings indicated that bamboo-structured buildings consumed less energy and emitted fewer carbon emissions while meeting the same functional requirements. Bamboo structures also had better thermal insulation properties. Additionally, through scientific management and technological applications, bamboo structures can more effectively facilitate resource recycling and reduce the environmental burden over the building's life cycle, particularly in terms of the use of recycled materials and construction waste recovery. Zhao et al., (2023) quantified the energy-saving and carbon reduction potential of bamboo in residential buildings in cold and extremely cold regions of China. By comparing the carbon emissions of bamboo laminated board (LBL) buildings in different cities, they demonstrated the carbon reduction effects of bamboo structures under various geographical and environmental conditions. Bundi et al., (2024) compared bamboo-structured buildings in the Philippines with concrete brick buildings and found that bamboo construction could reduce carbon emissions by 70%. Zea Escamilla et al., (2018) compared four types of building materials (round bamboo, brick, concrete hollow blocks, and engineered bamboo) in the Colombian region, analyzing the environmental impacts over their entire life cycle. They considered factors such as transportation and material production efficiency and found that bamboo structures had an environmental advantage due to their lightweight and low-density properties. Even with longer transportation distances, bamboo structures still resulted in lower environmental impacts. Rincón et al., (2023) compared the environmental impacts of traditional clay brick houses (CSB) in Colombia with those of light cement bamboo frame (LCBF) houses built using locally improved Guadua bamboo. The results showed that the carbon footprint of bamboo houses was approximately 36% of that of traditional brick houses.

Existing studies have demonstrated that bamboo-structured buildings offer clear advantages in terms of carbon emissions, positioning bamboo as a key driver in the construction industry's transition toward low-carbon solutions.

3.4. Carbon Reduction Strategies for Bamboo-Structured Buildings

Building upon research into the carbon emissions of bamboo-structured buildings, scholars have conducted a series of studies on carbon reduction strategies. Zea Escamilla and Habert, (2014) performed a life cycle assessment (LCA) on five types of bamboo-based construction materials and found that bamboo species and harvesting methods did not significantly contribute to the overall environmental impact, providing evidence for the environmental friendliness of bamboo.

The study also highlighted that as industrialization increases, so does the environmental impact, with electricity consumption emerging as a major influencing factor. They suggested changing the energy mix (e.g., reducing the proportion of coal-based electricity), as this would be more effective in reducing environmental impact than merely improving production efficiency. Additionally, since bamboo-based materials are lightweight and have relatively short transportation distances, the environmental impact from local transportation is limited. Therefore, the study recommended focusing bamboo cultivation in regions where production is concentrated and processing in areas with diversified or abundant renewable energy sources to further enhance the environmental performance of bamboo-based materials. Chang et al., (2018) applied the LCA method to the production of bamboo plywood from Moso bamboo in Taiwan, examining the environmental impacts of the production process and comparing them with other materials. They proposed a series of recommendations, including optimizing the processing steps, improving chemical treatments, enhancing energy structures, and increasing production efficiency to reduce the environmental impact of bamboo material processing. Zhang et al., (2021) compared the life cycle carbon emissions of a steel-bamboo composite frame (SBF) structure with a traditional reinforced concrete frame (RCF) structure. They found that the SBF solution showed carbon reduction potential at most stages of its life cycle, especially during the construction and material production stages. The study suggested focusing on the carbon emissions from the production of materials like steel plates and bamboo to further enhance the reduction effect.

These studies collectively emphasize the importance of strategic approaches to reducing carbon emissions associated with bamboo-structured buildings, including optimizing production processes, shifting to cleaner energy sources, and improving material efficiency throughout the supply chain.

4. EXISTING PROBLEMS

Accurate data support is crucial for carbon emission research on bamboo-structured buildings. However, there is currently a lack of authoritative bamboo carbon emission factor databases both domestically and internationally, which hinders the progress of related studies. In determining the carbon emission factors and resource consumption data for bamboo-structured buildings, some studies rely on limited surveys or literature data, which fail to accurately reflect the actual conditions across different regions and production processes. The application of bamboo materials is still in its early stages, with many bamboo processing enterprises being small and medium-sized businesses with relatively low market shares. As a result, obtaining accurate data on material consumption and energy use remains challenging. Furthermore, the diversity in bamboo production processes, differences in technical levels, energy consumption uncertainties, and regional disparities further complicate data collection and hinder the standardization of carbon emission calculations.

When calculating carbon emissions for bamboo-structured buildings, researchers often use life cycle assessment (LCA) theory, which covers all stages from raw material acquisition to building demolition. While research on bamboo structures and bamboo building materials has made progress, bamboo-structured residential buildings have not yet been widely adopted, and there is no authoritative carbon emission calculation standard specifically for bamboo structures. The existing methods for calculating carbon emissions in bamboo structures suffer from issues such as insufficient accuracy and inconsistency. In particular, research on the disposal phase of bamboo

structures lacks case studies, which results in an incomplete evaluation of carbon reduction across the entire life cycle of bamboo structures. This limitation makes it difficult to effectively compare results and hinders the application of research findings in guiding architectural design and construction.

Current research on carbon reduction strategies for bamboo-structured buildings tends to focus on increasing the use of bamboo-wood materials, which offer advantages in carbon sequestration and low carbon emissions, to replace traditional high-carbon building materials. Additionally, there is strong advocacy for the use of clean energy, such as solar and wind power, throughout the life cycle of bamboo-structured buildings to reduce dependence on fossil fuels and optimize the energy mix. Many researchers emphasize the importance of optimizing processes in each phase of the life cycle, recommending that studies cover production, transportation, construction, and demolition stages. Specific measures include optimizing transportation routes and increasing material recycling rates to reduce resource consumption and carbon emissions. However, most research currently focuses only on carbon emission calculations and basic comparisons. There is a lack of in-depth analysis of key carbon reduction areas and potential influencing factors. Although the carbon sources and carbon sinks at each stage are well-defined, there is still a lack of specific technical support and strategic guidance for effectively addressing high carbon emissions in the production phase. As a result, developing a comprehensive and actionable carbon reduction plan remains challenging.

5. SSUMMARY AND OUTLOOK

Public understanding of bamboo-structured buildings remains limited, yet their development plays a crucial role in the sustainable growth of the construction industry and the achievement of China's "dual carbon" goals. At present, research on bamboo-structured buildings faces several challenges, particularly in areas such as basic data, carbon emission calculation methods, and carbon reduction strategies.

To advance research on carbon emissions from bamboo-structured buildings and promote their wider adoption, future studies should focus on enhancing the understanding of bamboo carbon emission factors and other fundamental data. This involves considering regional differences and variations in processing methods, which will contribute to the development of a more robust and reliable database to ensure data accuracy and consistency. Establishing regulations and standards specific to bamboo materials and structures is also crucial. These standards should define appropriate carbon emission calculation models, tailored to the unique characteristics of bamboo structures, and provide precise carbon emission assessments for each stage of the building's life cycle. This would provide stronger theoretical support for the broader adoption of bamboo structures in construction.

Building on this foundation, researchers should focus on exploring carbon reduction strategies for bamboo-structured buildings, including quantifying the carbon reduction effects and further minimizing emissions during the production phase. The goal is to develop a comprehensive set of guidelines for low-carbon bamboo structure design, providing scientific evidence for architectural planning. Additionally, creating an accurate assessment methodology for carbon emissions in bamboo-structured buildings will help promote their use in the low-carbon building sector, advancing sustainable construction practices.

In the future, these efforts will not only promote bamboo-structured buildings as a sustainable construction solution but also contribute to global carbon neutrality goals by integrating them into mainstream building practices.

ACKNOWLEDGEMENTS

First, I would like to express my sincere gratitude to my supervisor and all the experts and scholars who have provided invaluable assistance throughout this research. Your guidance on the research direction, support in data analysis, and insightful feedback have been essential to the successful completion of this thesis. Secondly, I am deeply grateful to my family and friends for their constant encouragement and companionship, which have given me the perseverance to keep moving forward. Finally, I would like to thank all the institutions and organizations that have contributed to this research. Your support has been instrumental in my growth throughout this academic journey.

Alternative Approach to Simplified Energy Disaggregation: Heating Energy Estimation Considering Monthly Hot Water Energy Consumption in District Heating

Hyery Shin [1], Yumin Kim[2,]

[1] *Department of Building Energy Research, Korea Institute of Civil Engineering and Building Technology, Goyang-si, South Korea, hyeryshin@kict.re.kr*
[2] *Department of Building Energy Research, Korea Institute of Civil Engineering and Building Technology, Goyang-si, South Korea, ymkim@kict.re.kr*

SUMMARY
Buildings consume energy for various purposes, including heating, cooling, hot water supply, and cooking. While reducing energy consumption requires targeted measures for each purpose, direct monitoring is costly. The Simplified Energy Disaggregation (SED) methodology can separate heating, cooling, and baseload energy, but has limitations in reflecting changes in baseload energy. This study analyzed monthly variations in hot water energy consumption in district heating-supplied apartment complexes and evaluated the error rate compared to heating energy estimated by SED. Analysis of 142 apartment complexes showed that SED overestimated heating energy by 28% and underestimated hot water energy by 44%. As building insulation regulations become more stringent and heating energy proportion decreases, the possibility of larger estimation errors in SED's calculations increases, necessitating a new methodology for estimating hot water energy consumption.

Keywords: Apartment Buildings, Simplified Energy Disaggregation, Heating Energy Consumption, Hot Water Energy Consumption

1. INTRODUCTION

The Korean government has committed to achieve a reduction in greenhouse gas emissions in the building sector by 88.1% by 2050 compared to 2018 levels as part of its carbon neutrality goals (Korean government, 2021). To achieve this reduction target, detailed implementation measures are necessary, which requires distinguishing energy consumption by purpose for different energy sources used in buildings. Given Korea's climate conditions, heating energy shows the highest Energy Use Intensity(EUI)(Jin et al., 2020), necessitating the estimation of heating energy consumption and the development of specific implementation measures based on these estimates.

When disaggregating energy consumption data using methodologies such as Simplified Energy Disaggregation (SED), energy consumption is typically disaggregated into heating, cooling, and baseload energy consumption, with the baseload assumed to include purposes such as hot water supply and cooking (Meng et al., 2017). This study proposes a methodology to separately identify hot water energy consumption as an alternative approach to the existing SED methodology. Through this methodology, we aimed to improve the accuracy of heating energy consumption estimates.

2. SCOPE AND LIMITATIONS

As of 2023, the building sector in South Korea consumes approximately 56.6% of energy in the residential sector and 43.4% in the non-residential sector (Korea Real Estate Board). This study focused on analyzing the residential sector, which accounts for more than half of the total energy consumption. Specifically, we examined apartment buildings, which represent 73.4% of residential buildings and constitute the largest proportion of housing types in South Korea (MOLIT, 2024).

The heating energy sources in apartment buildings are mainly divided into city gas and district heating. While city gas is used for heating, hot water supply, and cooking, district heating is used exclusively for heating and hot water supply (Kim et al., 2024). Since this study aimed to estimate heating energy consumption more accurately by separating hot water energy consumption, we examined energy consumption data from apartment complexes using district heating, which consists solely of heating and hot water consumption.

The analysis was performed using data from 171 apartment complexes using district heating in the Seoul region, emphasizing the study of their energy consumption patterns and characteristics. In particular, we utilized the distinct feature of district heating systems that clearly separates heating and hot water energy consumption as an alternative approach to the existing SED methodology and attempt more accurate energy consumption estimates.

3. METHODOLOGY

3.1 Data Collection and Description

The Korea Real Estate Board has developed and maintained the National Building Energy Integrated Database (NBEIDB), combining building registration information and energy consumption billing data from the past decade (Ji et al., 2020; Seok et al., 2017). NBEIDB provides energy consumption information linked to nationwide building data, comprising approximately 6.25 billion electricity, gas, and district heating consumption records collected from about 50 million individual meters connected to approximately 7.3 million buildings across South Korea. Management costs for apartment complexes with 100 or more households are disclosed through the national Apartment Management Information System (K-apt), with billing costs for heating and hot water energy consumption separately reported for each complex.

In this study, we examined district heating consumption data from Seoul apartment complexes for 2023, the most recent year with complete 12-month data available. Furthermore, we obtained data on billing costs for heating and hot water energy consumption from 171 apartment complexes with 100 or more households through K-apt.

3.2 Data Preprocessing

The monthly energy consumption data from 171 apartment complexes using district heating was analyzed following disaggregating heating and hot water energy consumption and removing data outliers. Cases were excluded where monthly energy consumption data showed negative values, zero heating or hot water energy consumption over 12 months, and zero heating or hot water energy consumption during winter months (Jan.-Feb., Nov.-Dec.). The final analysis was performed

using data from 142 complexes.

3.3 Energy Disaggregation Method

The Simplified Energy Disaggregation (SED) methodology assumes that the energy consumption of the month with lowest energy consumption represents baseload energy consumption, with the remaining energy consumption classified as heating and cooling. For apartment complexes using district heating as their energy source in this study, since district heating is used only for heating and hot water supply, the baseload energy becomes hot water energy, and the remaining energy consumption is estimated as heating energy. Under the SED methodology, hot water energy consumption is assumed to remain constant over the 12-month period.

To disaggregate hot water energy consumption more realistically, this study utilized heating and hot water energy cost data from K-apt. We calculated the ratio of billing costs for heating energy consumption to the total sum of billing costs for heating and hot water energy consumption for 171 Seoul apartment complexes, and applied this ratio to district heating energy consumption to derive heating and hot water energy consumption.

4. DATA ANALYSIS

Heating energy consumption estimates using the existing SED methodology's baseload separation were on average 28% higher, and hot water energy consumption estimates were 44% lower compared to heating energy consumption derived from separating heating and hot water energy. Furthermore, when comparing the proportion of hot water energy consumption during winter months (Jan.-Feb., Nov.-Dec.), differences reaching 300% were observed (Table 1).

Table 1. Ratio of hot water energy consumption to total district heating energy consumption

Methodology \ Month	1	2	3	4	5	6	7	8	9	10	11	12
SED	7%	10%	15%	25%	41%	68%	77%	100%	84%	35%	13%	8%
Actual Consumption	21%	27%	38%	53%	70%	76%	75%	73%	74%	57%	31%	24%

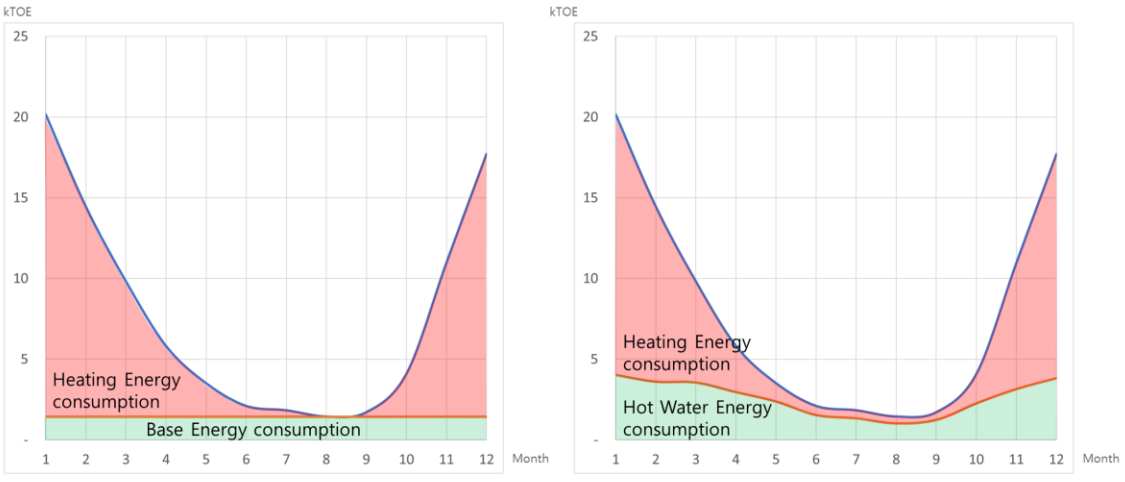

Figure 1. Monthly Heating and Hot Water Energy Consumption Patterns: SED vs. Actual Consumption

As shown in Figure 1, while the existing SED methodology assumes constant baseload energy (hot water energy) consumption throughout the 12-month period, our proposed methodology demonstrates variations in monthly hot water energy consumption. The results reveal that hot water energy consumption tends to increase during winter months, demonstrating that hot water energy consumption is also influenced by seasonal changes.

5. DISCUSSION AND CONCLUSION

This study aimed to improve the accuracy of heating energy consumption estimates by separating hot water energy consumption, considering the limitations of the existing SED methodology. Analysis of data from 142 apartment complexes using district heating in the Seoul region revealed that, compared to the method proposed in this study, the existing SED method overestimated heating energy by 28% and underestimated hot water energy by 44%. This indicates that the conventional method may tend to overestimate heating energy consumption. Considering seasonal variations in hot water energy use could enable more precise disaggregation of energy purposes, and this refinement is expected to serve as a more detailed policy reference when implementing carbon neutrality-related measures in the future.

As building insulation regulations continue to become more stringent, the proportion of heating energy is expected to decrease relative to hot water energy consumption in the future. This suggests that the estimation errors in heating energy using the SED methodology may become even larger, highlighting the need for a methodology to estimate hot water energy consumption. City gas is used as a heat source in many buildings, while electricity is used for cooling and various appliances. A detailed base load analysis is also necessary for these energy sources.

SUMMARY
Excessive CO_2 concentration in the car will affect the driver's mental state and driving safety. The CO_2 concentration in the cabin can be reduced by using fresh air mode. However, PM pollutants from outside will also be introduced into the cabin, and the high-temperature outside air will increase the air conditioner's energy consumption. This study recommends using energy recovery ventilators (ERVs) to improve cabin air quality and reduce air conditioning energy consumption. Furthermore, this study uses numerical analysis to investigate the performance of ERVs. The results showed that when the ERV was running at high-speed for 30 minutes, the CO_2 concentration of the five passengers dropped from 7557ppm when the ERV was not turned on to about 2418ppm. The number of suspended particles will also drop from 1089 particles/cm^3 when ERV is not turned on to approximately 530 particles/cm^3. The net energy savings for high-speed operation is 110.3W. Using ERV can simultaneously reduce cabin CO_2 and PM concentrations, achieve higher indoor air quality, and reduce energy consumption.

Keywords: numerical analysis, energy recovery ventilator, IAQ.

1. GENERAL INSTRUCTIONS/ INTRODUCTION

According to statistics released by Taiwan's Ministry of Transportation, traffic accidents increased from approximately 300,000 in 2014 to 400,000 in 2023 (Official Website, 2024). Although the reasons for these accidents were not reported, driver fatigue is known to be one of the leading causes of traffic accidents (Jaydarifard et al., 2024). Fatigue worsens through prolonged use of the recirculation air mode (RC mode), with the windows kept closed since this slows the exchange of air between the cabin and the outdoors and thus leads to a higher CO_2 concentration. Consequently, the development of engineering solutions that enhance cabin indoor air quality (IAQ) and maintain driver alertness has become a key focus of automotive researchers and road safety specialists.

To maintain the concentration of CO_2 in the cabin below the 1000 ppm threshold specified in the ASHRAE standard (ASHRAE, 2013), an increase in the flow rate of outdoor air is required. One of the most effective ways of achieving this is to increase the vehicle's speed, thereby increasing the leakage air flow rate (Chang et al., 2017). However, this is impractical in real-world driving conditions. Hence, most proposed methods involve opening the windows regularly or switching the ventilation system to the FA mode (Chang et al., 2023; Hudda and Fruin, 2018; Jung et al., 2017). However, both methods increase the level of PM pollutants within the cabin. Furthermore,

although this problem can be mitigated using a high-efficiency in-cabin filter, the introduction of outside fresh air makes it more challenging to maintain the cabin's thermal comfort, thereby increasing the cooling load on the air-conditioner.
Accordingly, the present study proposes using an Energy Recovery Ventilator (ERV) to perform heat exchange between the outgoing cabin air and the incoming fresh air, thereby enabling cold energy recovery. In this way, the ERV not only improves the cabin IAQ by facilitating the discharge of accumulated CO_2 but also reduces the energy consumption of the air-conditioner. In addition, the ERV incorporates a high-efficiency filter that effectively removes suspended particles from the incoming fresh air, further improving the IAQ in the cabin. The performance of the proposed ERV system is evaluated by performing numerical analysis to examine the concentrations of CO_2 and suspended particles given different numbers of occupants in the cabin and operating speeds of the ERV. Overall, the results confirm that the ERV improves the cabin IAQ and reduces the energy cost of the vehicle air-conditioner.

2. RESEARCH METHODS

Numerical analysis studies using approximate value algorithms in mathematical analysis problems. Numerical analysis often cannot obtain precise values in many issues, but it can obtain approximate solutions to a specific error. In the early days, numerical analysis usually used manual calculations, which took a long time and carried the risk of calculation errors. However, many programming language software have emerged to replace manual calculations with fast and accurate features.
In a ventilated cabin, carbon dioxide enters the cabin along with outdoor air, so the concentration of carbon dioxide in the cabin is related to the ambient concentration. However, carbon dioxide is also emitted naturally as part of the respiratory cycle. Hence, the concentration of carbon dioxide also changes with the number of passengers in the cabin and their activity levels, so the concentration of carbon dioxide in the cabin inevitably exceeds the outdoor concentration. Assuming the indoor air is thoroughly mixed, and the cabin is used as the control volume, Figure 1 shows the corresponding CO_2 transient mass balance diagram.

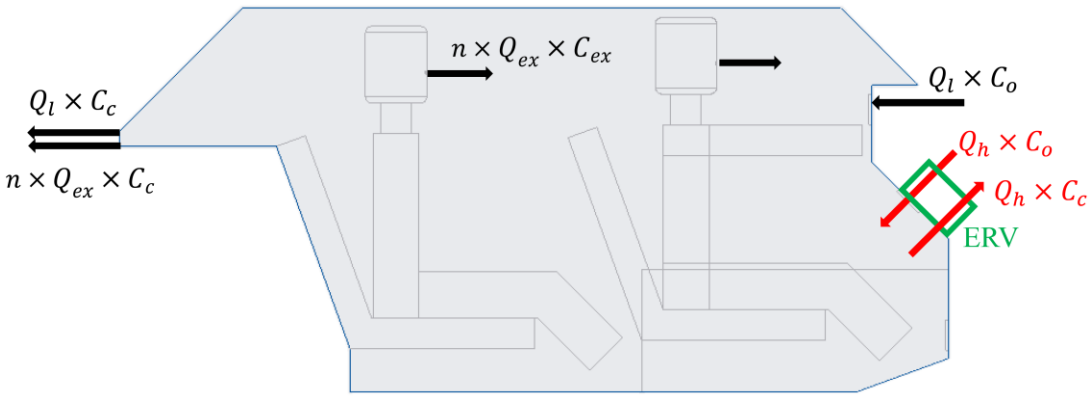

Figure 1. Transient mass balance diagram of CO_2 using cabin as control volume.

As shown in Figure 1, the CO_2 concentration is increased by the breathing of the passengers and reduced by the introduction of outdoor air with a volumetric flow rate Q and the exhaust of indoor air with a volumetric flow rate Q into the environment. Changes in the amount of CO_2 in the cabin. In other words, the change in CO_2 in the cabin over time equals the amount of CO_2 produced by

passengers minus the amount of CO_2 removed by ventilation. That is,

$$V_c \times \frac{dC_c}{dt} = n \times Q_{ex} \times C_{ex} + Q_l \times C_o + Q_h \times C_c - Q_l \times C_c - n \times Q_{ex} \times C_c - Q_h \times C_o \quad (1)$$

where n is the number of occupants within the cabin, Q_{ex} is the breath volume flow rate of each occupant, C_{ex} is the CO_2 concentration of each exhaled breath, C_c is the CO_2 concentration within the cabin, C_o is the CO_2 concentration in the outdoor environment, Q_l is the leakage ventilation volume flow rate, Q_h is the ventilation volume flow rate of ERV and V_c is the volume of the cabin. The present simulations evaluate the CO_2 concentration in the cabin under different conditions using the following finite difference equation derived from Eq. (1):

$$C_{c,k+1} = C_{c,k} + \frac{dt}{V_c} \times \{n \times C_{ex} \times Q_{ex} + (Q_l + Q_h) \times [C_o - C_{c,k}] - n \times Q_{ex} \times C_{c,k}\} \quad (2)$$

where dt is the time interval, and k is the time step.

Figure 2 is a schematic diagram of PM's transient mass balance diagram using the cabin as the control volume. Unlike the concentration of carbon dioxide, the vehicle's air conditioning system has a filter that can filter the suspended particles in the vehicle. In addition, the ERV proposed in this study also has a filter. Therefore, the filtration efficiency of the filter needs to be considered when calculating. Also, passengers' breathing does not cause an increase or decrease in suspended particles, so human exhalation is ignored when calculating the equation for suspended particles.

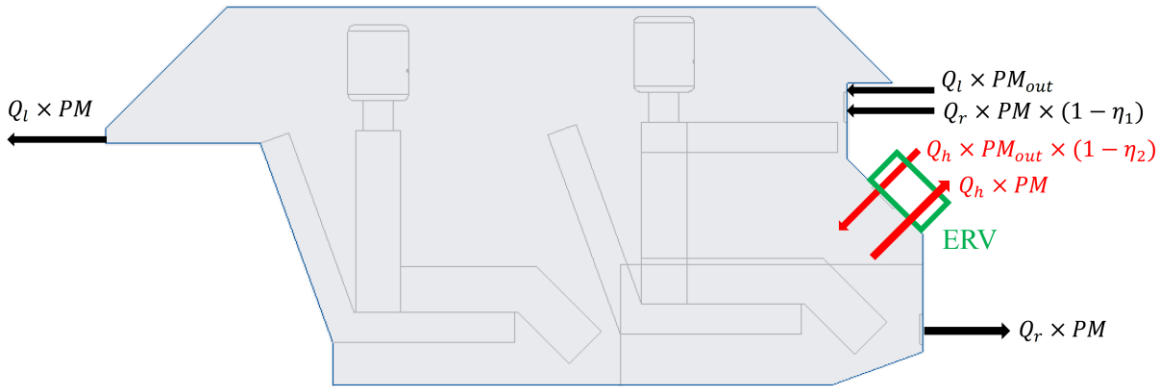

Figure 2. Transient mass balance diagram of PM using the cabin as control volume.

As shown in Figure 2, $Q_l \times PM_{out}$ is the outside suspended particulate matter that flows into the cabin through leakage ventilation, and $Q_l \times PM$ is the suspended particulates that flow out of the cabin due to leakage ventilation. When the air conditioner is in recirculation air mode, the suspended particles flow into the air conditioner is $Q_r \times PM$ and the suspended particles sent back into the cabin through the air conditioner filter is $Q_r \times PM \times (1-\eta_1)$. The suspended particles flow into the cabin through the ERV filter is $Q_h \times PM_{out} \times (1-\eta_2)$, and the suspended particles flow out of the cabin through the ERV is $Q_h \times PM$. Using the concept of control volume, the above PM inflow and outflow can be expressed as the suspended particulate mass balance equation:

$$V_c \times \frac{dPM}{dt} = Q_l \times PM_{out} + Q_r \times PM \times (1-\eta_1) + Q_h \times PM_{out} \times (1-\eta_2) - Q_l \times PM - Q_r \times PM - Q_h \times PM \quad (3)$$

where PM is the suspended particles concentration within the cabin, PM_{out} is the suspended

particles concentration in the outdoor environment, Q_r is recirculation air flow rate, η_1 is the filtration efficiency of in-car filter, η_2 is the filtration efficiency of ERV filter. The present simulations evaluate the suspended particle concentration in the cabin under different conditions using the following finite difference equation derived from Eq. (3):

$$PM_{k+1} = PM_k + \frac{dt}{V_c} \times \{Q_l \times [PM_{out} - PM_k] + Q_h \times [PM_{out} \times (1-\eta_2) - PM_k] - Q_r \times \eta_1 \times PM_k\} \quad (4)$$

Table 1 Parameters used in analysis.

number of occupants：n	1~5
The volume of the cabin：V_c (m^3)	3.821
The CO_2 concentration of each exhaled breath：C_{ex} (ppm)	40,000
The breath volume flow rate of each occupant：Q_{ex} (m^3/s)	0.0001145
The initial value of the CO_2 concentration in the cabin：$C_{c,k=1}$ (ppm)	420
The outdoor CO_2 concentration：C_o (ppm)	420
Time interval: dt (s)	1
The outdoor suspended particles concentration：PM_{out} (particles/cm^3)	8,000
The initial value of the suspended particles concentration in the cabin：$PM_{k=1}$ (particles/cm^3)	8,000
In-car filter filtration efficiency/ ERV filter filtration efficiency：η_1 /η_2	0.25 / 0.999
The ventilation flow rates when ERV operate at low speed/ high speed： Q_{hl} / Q_{hh} (m^3/s)	0.00675 / 0.00944
Leakage ventilation flow rate of cabin：Q_l (m^3/s)	0.00127
Recirculation air flow rate：Q_r (m^3/s)	0.03461

3. RESULTS AND DISCUSSION

3.1 Verification of CFD model

The validity of the numerical model was confirmed by comparing the simulation results for the CO_2 and PM concentrations in the cabin with the experimental results presented by Jung et al., 2017. For both sets of results, the ventilation system was set to the recirculation air mode for the first 23 minutes and was then switched to the fresh air mode for the next 15 minutes. The average CO_2 and PM concentrations were recorded every minute, as shown in Figs. 3(a) and 3(b), respectively. It is seen that the simulation results are in good agreement with the experimental data for both the CO_2 concentration and the PM concentration. Consequently, the feasibility of the proposed model is confirmed. The minor discrepancy between the two sets of results is most likely due to slight variations in the outdoor environment during the experimental measurement process, which are unknown and thus cannot be replicated in the simulations.

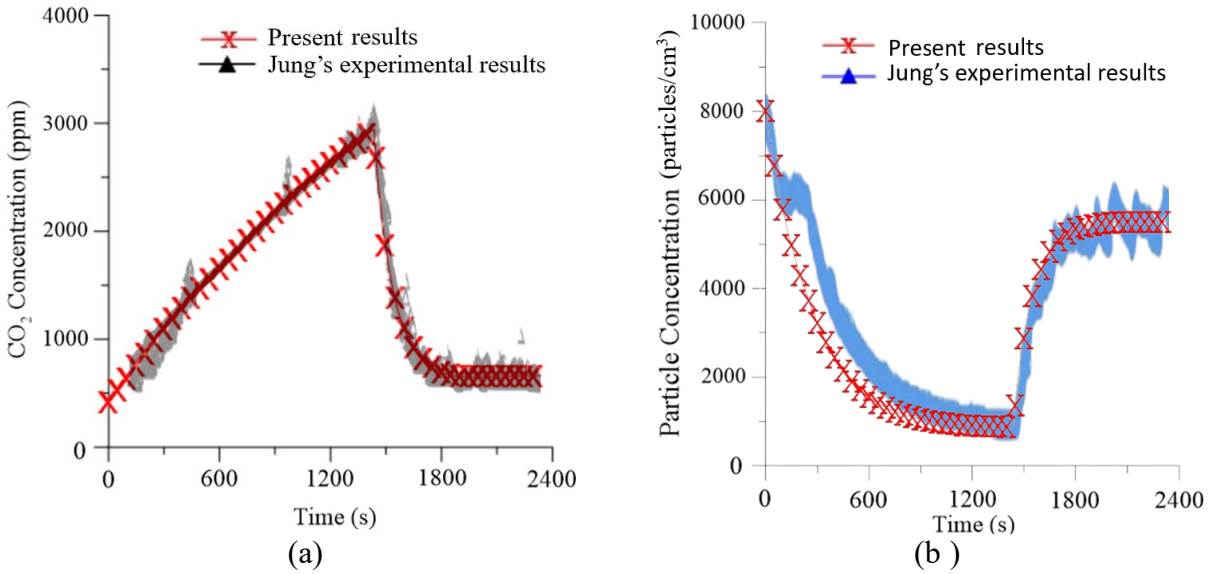

Figure 3 Comparison of simulation results and experimental values reported by Jung et al., 2017 for (a) CO2 concentration and (b) suspended particulate concentration.

3.2 Simulation results under different ERV operating conditions

3.2.1 Simulation results for IAQ when ERV is turned off

Figure 4 shows the variation in the CO_2 concentration over time for different numbers of occupants within the cabin when the ERV is not turned on. When using the recirculation air mode, the only fresh air entering the cabin ingresses through leakage ventilation. Consequently, the CO_2 concentration increases rapidly over time. For a single occupant, the CO_2 concentration reaches 1000 ppm after 539 seconds and 1989 ppm after 30 minutes. Moreover, the CO_2 concentration scales proportionally with the number of occupants. Thus, for five people in the cabin, the CO_2 concentration reaches 1000 ppm after only 101 seconds and climbs to 7557 ppm after 30 minutes.

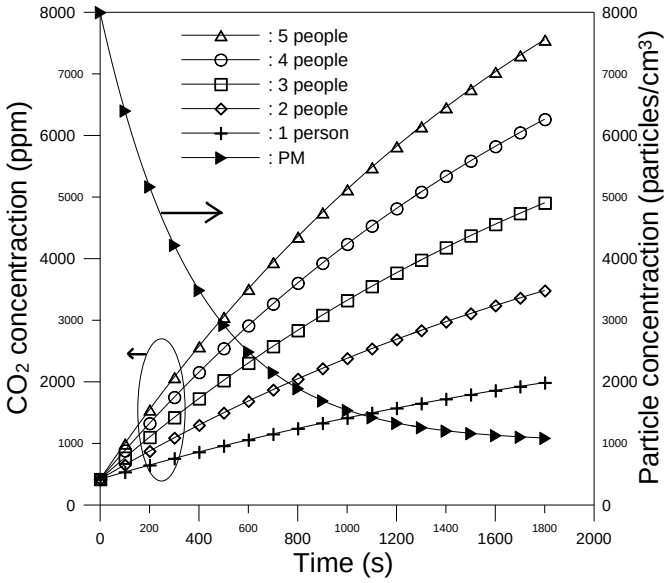

Figure 4 The variations in the CO_2 and PM concentrations over time for different numbers of occupants within the cabin when the ERV is not turned on

Figure 4 also shows the change in the average concentration of the suspended particles in the cabin

over time for 1–5 occupants when the ERV is not turned on. It can be seen that PM concentration is independent of the number of people from Equation (3). Moreover, since the air-conditioning system is set to the recirculation air mode, very little outside air enters the cabin. Consequently, the number of suspended particles reduces over time owing to the effects of the filter system in the air-conditioning unit. The suspended particle concentration decreases from the initial value of 8000 particles/cm^3 (see Table 1) to 1089 particles/cm^3 after 30 minutes.

3.2.2 Simulation results for IAQ when ERV operates at low speed

Figure 5 shows the variation in the CO_2 concentration over time for different numbers of occupants in the cabin when the ERV operates at a low speed (0.00675 m^3/s). Compared with the case when the ERV is not turned on, the overall concentration of CO_2 is reduced. Moreover, the rate of increase in the CO_2 concentration saturates after approximately 12 minutes, rather than increasing continuously, as shown in Fig. 4. Thus, after 30 minutes, the concentration of CO_2 is still lower than 1000 ppm for a single occupant in the cabin. Moreover, for the maximum occupancy case, the CO_2 concentration is approximately 3011 ppm, compared to 7557 ppm in Fig. 4. Figure 5 also shows the change in the average concentration of the suspended particles within the cabin. Compared to the case where the ERV is turned off (Fig. 4), both concentration values are significantly lower than those shown in Fig. 4 for the case where the ERV is not turned on. The ERV increases the AER between the inside and outside of the cabin, consequently, the CO_2 concentration decreases. Moreover, since the ERV incorporates a high-efficiency filter (99.9%), the particulate concentration also reduces. A comparison of Figs. 4 and 5 shows that using the ERV reduces the particulate concentration by almost half (~615 particles/cm^3) compared to the case where the ERV is not used (1089 particles/cm^3).

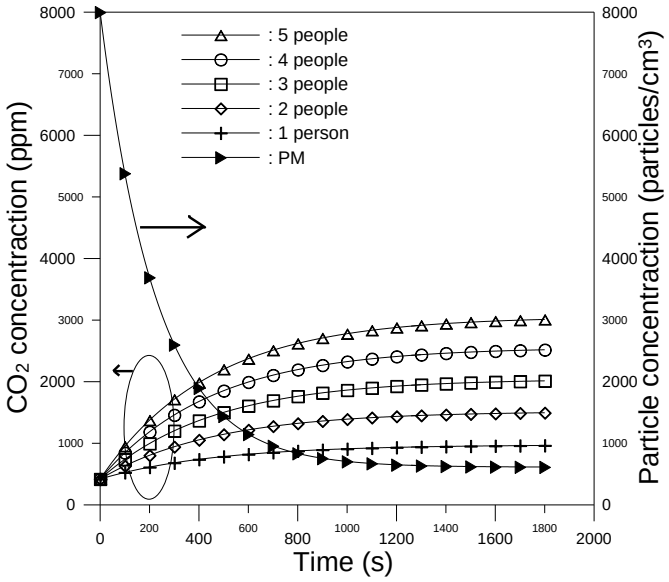

Figure 5 The variations in the CO_2 and PM concentrations over time for different numbers of occupants within the cabin when the ERV operates at a low speed

3.2.3 Simulation results for IAQ when ERV operates at high speed

Figure 6 shows the variation in the CO_2 concentration over time for different numbers of people in the cabin when the ERV operates at a high speed (0.00944 m^3/s). Compared with the case where the ERV is not turned on or is operated in the low-speed mode, the high-speed mode results in a

lower CO_2 concentration level and stabilizes the concentration more quickly. For a single occupant in the cabin, the CO_2 concentration stabilizes within around 10 minutes. Even with five occupants in the cabin, the CO_2 concentration approaches a constant value after approximately the same time. After 30 minutes, the CO_2 concentration for a single occupant is just 836 ppm, while that for five occupants is around 2419 ppm, which is about 20% lower than when the ERV is operated at a low speed. Figure 6 also shows the average concentration of suspended particles in the cabin for 1–5 occupants and the ERV operating at a high speed. As for the low-speed ERV mode, the suspended particulate concentration drops very quickly as soon as the ERV is turned on and stabilizes within approximately ten minutes (~530 particles/cm^3).

Comparing Figs. 4-6, it can be seen that the improved IAQ can be attributed to the greater AER under high-speed ERV operating conditions. For 2–5 occupants, the CO_2 concentration exceeds the ASHRAE standard of 1000 ppm. In fact, for 4 and 5 occupants, the CO_2 concentration is more than double the standard (2035 ppm and 2418 ppm, respectively). Nonetheless, as reported by Chang et al., 2023, cognitive function is not impaired even at CO_2 concentrations of around 2000 ppm, provided that the average driving time does not exceed 8 hours.

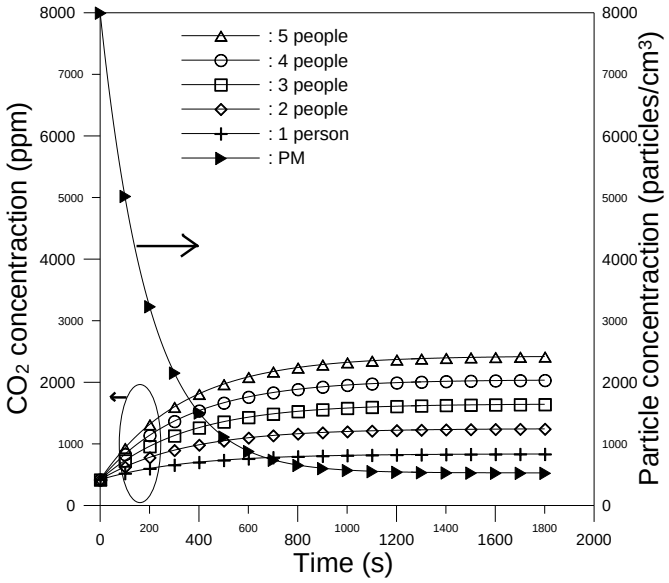

Figure 6 The variations in the CO_2 and PM concentrations over time for different numbers of occupants within the cabin when the ERV operates at a high speed

3.3 Estimated ERV energy savings

To estimate the energy savings of the ERV, the outdoor temperature and relative humidity were set to 35℃ and 80%, respectively (that is, the enthalpy value h_{out} was equal to 109.42 kJ/kg). The cabin temperature and relative humidity were set at 25℃ and 60%, respectively (h_{in}=55.45 kJ/kg). The enthalpy difference between outdoor and indoor air was thus 53.97 kJ/kg. By Cho et al., 2023, the enthalpy recovery efficiency was set as 60%. Consequently, the enthalpy recovery amount per unit mass of air exchanged was 53.97×0.6 = 32.38 kJ/kg. According to Chang et al.,2021, the coefficient of performance (COP) of electric vehicles in the air conditioning mode is around 3.18. The total amount of enthalpy recovery divided by the COP gives the energy consumption of the air conditioner saved. Subtracting the power consumption of the ERV (low-speed consumption: 1.9 W, high-speed consumption: 2.7 W) then gives the net energy savings provided by the ERV. As shown in Table 2, the ERV system considered in the present study achieved net energy savings

of 79.6 W and 110.3 W in low-speed and high-speed running conditions, respectively.

Table 2 Enthalpy recovery amount and net energy saving of ERV under low-speed and high-speed running conditions

	Air mass flow rate (kg/s) A	Total enthalpy recovery (W) B=A×32.38×1000	Air conditioning power reduction (W) C=B/3.18	ERV power consumption (W) D	Net energy savings (W) E=C-D
Low speed	0.008	259.1	81.5	1.9	79.6
High speed	0.0111	359.4	113	2.7	110.3

4. CONCLUSION

This study has proposed using an ERV to improve the IAQ of vehicle cabins and recover the cooling enthalpy to reduce the energy consumption of air conditioners. CFD simulations have been conducted to investigate the performance of the ERV in regulating the CO_2 and suspended particulate concentrations within the cabin at different numbers of occupants and ERV operating conditions (low and high speed). Overall, the results confirm that the ERV system not only improves the IAQ in the vehicle cabin but also reduces the air conditioning load and therefore lowers the energy consumption.

SUMMARY
This paper offers a detailed analysis of the South Korean government's green remodeling initiatives for public buildings. It explores the critical challenges and strategies associated with the mandatory implementation of green remodeling for public buildings, set to begin in 2025. The paper further investigates potential solutions, focusing on the development of a strategic roadmap, evaluation methodologies, and effective policy implementation, underpinned by technical and research methodologies designed to support South Korea's carbon neutrality goals.

Keywords: Green-Remodeling, Building Energy, Mandatory Green-Remodeling for Public Buildings

1. GENERAL INSTRUCTIONS

South Korea has committed to carbon neutrality by 2050, with substantial efforts across various sectors, including industry, transport, and buildings. The building sector, accounting for 24.6% of national greenhouse gas emissions in 2018, faces a target of a 32.8% reduction by 2030. Achieving this reduction remains a significant challenge(South Korea’s 2030 Nationally Determined Contributions (NDC)). To this end, the Green Buildings Construction Support Act (2012) encourages Zero Energy Buildings (ZEB) for new constructions and Green Remodeling (GR) for existing buildings. Green remodeling is considered a pivotal strategy, especially for public buildings, with mandatory green remodeling set to begin in 2025. This paper analyzes the current policies, identifies issues in the implementation of green remodeling for public buildings, and proposes solutions within the domains of policy, technology, and evaluation frameworks.

2. KOREAN GOVERNMENT POLICY : GREEN-REMODELING OF PUBLIC BUILDING

2.1. What is green-remodeling?

Green remodeling can be defined as the process of improving the performance of insulation, facilities, and other building systems in aging buildings to enhance energy efficiency, thereby reducing heating and cooling costs, lowering greenhouse gas emissions, and creating a more comfortable living environment. Nationally Determined Contribution(NDC) for the building sector in South Korea and the specific implementation measures are presented in Figure 1.

Building sector
Nationally Determined Contribution

green growth master plan ('23.4)

Division	Key tool	Means of implementation	
New building	Zero Energy Buildings	Public	• Mandatory zero energy building certification
		Private	• Strengthening design standards • Incentive
Existing building	Green Remodeling	Public	• Support project • Mandatory project
		Private	• Interest support • Accredited Accreditation System, etc.

Figure 1. Overview of South Korea's Carbon Neutrality Policy and Achieving Measures in the Building Sector

2.2. Green-remodeling…How is it promoted?

The South Korean government's strategy for green remodeling presents the vision of "leading the transformation of aging public buildings into green buildings and expanding this approach to private buildings." The green remodeling initiatives in the public sector can be divided into four stages, as outlined below.

- Initiation Phase (2013-2019) : Pilot projects, providing partial funding for 15 sites annually.
- Adaptation Phase (2020-2024) : Financial support for approximately 200 billion KRW allocated annually to 700 public buildings, preparing for the mandatory phase.
- Stabilization Phase (2025-2029) : Large-scale funding for both "Support Projects" (phased out) and "Mandatory Projects" (phased in).
- Expansion Phase (2030 onward) : Widening the scope to include private buildings.

2.3. Green-remodeling for public buildings…what's next?

As a detailed measure within the medium- and long-term reduction strategies for the building sector outlined in the "First National Carbon Neutrality & Green Growth Master Plan (April 2023)," the Korean government has emphasized the promotion of green remodeling for existing buildings. In the public sector, these efforts are primarily categorized into two main initiatives: the "Support Projects" and the "Mandatory Projects" (Figure 2).

The First national carbon neutrality and green growth master plan (sector) promotion work

Transition	Industry	Building	Transport	Agricultural, livestock and fisheries
- Reducing coal power generation - Nuclear power plant + renewable energy ↑ - Demand efficiency	- Core technology secure - Company support - Advanced emissions reduction	- Expanding zero-energy buildings - Green remodeling	- Supply zero-emission vehicle - Low-carbonization or railways, ports and shipping	- Transition to a low-carbon agricultural structure - low-carbonization of fishing vessels and facilities

- **Green remodeling of existing buildings** (※ Detailed tasks for mid to long-term reduction measures by sector)

○ **Expanding the support target and making it mandatory for green remodeling projects for public buildings**
(Ministry of Land, Infrastructure, and Transport)

· **Expanding the support target to include energy-intensive facilities, a large quantity facilities, etc., and discovering business models to activate remodeling**

· To expand green remodeling of old public buildings, phased application of mandatory green remodeling of old public buildings ('25~, 'The green buildings construction support act' revision promotion)

Figure 2. First National Carbon Neutrality & Green Growth Master Plan on South Korea

2.3.1. Green-remodeling 'support project' for public buildings

The Green Remodeling Support Program for Public Buildings was launched by the public sector in 2020 to lead the widespread adoption of green remodeling. This initiative began with hospitals, health centers, and daycare centers, and is a nationwide project that will invest approximately 900 billion KRW into around 3,400 public buildings by 2024. An analysis of the 2,908 buildings targeted from 2020 to 2023 shows an estimated reduction of 118,363 tons of greenhouse gas emissions and an energy cost savings of approximately 9 million KRW per building. This contributes to the achievement of national greenhouse gas reduction goals and is regarded as a successful integration of Korea's green remodeling industry and market (Source: 2024 Green Building Conference, Oh Se-min, "Strategies for the Implementation of Mandatory Green Remodeling of Public Buildings," partially cited, Table 1).

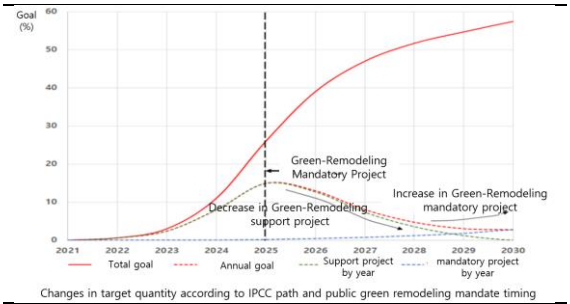
Table 1. Progress of the Public Building Green Remodeling Support Program (As of December 2024)

Division	(unit : billion KRW)			(unit : number of buildings)					
	Total	**Governmental expenses**	**Local governmental expenses**	**Total**	**Daycare center**	**Health center**	**Hospital**	**Senior citizen center**	**Library**
2020	**3,260**	2,180	1,080	**821**	411	369	41	-	-
2021	**3,197**	2,141	1,056	**895**	443	395	57	-	-
2022	**2,806**	1,836	970	**575**	271	276	28	-	-
2023	**2,545**	1,709	836	**617**	72	127	4	376	38
2024	**1,520**	1,031	489	**562**	58	163	1	340	-
Total	**13,334**	8,901	4,433	**3,470**	1,255	1,330	131	716	38

Considering the limited national resources, the achievement of the 2030 NDC targets, and the various types and sizes of public buildings, a scenario for the 'Support Program' has been proposed as follows. The aim is to maximize the expected benefits of large-scale national financial investments in the 'Support Program' while gradually transitioning to the 'Mandatory Program' in 2025. The transition will begin with the most common building types in 2025-2026 and gradually reduce the scope over time (Table 2).

- Implementation Strategy : (Priority 1) : Buildings primarily used by vulnerable groups (e.g., health centers, hospitals, daycare centers, etc., until 2023), (Priority 2) : Energy-intensive buildings (e.g., educational and research facilities, neighborhood service facilities, public facilities, etc., until 2027), (Priority 3) : Public buildings with a large variety of functions (e.g., other public facilities, museums, fire stations, etc., until 2029).

Table 2. Proposed Implementation Strategy for Public Building Green Remodeling 'Support Program'



Changes in target quantity according to IPCC path and public green remodeling mandate timing

Status of priority setting by building uses		
Division	Building uses	note
1st	health centers, hospitals, daycare centers, etc.	vulnerable groups
2nd	library, welfare facilities for senior citizens, etc.	energy- intensive facilities
3rd	educational facilities, other educational research facilities, etc.	
4th	other public facilities, social welfare facilities, etc.	a large quantity facilities
5th	museum, fire station, etc.	

Number of green remodelling support purposes by year (target)									
2020	2021	2022	2023	2024	2025	2026	2027	2028	2029
3 types	3 types	3 types	5 types	4 types	9 types	10 types	9 types	7 types	3 types

2.3.2. Green-remodeling 'mandatory project' for public buildings

The Korean government aims to prioritize the mandatory implementation of green remodeling for public buildings, while simultaneously encouraging its expansion to the private sector. To achieve this, the government seeks to establish a detailed policy framework for the mandatory green remodeling of public buildings and present a leading model to ensure the private sector's acceptance. The details of these efforts are summarized in Figure 3, which outlines the 'Support Program' and 'Mandatory Program' for public building green remodeling.

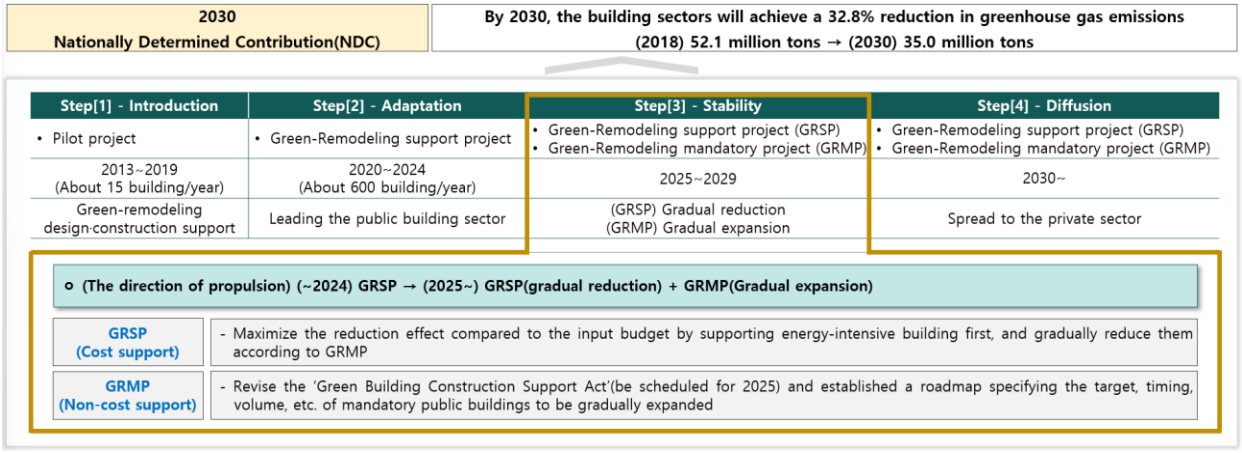


Figure 3. South Korea's National Strategy for Green-Remodeling

3. VARIOUS ISSUES AND RESPONSE STATUS OF GREEN-REMODELING PROJECT FOR PUBLIC BUILDING

3.1 Issues in green-remodeling of public building on south korea

In order to gradually promote the green remodeling mandatory project for public buildings, related standards and grounds must be established. In order to establish a plan to promote mandatory green remodeling of public buildings, it is necessary to clearly define public buildings and organize data on public buildings suitable for mandatory green remodeling of public buildings. Based on this, a promotion system that includes criteria for selecting mandatory targets to achieve reduction goals, promotion procedures, participating organizations, and roles must be established. In addition, in order to evaluate the performance improvement effect of buildings subject to mandatory green remodeling, evaluation methods and tools suitable for green remodeling should be developed.

In order to systematically promote the mandatory project, we are carrying out various tasks in stages, such as preparing public building data, developing evaluation methods and tools, and the current status is as shown in Section 3.2.

3.2. Development of roadmap for mandatory green-remodeling of public buildings

3.2.1. Preparing public building data-sets

In order to establish a medium- and long-term roadmap for the mandatory green remodeling of public buildings, it is essential to first understand the current state of public buildings. This study utilizes the National Building Energy Integrated Database (NBEID) operated by the South Korean government (Ministry of Land, Infrastructure and Transport) to construct a dataset for public buildings. The dataset is based on the reference year 2018, which aligns with South Korea's 2030 Nationally Determined Contributions (NDC), and considers the target years of 2030 and 2050. The

procedure for constructing the dataset is outlined below, and further details can be found in the research report titled "Establishing the Implementation Plan for the Mandatory Green Remodeling of Public Buildings."

- Identification of Public Building Targets : Extract public buildings owned by the public sector from South Kores's 7.45 million buildings using the 2018 and 2023 building registry data
- Ownership Proportions of Public Buildings : Detemine the public-private ownership proportions in buildings with partial ownership
- Identification of Ownership Types of Public Buildings : Idenitify public buildings for mandatory green-remodeling by examining ownership status and defining those 100% owned by a single public entity
- Construction of Public Building Dataset : Create a data-set to track public building current status and support the development of a roadmap for mandatory green-remodeling

As of 2023, the total number of public buildings in South Korea is identified as 417,066, with 232,657 buildings being fully owned by the public sector. Considering the feasibility and ease of implementing the mandatory green remodeling of public buildings starting in 2025, the scope for mandatory green remodeling will be defined by excluding certain building types (e.g., small-scale buildings under 100m², military facilities, etc.). This target group is responsible for 45.8% (6,042,000 tCO_2eq) of the total greenhouse gas emissions from public buildings, with 39.9% (793,000 tCO_2eq) from direct emissions and 46.9% (5,249,000 tCO_2eq) from indirect emissions (Table 3).

Table 3. Dataset Construction (Partial) and Proposed Scope for Mandatory Green Remodeling of Public Buildings

Criteria for Distinction				No. of Buildings	GFA (m^2)	Energy Consumption (toe)	GHG emissions ($tCO_2eq.$)
Included building uses	100% public ownership	Sole ownership	Individual	37,272 (8.94%)	111,869K (33.52%)	952.9K (31.20%)	4,277K (32.40%)
			Multi-unit	131 (0.03%)	768K (0.23%)	5.2K (0.17%)	22K (0.17%)

			Multi-unit	501 (0.12%)	2,090K (0.63%)	19.6K (0.64%)	76K (0.57%)
		Fractional ownership	Individual	47,035 (11.28%)	11,696K (3.50%)	222.3K (7.28%)	1,036K (7.85%)
			Multi-unit	98,934 (23.27%)	39,885K (11.95%)	381.0K (12.48%)	1,364K (10.34%)
Total				417,066 (100%)	333,760K (100%)	3,054K (100%)	13,199K (100%)

3.2.2. Development of roadmap for mandatory green-remodeling of public buildings

Based on the previously constructed dataset of public buildings, this paper aims to propose a roadmap for the implementation of mandatory green remodeling in public buildings. Considering the direct emission reduction targets for the building sector outlined in South Korea's 2030 Nationally Determined Contributions (NDC) and 2050 carbon neutrality scenarios, it is deemed essential to establish the roadmap based on direct emissions. It is also necessary to plan a phased expansion, taking into account factors such as building usage, scale, age, and ownership type.

- Phase 1 (2025-2030) : (Scale) floor area of 3,000 m² or more, (Usage) 6 building types, (Ownership) Public sector ownership only (general buildings).
- Phase 2 (2031-2035) : (Scale) floor area of 500 m² or more, (Usage) 6 building types, (Ownership)

Public sector ownership only (general buildings).

- Phase 3 (2036-2040) : (Scale) floor area of 3,000 m² or more, (Usage) 10 building types, (Ownership) Public sector ownership only (general buildings).
- Phase 4 (2041-2045) : (Scale) floor area of 500 m² or more, (Usage) 16 building types, (Ownership) Public sector ownership only (general buildings).
- Phase 5 (2046-2050) : (Scale) floor area of 500 m² or more, (Usage) 16 building types, (Ownership) Public sector multiple ownership (general buildings).

3.3. Development of green-remodeling evaluation method

Given the heterogeneity of existing buildings, a dual evaluation approach Asset Rating (AR) and Operational Rating (OR) is proposed. AR assesses energy performance based on simulation models, while OR evaluates post-retrofit energy savings through actual usage data.

3.3.1. Development of simulator for setting energy performance improvement targets in the pre-construction phase of green-remodeling

The dynamic energy analysis of buildings based on EnergyPlus allows for the interpretation of thermal behavior within a building when applying interconnected green remodeling technologies. Unlike new buildings, which have relatively uniform operation conditions, existing buildings exhibit diverse operational conditions and usage patterns. Therefore, we aim to develop a dynamic evaluation program that reflects these characteristics and incorporates such diversity.

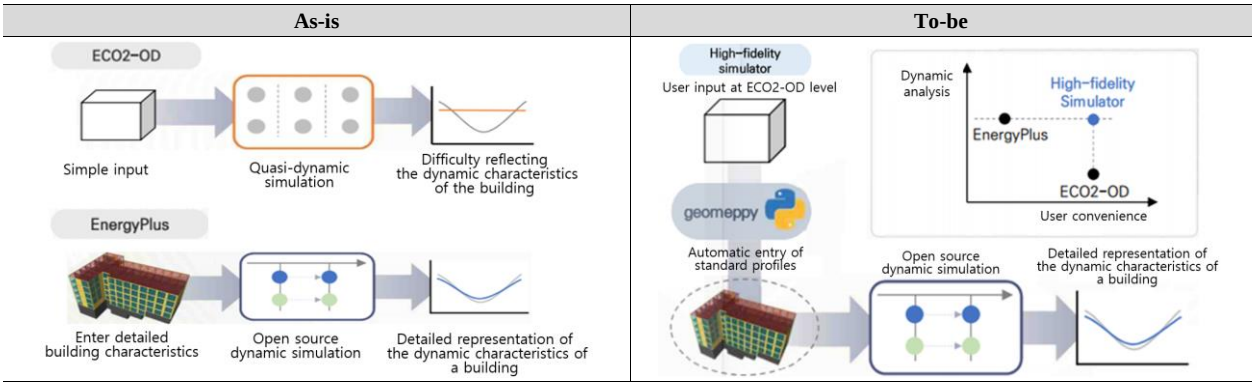

Figure 4. Approach for development of green-remodeling simulator
(Dong-A Univ., Seoul National Univ., 2024, Development of a prototype energy and greenhouse gas simulator for existing buildings, Progress report presentation material)

3.3.2. Development of evaluation method based on actual energy use post-construction phase of green-remodeling

The effectiveness of green remodeling can be assessed through various approaches. The first is relative evaluation, which compares the target building with a group of similar buildings to assess the change in energy performance. The second is absolute evaluation, which quantifies energy savings or greenhouse gas reductions by comparing the energy consumption or emissions of the building before and after green remodeling. The third is change point method (CPM), which is a methodology to analyze the energy consumption pattern of a building based on the relationship between monthly energy usage and average outdoor temperature. Each of these evaluation methods has its own strengths and limitations. In order to increase the robustness of green remodeling performance evaluation, we are developing an evaluation model that integrates the

results of relative evaluation, absolute evaluation, and CPM analysis to ensure a more comprehensive and accurate evaluation of energy savings and greenhouse gas reductions (Figure 5).

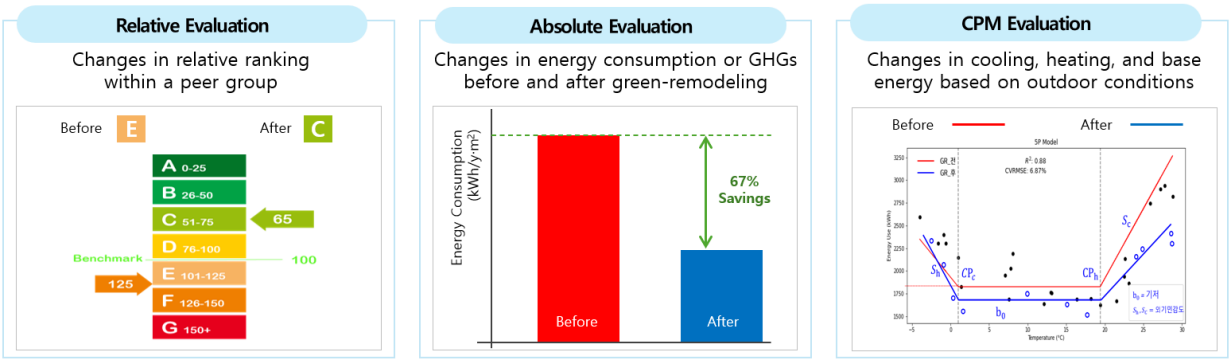

Figure 5. Framework of the comprehensive evaluation model for green remodeling

3.4. Calculation of greenhouse gas emission reduction factors through green-remodeling

The greenhouse gas emissions of individual buildings through green remodeling are calculated based on actual energy usage data. However, there are various alternatives that can apply green remodeling technology in the planning stage before actual construction. Reviewing these alternatives requires a lot of manpower, time, and resources. To solve this problem, we developed a "green remodeling greenhouse gas emission reduction factor(Table 4)" using dynamic simulation, deep learning techniques, etc. (Figure 6). This factor serves as a threshold for quickly and easily evaluating the greenhouse gas reduction amount through green remodeling in the early planning stage, and the factor may change if the building use, etc. are subdivided in the future.

Table 4. Green Remodeling Greenhouse Gas Emission Reduction Factor

Building Use	Reduction Coefficient ($kgCO_{2,eq}/m^2$)	Building Use	Reduction Coefficient ($kgCO_{2,eq}/m^2$)
① Detached house	31.2	⑪ Children's facilities	4.3
② Business facility	5.0	⑫ Elementary/Middle/High school	4.6
③ Police substation	14.7	⑬ University	3.4
④ Fire station	10.4	⑭ Research institute	4.4
⑤ Post office/Telephone office	7.2	⑮ Training facility	10.6

⑨ Railway/Airport	6.3	⑲ Business support facility types	10.7
⑩ Haspital	10.0	⑳ Library types	7.1

4. CONCLUSION

This paper analyzes the green remodeling policies and initiatives for public buildings currently being promoted by the South Korean government. It also discusses the key issues and corresponding solutions for the mandatory implementation of green remodeling in public buildings, set to begin in 2025. Various technological and research methodologies have been explored to provide solutions to these key issues.

In South Korea, public building green remodeling is being pursued through two distinct approaches: the "Support Program" and the "Mandatory Program." The Support Program will gradually scale down, while the Mandatory Program will gradually expand, as part of the strategy to achieve the 2030 NDC and 2050 carbon neutrality goals. To facilitate this, a dataset for public buildings (totalling 417,066 buildings) has been established, and a roadmap for the mandatory implementation

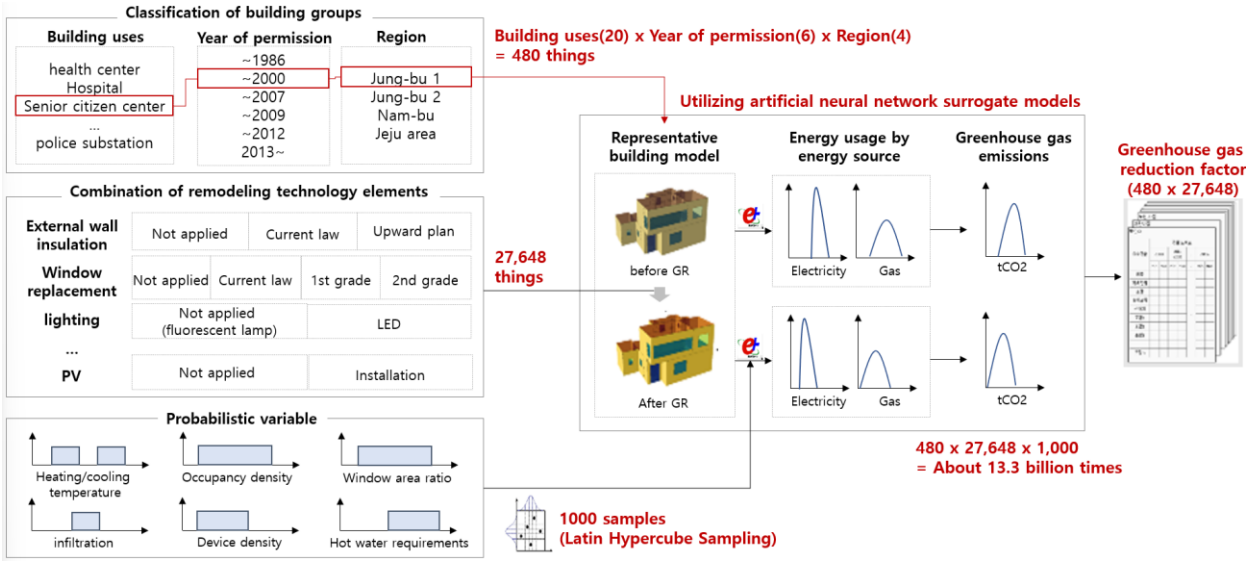

Figure 6. Overall process of deriving greenhouse gas emission reduction factors through green-remodeling
(Dong-A Univ., Seoul National Univ., 2024, Development of a prototype energy and greenhouse gas simulator for existing buildings, Progress report presentation material)

of green remodeling has been outlined, spanning through to 2050. Additionally, two evaluation methodologies, Asset Rating (AR) and Operational Rating (OR), have been proposed for green remodeling, and a greenhouse gas emission reduction coefficient through green remodeling is currently being developed. The results presented in this paper from the policy, technical, and research perspectives are expected to serve as valuable tools for future government policies and regulations and contribute to achieving national greenhouse gas reduction targets.

ACKNOWLEDGEMENTS

This research was funded by the South Korean government's “Green Remodeling Program for Public Buildings”.

SUMMARY
This study introduces an application of Two One-Sided Test (TOST) to validate weather normalization in building energy consumption analysis. Unlike traditional hypothesis testing which focuses on detecting differences, TOST directly tests for practical equivalence by defining acceptable bounds of similarity. Heating energy use intensity (EUI) data from 30,894 buildings was analyzed across three years (2018-2020), with weather normalization applied to adjust for climate variations. Buildings were stratified by regions and building types, and both paired TOST and Wilcoxon Signed-Rank based TOST were employed depending on data normality to verify the statistical equivalence of normalized energy consumption between years within each stratum. The effectiveness of this approach was validated using multi-year energy consumption data, with 2018 as the baseline year, offering a rigorous framework for building energy analysis while considering building characteristics and regional factors.

Keywords: equivalence testing, weather normalization, building energy consumption, Two One-Sided Test (TOST)

1. INTRODUCTION

The importance of weather normalization in analyzing building energy consumption has been widely recognized (Hong et al., 2016). Numerous studies have implemented weather normalization techniques to account for the significant impact of weather variations on heating and cooling energy use (Yu et al., 2011). This normalization process is crucial for accurately assessing energy performance improvements over time, independent of climatic fluctuations.

While the application of weather normalization is prevalent, the methods used to validate its effectiveness have been limited in their approach. The majority of existing studies rely on quantitative analyses such as variance reduction, t-tests, or ANOVA to demonstrate the absence of significant differences post-normalization. These methods typically focus on proving that weather-normalized data sets do not differ significantly.

However, these conventional statistical approaches may not be sufficient to fully validate the effectiveness of weather normalization. The absence of a significant difference does not necessarily equate to equivalence, which is the true goal of weather normalization. This study proposes a novel approach to address this gap in the current methodology.

In this study, the Two One-Sided Test (TOST) procedure is applied to validate weather

normalization. Unlike traditional difference-based tests, TOST is specifically designed to establish statistical equivalence (Schuirmann, 1987; Rogers et al., 1993; Wellek, 2010). This method allows for a more rigorous and appropriate validation of weather normalization by demonstrating that normalized data sets are equivalent within a predefined range of practical insignificance.

In this research, a multi-year energy consumption dataset from 30,894 buildings is analyzed. Weather normalization is performed using 2018 as the baseline year. The effectiveness of this normalization is then validated using TOST, providing a statistical confirmation of equivalence that has not been achieved in previous studies.

This novel application of TOST in weather normalization validation addresses a critical gap in current research methodologies. The findings underscore the importance of appropriate statistical techniques in energy analysis and pave the way for more accurate and reliable long-term evaluations of building energy efficiency.

2. THEORETICAL BACKGROUND OF EQUIVALENCE TESTING

The limitations of traditional hypothesis testing methods in demonstrating equivalence have been well documented in statistical literature. In conventional t-tests, the null hypothesis of no difference (H_0: $\mu_1 - \mu_2 = 0$) is tested against an alternative hypothesis of difference existence (H_1: $\mu_1 - \mu_2 \neq 0$). However, a failure to reject this null hypothesis cannot be interpreted as proof of equivalence; rather, it merely indicates insufficient evidence for difference detection. This limitation is particularly pronounced in weather normalization validation, where equivalence demonstration between normalized energy consumption values across years is sought. The Two One-Sided Test (TOST) methodology has been developed to address this statistical constraint through a reversed hypothesis structure. In TOST, the null hypothesis is formulated to assume differences beyond specified bounds (H_0: $|\mu_1 - \mu_2| \geq \theta$), while equivalence within these bounds is directly tested through the alternative hypothesis (H_1: $-\theta < \mu_1 - \mu_2 < \theta$), where θ represents the predetermined equivalence bound. Through this reformulation, a more rigorous statistical framework is established, wherein practical equivalence in building energy consumption can be demonstrated with statistical validity.

3. METHODS

3.1 Development of weather normalization coefficient

Weather normalization coefficients were developed to standardize building energy consumption across different climate conditions. The degree-days method was employed using hourly outdoor temperature data. Heating degree days (HDD) were calculated using a base temperature of 18°C, which represents the outdoor temperature threshold below which heating is typically required. The calculation was performed according to Eq. (1), as formulated by ASHRAE (2013):

$$\mathrm{HDD} = \sum_{d=1}^{365}\left[\frac{\sum_{i=1}^{24}\left(T_{base}-T_{o_i}\right)^{+}}{24}\right] \quad (1)$$

Where T_{base} is the balance point temperature (18 ℃), and T_{o_i} is the hourly outside air temperature (℃). Seoul was designated as the standard region for normalization based on its central geographical location and representative climate conditions for the country. The weather normalization coefficient (location) for each region was determined as the ratio of local HDD to

the standard region's HDD, as shown in Eq. (2):

$$C_{location\#} = \frac{HDD_{location\#}}{HDD_{standard}} \quad (2)$$

The normalized energy use intensity ($EUI_{normalized}$) was then calculated by applying this coefficient to the original EUI value, as shown in Eq. (3):

$$EUI_{normalized} = \text{EUI} \times \frac{1}{C_{location}} \quad (3)$$

The normalization coefficient functions as a scaling factor that adjusts the energy consumption values to account for regional climate differences. Regions with higher HDD values (colder climates) will have normalization coefficients greater than 1, resulting in lower normalized EUI values. Conversely, regions with lower HDD values (warmer climates) will have coefficients less than 1, resulting in higher normalized EUI values. This approach effectively standardizes energy consumption as if all buildings were operating under the climate conditions of the reference region (Seoul), enabling more accurate comparisons across different geographic locations.

3.2 Data collection and processing

Data for this study was obtained from the National Integrated Building Energy Database (NBED) (Ji et al., 2017; Cho and Le, 2017; Ji et al., 2020), focusing on public buildings to address privacy concerns. The initial dataset contained 136,254 public buildings across South Korea. A systematic data cleaning process was implemented to ensure data quality and reliability. Buildings with invalid identification codes, missing electricity meters, and incomplete floor area information were excluded in the primary validation phase. Technical validation was performed to eliminate cases with anomalous meter usage periods and insufficient energy usage pattern correlations (R^2). Buildings exhibiting heating energy consumption below 0.1 kWh/m² or lacking weather normalization coefficients were removed from the dataset. Outliers were identified and excluded using the interquartile range (IQR) method with a threshold of three times the IQR, following established statistical practices (Tukey, 1977; Hoaglin et al., 1986). To ensure statistical significance, only buildings with floor areas between 100m² and 30,000m² were included, and a minimum sample size of 10 buildings per building type and region was established. Through this comprehensive filtering process, the final dataset was reduced to 30,894 buildings. The weather normalization coefficients were then applied to standardize the energy consumption data across different climate conditions, with Seoul serving as the reference region.

3.3 Equivalence Testing

The equivalence testing process was conducted through a two-phase approach based on data normality. Since the analysis involved repeated measurements of the same buildings across different years, paired testing methods were employed. The Shapiro-Wilk test was performed on the year-to-year differences in energy consumption, with paired TOST applied for normal distributions ($p > 0.05$) and Wilcoxon Signed-Rank based TOST for non-normal distributions. The Shapiro-Wilk test was selected due to its superior power for detecting departures from normality compared to alternative tests such as Kolmogorov-Smirnov, particularly for the sample sizes encountered in this study (Razali and Wah, 2011; Ghasemi and Zahediasl, 2012). For non-normal distributions, the Wilcoxon Signed-Rank test was chosen as it makes no assumptions about the

underlying distribution and is robust against outliers (Kitchen, 2009; Derrick & White, 2017). This non-parametric approach is particularly suitable for building energy data, which often exhibits skewed distributions (Kim et al., 2020).

The equivalence bounds framework was initially designed to vary with the coefficient of variation (CV), with proposed thresholds of ±3% for stable energy consumption patterns (CV < 30%), ±5% for moderate variability (30% ≤ CV < 50%), and ±10% for high variability (CV ≥ 50%). This adaptive approach accounts for the inherent variability differences across building types, providing more appropriate equivalence criteria for each category.

Pairwise comparisons were conducted between years (2018-2019, 2019-2020, and 2018-2020). For normal distributions, the test evaluated mean differences between paired observations, while median differences were used for non-normal distributions. The maximum p-value among these comparisons was adopted for conservative interpretation, with statistical equivalence concluded at $\alpha = 0.05$.

4. RESULTS AND DISCUSSION

From the total dataset of 30,894 buildings analyzed in this study, the equivalence testing plots shown in Figure 1 represent a sample case of Class 1 neighborhood living facilities in Seoul (N=891). This sample was selected as a representative case to demonstrate the detailed results of the equivalence testing methodology. The analysis reveals significant improvements in energy use consistency after weather normalization.

Before normalization (Group 0), the median difference was 5.919, showing considerable deviation from zero. However, after weather normalization (Group 1), the median difference substantially decreased to 0.88, demonstrating a clear convergence toward zero. This convergence indicates that the weather normalization effectively reduced the variations in energy use intensity.
Moreover, the equivalence test results show that while the 90% confidence interval before normalization fell outside the equivalence bounds, it satisfied the equivalence criteria after normalization, falling within the bounds of -6.47 to 6.47. This improvement in the equivalence test results provides statistical evidence that weather normalization successfully enhanced the consistency and comparability of energy use intensities across different time periods.

The advantages of TOST over traditional hypothesis testing are clearly demonstrated in Figure 1. The plot shows both 95% confidence intervals (CI) for traditional hypothesis testing(t-test) and 90% CI for TOST, along with the predefined equivalence bounds. Although traditional hypothesis testing can show that two groups are not significantly different when the 95% CI includes zero, this does not necessarily mean the groups are equivalent. In contrast, TOST provides direct evidence of equivalence by showing that the 90% CI falls completely within the equivalence bounds after normalization. This illustrates how TOST not only detects the absence of significant differences but positively confirms practical equivalence within specified bounds, providing a more rigorous validation of weather normalization effectiveness.

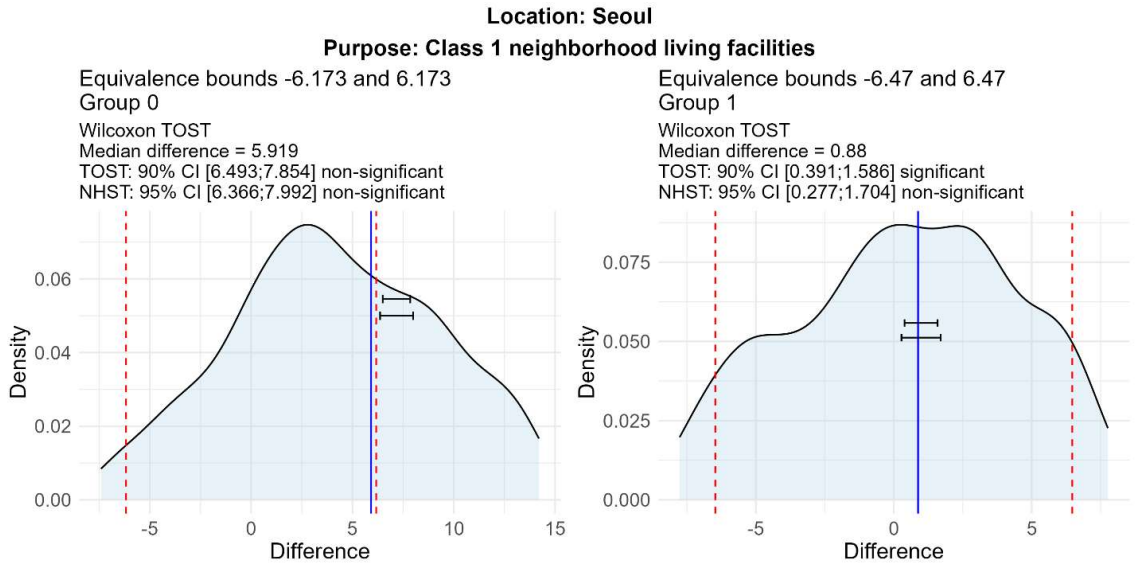

Figure 1. Equivalence test results for a sample case of Class 1 neighborhood living facilities in Seoul

This study primarily focused on public buildings that serve various community functions. The buildings in the dataset are predominantly operated for public service purposes, ranging from educational facilities to administrative buildings and community centers.

The effectiveness of weather normalization varied significantly across building types, which can be attributed to the diversity of specific uses within each building category.

Despite this inherent complexity in building operations and uses, the success rates of weather normalization showed an overall increasing trend across most building types as shown in Figure 2, although religious facilities exhibited lower improvement in normalized results. This suggests that weather normalization can be effective in standardizing energy consumption patterns across different time periods, while acknowledging that the effectiveness may vary depending on specific building characteristics and operational patterns.

The analysis revealed that some building types, particularly educational facilities and business facilities, exhibited substantial improvement after weather normalization. This can be attributed to their relatively consistent operational schedules and standardized usage patterns. Educational facilities typically operate on fixed academic calendars with predictable occupancy patterns, while business facilities generally maintain regular working hours and stable internal loads.
In contrast, religious facilities showed decreased success rates after normalization, likely due to several factors: inconsistent usage patterns (varying attendance at services), diverse architectural characteristics (often including large, high-ceiling spaces that are challenging to heat uniformly), and variable operational schedules (intermittent usage with periods of full occupancy followed by minimal activity).

Cultural and assembly facilities demonstrated slightly improvement. Their energy consumption patterns are influenced by operation-based usage, which introduces variability that weather normalization alone cannot fully address.

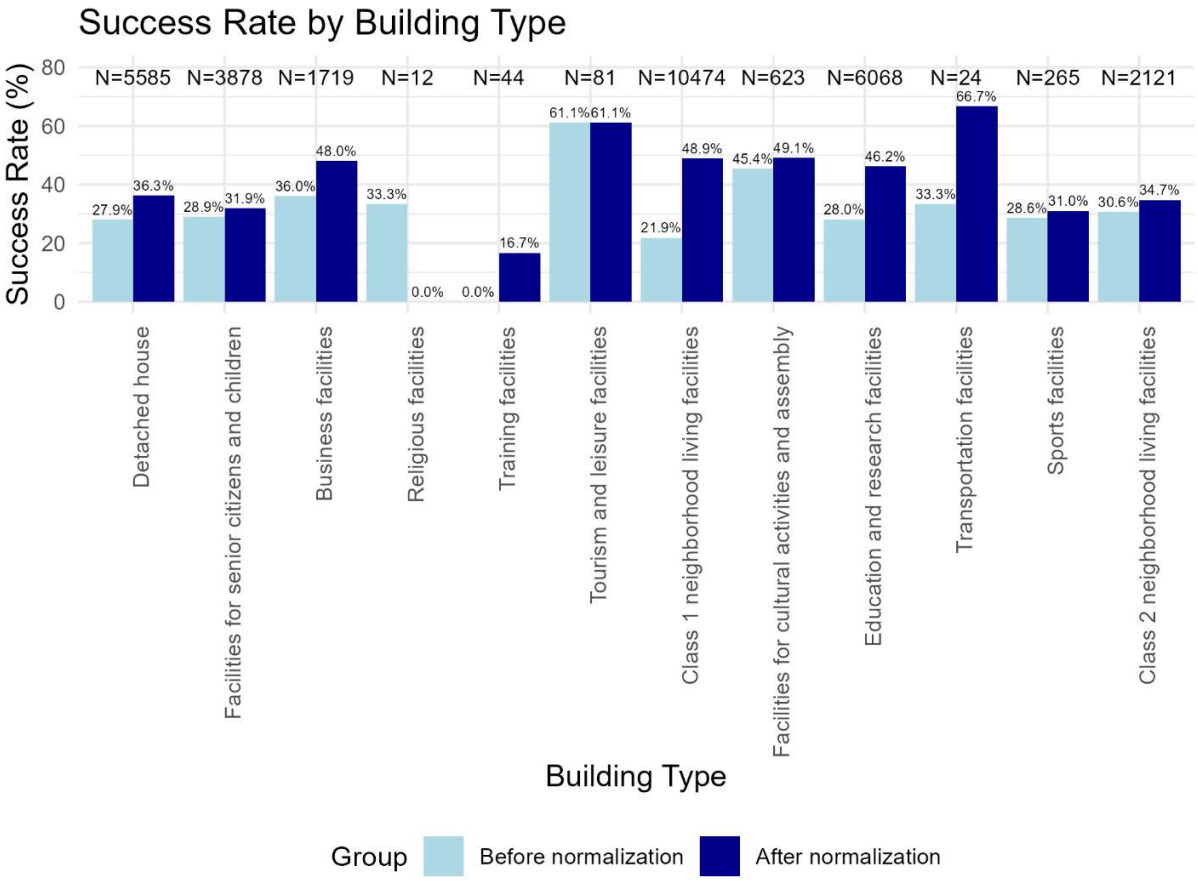

Figure 2. Success rate by building type (p-value < 0.05)

5. CONCLUSION

This study introduces a novel application of Two One-Sided Test (TOST) for validating weather normalization in building energy consumption analysis, addressing a significant methodological gap in the field. Through the analysis of 30,894 public buildings across South Korea over a three-year period (2018-2020), several key findings emerge:

First, the study demonstrates that TOST provides a more rigorous and appropriate framework for validating weather normalization compared to traditional hypothesis testing methods. By directly testing for practical equivalence rather than merely the absence of significant differences, TOST offers a more reliable approach to confirming the effectiveness of weather normalization procedures.

Second, the implementation of adaptive equivalence bounds based on coefficient of variation (CV) proves effective in accounting for different building types' inherent variability in energy consumption patterns. This flexible approach allows for more meaningful comparisons across diverse building categories while maintaining statistical rigor. However, the selection of appropriate equivalence bounds remains challenging and context-dependent, representing a limitation of the TOST approach that requires careful consideration in future applications. The

choice of equivalence bounds significantly affects the success rate of equivalence testing. The adaptive bounds approach used in this study accounts for the inherent variability of different building types, but it has limitations. Too narrow bounds might reject practical equivalence when it exists, while too wide bounds might accept equivalence when meaningful differences persist.

Third, the results show improvements in energy use consistency after weather normalization, as evidenced by the convergence of normalized data within established equivalence bounds. This improvement was particularly notable in certain building types, suggesting that the effectiveness of weather normalization varies with building characteristics and operational patterns.
Educational and business facilities showed the most significant improvements, while religious facilities demonstrated limited benefit from weather normalization alone. These findings highlight the importance of considering building-specific characteristics when applying weather normalization techniques. While weather normalization successfully improves energy consumption comparability across years for most building types, its effectiveness is moderated by factors such as operational schedules, occupancy patterns, and architectural features.
The varying effectiveness of normalization across building types suggests that complementary approaches may be necessary for buildings with highly variable usage patterns. For instance, religious facilities might benefit from additional normalization factors that account for occupancy patterns and usage intensity, beyond simple weather adjustments. This indicates that a one-size-fits-all approach to weather normalization may not be appropriate for all building categories.

These findings have important implications for building energy analysis and policy development. The methodological framework presented here provides a more robust foundation for comparing building energy performance across different climate conditions and time periods. This enhanced analytical approach can support more accurate energy efficiency assessments and better-informed decision-making in building energy management. Future research directions include exploring complementary normalization approaches for buildings with high variability, investigating the optimal selection of equivalence bounds for different building categories, and extending the TOST methodology to other aspects of building performance assessment.

SUMMARY
This study proposed a cluster analysis-based benchmarking approach using public data to address data acquisition limitations and better reflect energy consumption characteristics. The approach was applied to hospital building stock in South Korea, employing k-means clustering to classify peer groups and develop benchmarks. Two energy consumption indicators and four feature combinations were tested, with clustering results validated using the elbow method, silhouette index, Davies-Bouldin index, and ANOVA. As a result, five clusters were identified, and thirteen features were selected, including total floor area, annual energy consumption, cooling/heating/mid-season energy ratios, number of elevators, doctors, and beds, along with five dummy variables representing hospital types. The clustering results were analyzed based on the two energy consumption indicators. This approach demonstrated a practical method for analyzing building stock without additional data collection. It provides a valuable tool for researchers and policymakers to understand and manage energy consumption using public data.

Keywords: Building energy benchmark, Clustering analysis, Hospital

1. INTRODUCTION

Defining appropriate peer groups and benchmarks is essential for fair and effective energy benchmarking. The most common approach normalizes values within peer groups classified by building use, floor area, and region (Oh et al., 2023). While widely used, this method overlooks variations in energy consumption. Alternative approaches, such as regression models and machine learning techniques have been introduced to improve benchmarking accuracy (Capozzoli et al., 2016; Kim et al., 2023; Oh et al., 2023; Wu et al., 2023). However, these require extensive data collection such as national-level surveys or detailed building audits, often limiting analysis to subsets of buildings. Furthermore, benchmarking results may vary depending on the selected indicators, necessitating a comprehensive review of multiple indicators (Capozzoli et al., 2016). This study addresses these challenges by introducing a clustering-based approach using public data, focusing on hospital buildings, which account for significant energy consumption in the building sector. In South Korea, hospitals rank third in energy use per building, following retail and office building (KOSIS, 2024).

2. METHODS

This study utilizes two major databases: the National Building Energy Integrated Database (NBEID) and the Health Insurance Review and Assessment Service Database (HIRAD). NBEID contains building registration and monthly utility billing data (Kim et al., 2024), while HIRAD provides information on status of hospitals and pharmacies facility nationwide (HIRA, 2024). In this study, the building and monthly energy data from January to December 2022 were analyzed. To ensure that building characteristics were not diluted by mixed-use facilities, the analysis was restricted to buildings that contained only a single building and hospital on a given lot (Kim et al., 2024) Among various types of medical facilities, this study focuses on hospital-level buildings that provide inpatient care and have designated bed capacities. Facilities without inpatient services and tertiary hospitals were excluded. After the data cleansing procedure, a total of 933 buildings were included in the analysis, comprising 426 convalescent hospitals, 309 hospitals, 72 general hospitals, 62 oriental medicine hospitals, 47 psychiatric hospitals, and 17 dental hospitals.

Table 1. Feature combinations for clustering analysis.

id	Features	Source	Type	Set1	Set2	Set3	Set4
X1	TFA	NBEID	Float	●	●	●	●
X2-13	12-month energy consumption	NBEID	Float	●	●	●	
X14	Annual energy consumption	NBEID	Float				●
X15-X17	Heating, cooling, and mid-season energy consumption ratio	Calculated from X2-13	Float	●	●	●	●
X18	Number of elevators	NBEID	Int		●	●	●
X19	Number of doctors	HIRAD	Int		●	●	●
X20	Number of beds	HIRAD	Int		●	●	●
X21-X25	Dummy variables for six hospital types	HIRAD	Binary			●	●

Despite being categorized under the same medical facility type, variations exist in building use, scale, region, and operations. To account for this, k-means clustering was used, with all features normalized using a min-max scaler. Clustering results were validated using the elbow method and cluster Validity Indices (VIs), including the Silhouette Index ($Si_{Avg.}$) and Davies-Bouldin Index (DBI) (Bourdeau et al., 2021). ANalysis Of VAriance (ANOVA) tested statistical significance of clustering results. This study considered two key energy consumption indicators. Total Energy Consumption (TEC) represents absolute energy use, while Energy Use Intensity (EUI) normalizes consumption by Total Floor Area (TFA) for comparative analysis. Four feature sets were tested, summarized in Table 1, selected based on prior research (Oh et al., 2023) and correlation analysis of available data from NBEID and HIRAD.

3. RESULTS AND DISCUSSION

The elbow method showed a sharp decline in error when the number of cluster (k) ranged from 2 to 6. Clustering was conducted for these values, and results were evaluated using $Si_{Avg.}$ and DBI, as summarized in Fig. 1. For k = 2, feature sets 1 and 2 performed best ($Si_{Avg.} \approx 0.8$, DBI ≈ 0.5), but the mid-season energy ratio (X17) was found to be statistically insignificant based on the one-way ANOVA test. Excluding these cases, feature set 4 achieved the best performance across all evaluations. Specifically, for k = 5 and k = 6, feature set 4 yielded the highest $Si_{Avg.}$ and the lowest

DBI for both energy consumption indicators. As indicated in Fig. 1, TEC-based clustering achieved 5% higher $Si_{Avg.}$ and 11% lower DBI than EUI-based clustering. While clustering with k = 6 successfully distinguished six hospital types, the small sample size of dental hospitals (n = 17) led to the final selection of k = 5. With k = 5, clusters remained classified by hospital types, grouping dental hospitals with hospitals.

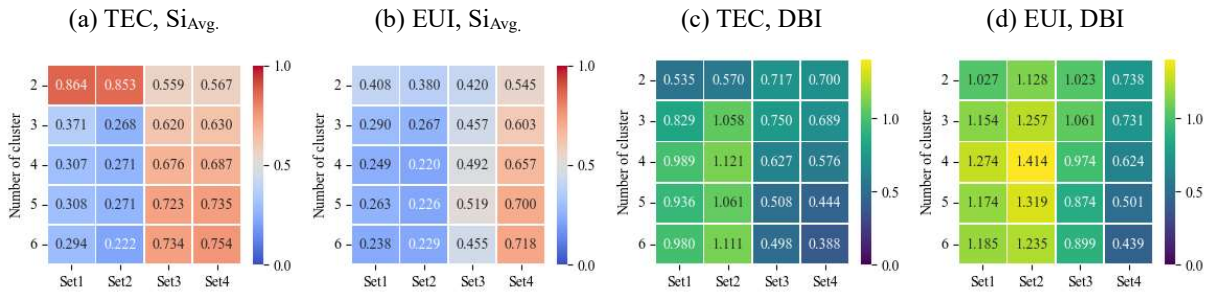

Figure 1. $Si_{Avg.}$ and DBI results by indicators, feature sets, and the number of k.

The clustering results showed that feature set 4 with k = 5 achieved the best VIs for both TEC and EUI. Based on these findings, the results of these two indicators were compared and discussed. To establish meaningful benchmarks, it is essential to verify whether energy consumption differences among clusters are statistically significant. The normality of energy consumption distributions was tested using the Kolmogorov-Smirnov test, where the null hypothesis ($\boldsymbol{H_0}$) states that the data follows a normal distribution. The results indicated that some clusters did not follow a normal distribution ($p<0.05$, $\boldsymbol{H_0}$ rejected). Consequently, both one-way ANOVA and the Kruskal-Wallis test were conducted, with the latter supplementing ANOVA due to its sensitivity to non-normality. As a result, the statistical tests confirmed significant differences in energy consumption values among indicators and clusters.

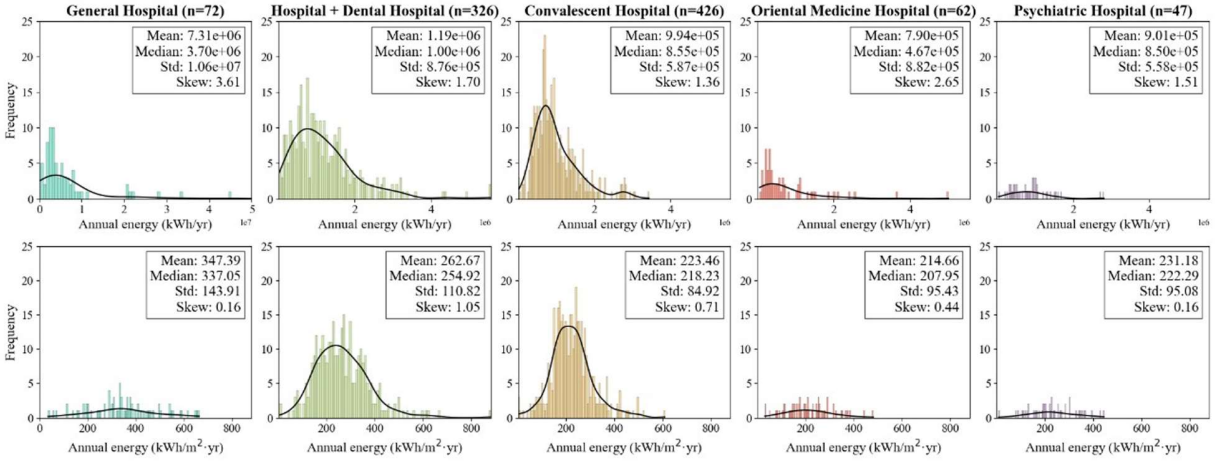

Figure 2. Distribution of annual energy consumption by indicators and clusters with feature set4 and k=5.

Fig. 2 illustrates annual energy consumption distributions for TEC and EUI with feature set 4 and k = 5. All clusters exhibited positive skewness, but EUI clusters normalized by TFA had skewness values below 1.0, making EUI a more balanced benchmarking metric. The largest skewness

difference (3.45) was found in general hospitals, followed by oriental medicine hospitals (2.21) and psychiatric hospitals (1.35). These findings suggest that TEC-based clustering should incorporate additional segmentation based on TFA to improve balance. This is particularly relevant for general hospitals, where large facilities introduce variability in energy consumption. Further preprocessing, such as refining cluster segmentation, is recommended. The results of the statistical tests support prioritizing median values over mean values to ensure more robust benchmarks.

4. CONCLUSION

This study proposed a cluster analysis-based benchmarking approach using public data to address data acquisition limitations while incorporating energy consumption characteristics. The results demonstrated that this approach effectively classifies peer groups and develops benchmarks without requiring additional data collection. Although applied to hospital building stock in South Korea, this approach can be extended to other countries or building types if relevant data is available. The findings highlight that TEC-based clustering and EUI-based clustering yield different peer groups, emphasizing the importance of selecting appropriate indicators for benchmarking. This approach provides a robust framework for researchers and policymakers, enabling data-driven energy benchmarking and more effective building energy management using publicly available data. Hospital administrators and policymakers can use the resulting peer group benchmarks to identify inefficiencies and set realistic energy conservation targets based on comparable facilities.

Harnessing infrared thermography and motion cameras to explore outdoor thermal adaptive behaviors - insights from an urban park investigation

Xiling Lu, Jiading Zhong, Shaowen Wang, Yang He, Jianlin Liu*

College of Environmental Science and Engineering, Donghua University, Shanghai 201620, China, jianlin.liu@dhu.edu.cn

SUMMARY
Frequent extreme high temperatures and the urban heat island effect worsen outdoor thermal environments, driving people to adopt adaptive behaviors for thermal comfort. This study in an urban park during summer monitored thermal conditions at four sites, recorded pedestrian behaviors and skin temperatures with the motion camera and infrared thermography. Results identified seven thermal adaptive behaviors, with the four most common ones (using sunshades, seeking tree shade, drinking cold water, seeking building shade) accounting for 30.4%, 25.9%, 16.5%, and 8.6% respectively. Meanwhile, quantitative analysis was performed in combining physiological equivalent temperature (PET) to examine the relationship between skin temperatures of various behaviors and outdoor thermal comfort. When PET is below 35°C, skin temperature cannot predict people's thermal comfort with thermal adaptive behaviors. This research summarizes multiple human thermal adaptive behaviors, fueling urban park design, and the exploration of the potential applications of infrared thermography technology in predicting outdoor thermal comfort.

Keywords: outdoor thermal comfort, infrared thermography, thermal adaptation, skin temperature.

1. INTRODUCTION

Global warming is giving rise to extreme climate events. The continuously increasing extreme high - temperature weather leads to frequent and severe heat stress Ebi et al. (2021); (Jay et al. 2021), which in turn affects the thermal comfort of outdoor residents in cities. Outdoor environments are more diverse than indoors, with pedestrians being directly exposed to an unsteady environment with dynamic wind speeds and solar radiation (Gehl 2001; Niu et al. 2015). Consideration of human initiative and thermal adaptive behavior is critical to understanding the relationship between the outdoor thermal setting and thermal comfort. The types of outdoor activities and their intensities can affect the human body's heat production and dissipation capabilities, thus influencing human thermal comfort. Peng et al. (2019) investigated the thermal comfort of outdoor activities like sitting, standing, strolling, and walking in squares, and found that people prefer shaded areas, confirming the correlation between thermal comfort and behavior. People tend to maintain body temperature stability through behavioral regulation. Nakano and Tanabe (2020) discovered that in the semi-outdoor environment of Tokyo, clothing adjustment is the primary form of behavioral adaptation, and the daily average outdoor temperature is the main factor influencing clothing adjustment.

Research methods for outdoor thermal comfort mainly include horizontal investigations and longitudinal trials. Outdoor thermal comfort studies often combine subjective questionnaires with objective measurements to obtain comprehensive and accurate data, but the questionnaire survey

has issues such as subjective authenticity, subjective authenticity. The application of non-contact technology compensates for the limitations of traditional subjective questionnaires. Non-contact measurement can capture the human body's physiological responses to changes in the outdoor thermal environment, such as skin temperature. Liu et al. (2020) used local skin temperature and heat load as inputs and observed that monitoring the skin temperature of two local body parts can effectively understand the body's outdoor thermal state. Speak et al. (2021) used infrared thermography to measure the forehead temperature of subjects to evaluate outdoor thermal comfort. The results showed that tree shade can significantly reduce heat stress and improve comfort, indicating that this technology is an effective tool for assessing human thermal sensation. Non-contact technology can also identify the human behavior outdoors (Kim and Brown 2022). Nevertheless, the current non-contact technologies are relatively limited in outdoor applications and have not yet combined thermal environmental parameters, human thermophysiological and crowd behavior recognition.

This study adopts the infrared thermography and the motion camera to record people's thermal adaptive behaviors as well as their physiological parameters, and analyses outdoor thermal comfort of thermal behaviors by the physiological equivalent temperature (PET). The main objectives were to: 1) determining human skin temperature and PET values with various thermal behaviors; 2) exploring the relationship between human behavior and outdoor thermal comfort; 3) providing references for urban design to enhance outdoor comfort.

2. METHODS

2.1. Research sites

The panel experiment was conducted in an urban park of approximately 200,000 square meters at the central area of Shanghai. Considering the diversity of human behavior, we chose four high-traffic sites in the park to carry out our research: the Milan Square, the Atrium Pergola, the Leisure Plaza, the Tree-lined Runway, respectively. Fig. 1 presents their environmental characteristics. The Milan Square (MS) contained a large area for recreation, surrounded by greenery; the Atrium Pergola (AP) was a corridor-like structure that provided artificial shade; the Leisure Plaza (LP) had stone piers for resting under the trees; the Tree-lined Runway (TR) was mainly for walking and connecting the par's attractions. These measurement locations involved various usage situation and nature-artificial shade, with multiple pedestrian thermal behaviors. Incidentally, subsequent references to the above study sites are abbreviated.

Figure 1. The field measurements were taken in the city parks: (1) the Milan Square (MS), (2) the Atrium Pergola

(AP), (3) the Leisure Plaza (LP), (4) the Tree-lined Runway (TR).

2.2 . Field experiments

Outdoor pedestrians had relatively low clothing thermal insulation, and the skin surface area directly exposed to the outdoors was the largest, thus it's easily to observe and record the individuals' physiological responses. The researchers utilized a handheld infrared thermography (IRT) to obtain human thermal infrared image, which analyzed their skin temperature. To capture timely pedestrian thermal condition when they developed thermal behaviors, a portable backpack with the meteorological monitoring sensors (the backpack weather station, BWS) was wore by the investigators to record climate parameters where people stayed, containing outdoor air temperature (T_a), relative humidity (RH), wind speeds (v), and the global solar radiation (G_r). And a sports camera on the shoulder belt of the backpack to shoot and document some information of pedestrians, including personal basic information, clothing, types of activities, and thermal adaptive behaviors. The survey took place on 15 rain-free days of the period July 27 to August 25, 2023, with each measured site being visited once or twice a day for a sustained period of 30 minutes between 11:00 and 15:00. The experimental equipment used for the study are shown in Fig. 2 and listed in Table 1–2 with their detailed specifications, which were calibrated prior to the investigation and fulfilled the standard ISO (2001).

Figure 2. Experimental instruments in this survey: (a) backpack weather station (BWS), (b) infrared thermography (IRT), (c) sports camera.

Table 1. Specifications of the backpack weather station on outdoor meteorological parameters.

Parameter	Type	Measuring range	Deviation
Air temperature（T_a）	S-THB-M002	−40℃ ~ 75℃	± 0.21℃（0℃~50℃）
The relative humidity（RH）	S-THB-M002	0 ~ 100%	± 2.5%（10%~90%）
The global solar radiation（G_r）	S-LIB-M003	0 ~ 1280 W/m^2	± 10 W/m^2（±5%）
Wind speed（v）	S-WSB-M003	0 ~ 75 m/s	± 1.1 m/s（±4%）
The skin temperature（T_{sk}）	Testo 865	-20 ~ 280℃	± 2℃

Table 2. The type and general parameters of the sports camera.

Type	Angle of view	Resolution	Range of focus	Operating temperature (℃)
Osmo Action 3	155°	4096 × 3072 (60fps)	0.3 m ~ ∞	-20 ~ 45℃

2.3. Data analysis and processing

Using the Testo software IRSoft to draw measurement boxes on images to obtain people's skin temperatures of the forehead (T_{face}) and forearms (T_{arm}), with an emissivity setting of 0.98 (Clark et al. 1977) and a reflected temperature set to air temperature. After aligning the time codes of the infrared camera and the motion camera, comparing the thermal images of the same individual with corresponding video frame snapshots, recording basic information such as gender, age group, clothing, activity types, and thermal adaptive behavior. The physiological equivalent temperature (PET) was chosen to assess outdoor human thermal comfort (Höppe 1999), and its calculations were performed by RaymanPro software (Lee and Mayer 2016) with input parameters including thermal environment parameters, geographic location information, and basic information about outdoor pedestrians (gender, age, height, weight, activity level, metabolic rate, and overall clothing thermal insulation).

3. RESULUTS AND DISCUSSION

3.1. Demographic parameters

Fig. 3 shows the gender and age distribution of the research subjects. A total valid sample size of 720 are acquired, involving 56.9% of males and 43.1% of females. And four age groups are covered, with 4.3% of adolescents (< 18 years old), 36.4% of young person (18 – 39 years old), 43.8% of middle-aged person (40 – 59 years old), and 15.5% of the elderly (> 59 years old).

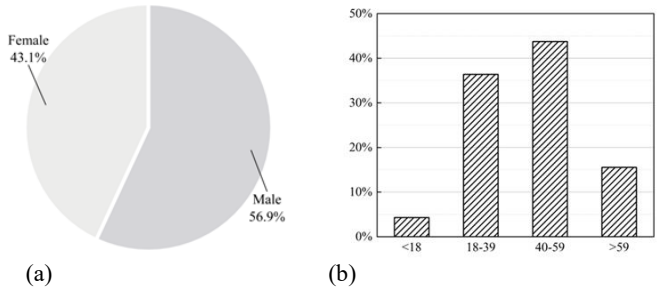

Figure 3. The distribution of subjects: (a) gender, (b) age.

Table 3. The survey participants' garment thermal insulation and metabolic rate values.

Variable	Location	Mean	Max	Min	Standard deviation
Clothing insulation, I_{cl} (clo)	MS	0.34	0.38	0.24	0.05
	AP	0.35	0.63	0.14	0.07
	LP	0.34	0.63	0.12	0.07
	TR	0.33	0.63	0.12	0.06
Metabolic rate, M (met)	MS	2.3	3.8	1.0	1.1
	AP	1.3	2.6	1.0	0.4
	LP	1.2	3.8	1.0	0.5
	TR	2.1	3.8	1.0	0.4

The clothing thermal insulation (I_{cl}) and metabolic rates (M) shown in Table 3 against the standard values in the ASHRAE (2023). The mean values of clothing insulation and metabolic rate for people at the four sites range from 0.33-0.35 clo and 1.2–2.3 met, respectively. At the MS, the

respondents have the less variation in clothing thermal resistance, a maximum o–f only 0.38 clo, while the average metabolic rate reaches 2.3 met. Compared to the other sites, site AP has the highest mean clothing thermal insulation of 0.35 clo, yet the mean metabolic rate is low at 1.3 met. The above human factors parameters of site LP are similar to the site AP. Folks at the TR walk slowly, and their metabolic rate is 2.1 met, second to the measured site MS.

3.2. Meteorological parameters of measured sites

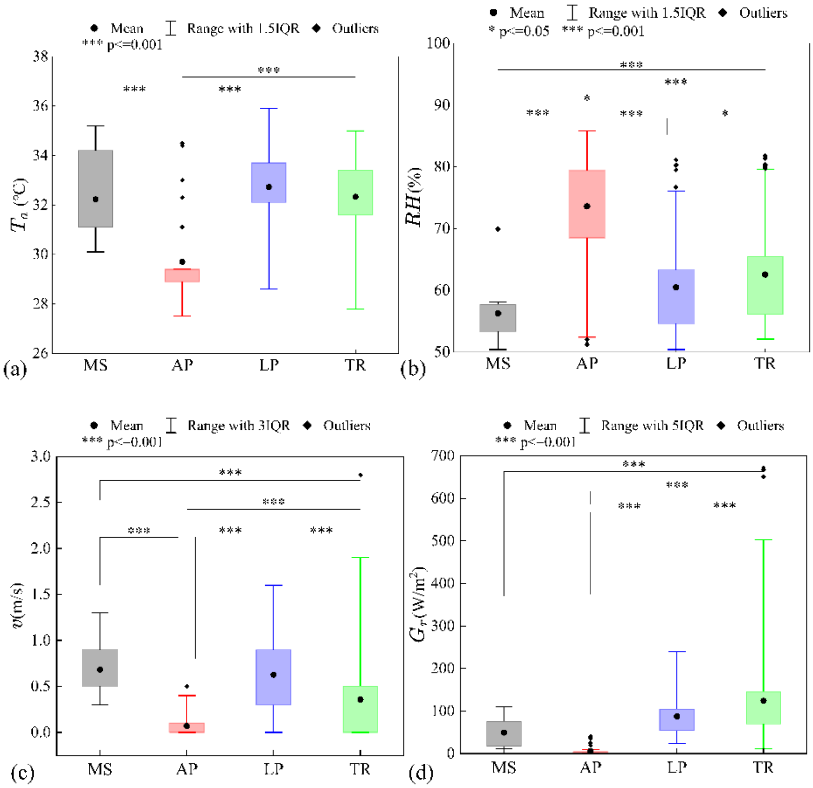

Figure 4. Distribution of different environmental parameters at four measured locations: (a) the T_a, (b) the *RH*, (c) the *v*, (d) the G_r. (* p<=0.05, *** p<=0.001)

Four scenarios' climatic conditions are shown in the Fig. 4. Site AP has the lowest average air temperature of 29.7°C, which is 2–3°C lower than the site MS (32.2°C), LP (32.8°C), and TR (32.5° C). And this urban park has an ornamental lake and high ambient humidity. The most elevated average relative humidity value of 73.6 % is found at the AP compared to the other three survey locations. The monitored place AP is primarily located in a shaded area and is closer to the lake. Significant differences ($p < 0.001$) in the T_a and *RH* values of the AP with respect to the others can be noted from Fig. 4 (a–b). The mean of *v* at the MS, AP, LP, TR are 0.7 m/s, 0.1 m/s, 0.6 m/s and 0.4 m/s, respectively. Due to the large amount of vegetation in the park, it is primarily in low winds. The *v* of the AP and TR differ prominently ($p < 0.001$) compared to the other locations. As observed for the AP (Fig. 4(c)), the wind speeds are lower with less variation, whereas the site TR experiences relatively higher wind speeds with a wider range of fluctuations. The global solar radiation values of the MS and AP areas are considerably smaller than that of the LP and TR areas, with the site AP having the lowest average G_r (5.9 W/m^2). The results on the one hand are attributed to the shading of trees and building galleries at the tested site, and on the other hand to the human

recreational time. The older people, for example, always gather in the Milan Square (MS) in the afternoon to exercise, during which time the intensity of the solar radiation is on a weakening trend. In addition, the G_r values of tested location TR are quite variable and markedly distinct from the rest of other three research places ($p<0.001$). Since the tree-lined runway (TR) is a necessary access to other parts of the park where the folks pass through at various times during the survey period, they will be exposed to broader values of solar radiation intensity here.

3.3. Thermal adaptive behavior

3.3.1. Classification of human various thermal behaviors

Thermal adaptive behaviors of pedestrians at different measured locations in the urban park were recorded by a motion camera during the field survey, and the IRT was used to capture people's thermographic images when performing these behaviors, thereby acquiring their physiological parameters in real time. Fig. 5 shows the proportion of thermal adaptive behaviors at different locations in the park. In this study, seven heat adaptive behaviors are identified, including moving to building or tree shade, using sunshade devices, drinking cold beverages, fanning, undressing, and wiping sweat. It can be found that the thermal adaptation behaviors mainly appear at TR and LP sites, which account for 48.8% and 33.1%, respectively, while MS and AP sites collectively make up 18.1% of the total. At the three locations—the MS, AP, and LP—occupants predominantly resort to the thermal adaptation strategy of relocating to areas shaded by buildings or trees. Specifically, the prevalence of such behavior is 4.4% at the MS, 8.6% at the AP, and 20.7% at the LP. Notably, a different phenomenon is observed at the TR. Here, a substantial 48.1% of the individuals choose to regulate their physiological states (the blue color block in Fig. 5) as their primary means of adapting to the thermal environment. This is because the individuals observed at location TR are mostly those making brief stops, such as commuters. And people spend extended periods at the other three locations, engaging in activities like resting or physical exercise. This significant disparity indicates that when people adopt thermal adaptation behaviors, they are influenced not only by the current thermal environment but also by the functional uses they assign to different places.

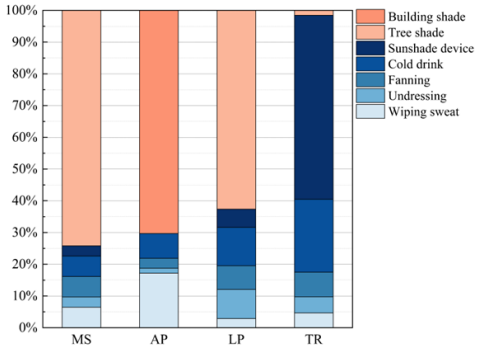

Figure 5. The percentage of human outdoor thermal adaptive behaviors during the investigation with various measured sites.

3.3.2. Evaluation of outdoor thermal comfort by PET

Fig. 6 present the relationship between skin temperature of forehead and forearm and PET for populations with different thermal adaptation behaviors, respectively. For pedestrians with thermal adaptation behaviors such as moving to building shade, tree shade, drinking cold beverages, fanning, undressing, wiping sweat, as well as those without thermal adaptation behaviors, there is

a positive linear correlation between the skin temperature and PET values. While a positive correlation exists between the skin temperature and PET for individuals engaging in other thermal adaptation behaviors as well as those without thermal behaviors. For people with using sunshade devices, the T_{sk} of they have an exponential positive correlation with PET values. Based on the magnitudes of the slopes of T_{sk} with respect to PET, we can rank the thermal sensitivities of people with different thermal adaptation behaviors as follows: undressing > wiping sweat > fanning > drinking cold drinks > moving to building shade > moving to tree shade. The group using sunshade equipment is rather special, as its thermal sensitivity weakens as PET increases. Furthermore, the order of the cooling effects of these thermal adaptation behaviors on skin temperature, from strongest to weakest, is opposite to the order of thermal sensitivity in these behaviors. Moreover, it can be observed that when PET < 35°C, as PET decreases, the skin temperatures of the surveyed individuals engage in thermal behaviors begin to gradually drop below that of those without thermal behaviors. This indicates that when PET values are less than 35°C, the T_{sk} cannot serve as a direct indicator for predicting the human thermal comfort with adopting thermal adaptative behaviors in the park. However, when PET < 33°C or PET > 39°C, the skin temperature cannot be directly used as an indicator to judge the thermal comfort of people when they adopt the thermal adaptation behavior of using sunshade devices.

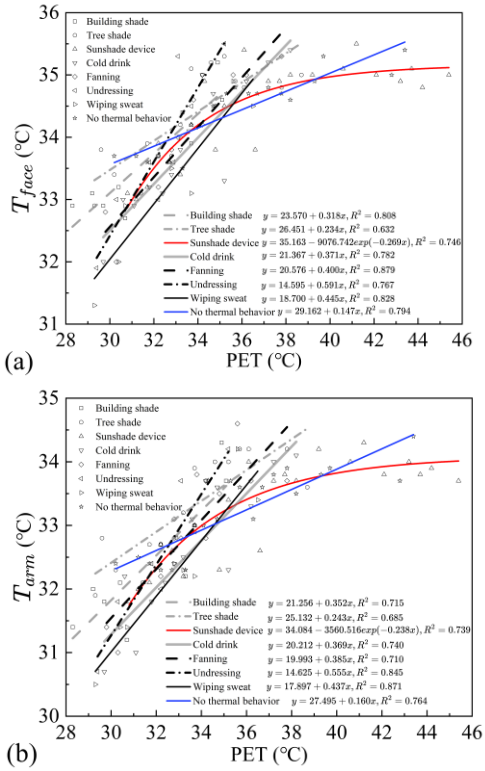

Figure 6. The relationship between human skin temperature and PET with different thermal adaptive behaviors: (a) T_{face}, (b) T_{arm}.

4. CONCLUSIONS

In this research, a motion camera was utilized to capture the human thermal adaptative behaviors in the park, while their skin temperatures were monitored in real time using an IRT. Aiming to explore the differences in outdoor thermal comfort with various thermal adaptation behaviors. The

principal findings are as follows: 1) the four common thermal adaptation behaviors in the park are using sunshade devices, seeking tree shade, drinking cold beverages, and staying in building shade, accounting for 30.4%, 25.9%, 16.5%, and 8.6% respectively; 2) people choose thermal adaptive behaviors with the following priorities in descending order: seeking tree shade, staying in building shade, drinking cold drinks, fanning, wiping sweat, and undressing, and when the PET values exceed 40°C, usage of sunshade devices become the preferred choice; 3) each type of thermal adaptation behavior has its specific critical PET value, when PET exceeds this value, the Tsk can be regarded as a direct indicator for predicting human thermal comfort with particular thermal adaptation behavior.

SUMMARY

This study aimed to develop a reliable in-situ evaluation method to capture parameters needed for thermal modelling of the point thermal transmittance and use them to calibrate the finite element thermal simulation. Farrat's structural thermal breaks were used to thermally break the heat transfer from the point thermal bridge connection created at the Energy House (EH) at the University of Salford. The numerical modelling was conducted in ABAQUS and calibrated using the experimental data. The findings revealed that using STBs reduced the χ-value of the bare wall by 6.73% and that of the externally insulated wall by 15.43%. These results highlight two key points: firstly, the significance of employing STBs to mitigate heat transfer through point TBs, achieving at least a 6.73% reduction; and secondly, the more pronounced impact of STBs in well-insulated structures. Furthermore, this research established a dependable in-situ method to gather the necessary parameters for evaluating thermal bridges.

Keywords: Thermal Bridging, Experimental measurement, Calibrated numerical modelling

1 INTRODUCTION

Point Thermal Bridges (TBs) are localised thermal anomalies that significantly impact the thermal performance of building envelopes. These TBs are characterised by their point-thermal transmittance, commonly called the chi-value ('χ-value'). The complex 3D heat flux associated with point TBs poses a significant challenge for accurate measurement and evaluation (Pemberton, 2024). Currently, no standardised measurement method exists for point TBs, leading to a reliance

on numerical calculations guided by standardised protocols (ISO, 2017b). This reliance introduces potential performance gaps due to the assumptions required for sensitive parameters such as surface resistance (Fitton, 2016).

In this study, we aim to address this challenge by integrating experimental data into the numerical modelling of the thermal characteristics of point connections, both with and without structural thermal breaks (STBs). STBs are designed to interrupt the thermal path and reduce heat transfer, thereby improving the overall thermal performance of the building envelope. By incorporating experimental measurements, we seek to enhance the accuracy of numerical models and provide a more reliable assessment of point TBs. The experimental setup involved measuring the U-value of the wall, as well as internal and external temperatures and surface resistances. These measurements were then incorporated into a numerical thermal model to simulate the thermal behaviour of point connections. The primary objective was to calibrate the parameters within a 3D finite element (FE) model, which is essential for quantifying point-TB transmittance accurately.

2 METHODOLOGY

2.1 Experiment

The experimental design was developed at EH, a climatic-controlled test facility at the University of Salford. A 0.5 m long steel-beam cantilever was bolted to the external wall, representing a single cantilever support (Fig. 1, left). This setup created a point penetration in the thermal envelope, enabling measurement of the 3D heat transfer through this TB both with and without STBs. We used Farrat's Struktra^{TM} STBs (Fig. 1, middle), which have a compressive strength comparable to steel and a thermal conductivity akin to wood (Table 1).

Table 1: Material properties of Farrat TBK material (Farrat, 2025)

Property	Farrat TBK	Property	Farrat TBK
Characteristic {Design} compressive strength [MPa]	312 {250}	**Density [kg/m^3]**	1465
Elastic modulus [MPa]	5178	**Water Absorption**	0.14%
Thermal conductivity [W/mK]	0.187	**Long term creep**	20%

Four test phases were conducted to understand the impact of the STB, with one factor changed at a time. Unquestionably, this approach could determine how altering a variable affects a given output, which resonates well with the current study. These phases were as follows:

- Phase 1 – Bare wall, steel only
- Phase 2 – Bare wall, steel thermally broken with STB
- Phase 3 – EWI wall, steel only
- Phase 4 – EWI wall, steel thermally broken with STB

Since this setup does not represent typical STB product utilisation, attempts were made to exacerbate the thermal bridging effect by retrofitting external wall insulation (EWI) to the wall in phases 3 and 4. The hypothesis was that the beam itself bridges more insulation, increasing the relative effects of bridging. Hence, a greater reduction can be measured when applying the STB solution. The EWI layers comprised soft mineral wool glued to EPS on plasterboard, chosen so that when retrofitted to the wall, the soft mineral wool would close the air gaps caused by the rough wall surface (see Fig. 1, right).

Fig. 1: The experiment set-up at EH (left), Farrat 25mm TBK STB (middle), and the external wall insulation retrofitted to the brick (right).

2.1.1 *Sensor Array:*

Internally, a T-type Thermocouple (TC) array ran parallel to the high-ε tape, linking the unaffected to the affected zone using vertical and horizontal lengths intersecting at the cold spot. Two heat flux meters (Hukseflux) were installed in the unaffected zones, all located with qualitative IR. T-type TCs monitored internal and external air temperatures, which were used to set up the simulation and U-value calculation (with heat flux), considering proper error propagation in the uncertainty analysis. Four 'FluxTeq' thin-film flux sensors (measuring flux and temperature) were embedded within the connection on either side of the break to measure the heat flux through the break itself. Measurements were compared with the model's probed responses for re-calibration. Table **2** lists the sensors used in the experiments and their absolute and relative uncertainties. The data logger also introduces a systematic error that applies to all detected signals, assumed to be 0.1% as per the manufacturer's specification.

Table 2: Absolute and relative uncertainties of sensors used in this experiment.

Sensor/Equipment	Measurement	Unit	Absolute Uncertainty	Relative Uncertainty
FluxTeq HFM	Heat Flux	W/m^2	±0.03 [W/m^2]	± 5%
T-type TC	Temperature	°C	± 1°C	± 1%
PT100 TC	Temperature	°C	± 1 °C	± 0.5%
Hukseflux HFM	Heat Flux	W/m^2	specific to individual sensors	± 6%

2.2 **Calculation:**

Due to the exciting internal airflow, it was deemed necessary to understand the internal surface-fluid HTC [W/m²K]. Therefore, measurements (fluid/surface heat flux along with local air and surface temperatures) were captured on each surface exposed to the internal and external environments. SR can be calculated using (1 – encapsulating both the convective and radiative terms in one expression (CIBSE, 2015):

$$\mathrm{SR} = \frac{1}{\frac{Q}{Ta - Ts}} \tag{1}$$

where 'SR' is the SR [m²K/W], 'Q' is the heat flux [W/m²], 'Ta' is the air temperature [K], and 'Ts' is the surface temperature [K]. Input parameters can be adjusted within their confident uncertainty intervals to calibrate the model. The sensitivities of 'dT' and the 'flux' estimates to the calculated measurand were calculated and then multiplied with the combined standard uncertainty for the respective estimate. These were then combined in quadrature (RSS–squared and summed) before the square-root. We avoided getting into details of uncertainty due to limited space here.

The U-value of the wall can be calculated using (2):

$$\mathrm{U} = \frac{\mathrm{Q}}{Tai - Tao} \tag{2}$$

where 'U' is the thermal transmittance [W/K], 'Q' is the heat flux [W/m²], 'Tai' is the inside air temperature [K], and 'Tao' is the outside air temperature [K].

The chi-value (χ-value) of point thermal bridging can be calculated using Eq. 3 ((ISO, 2017b; Ward et al., 2016):

$$\chi = L_{3D} - \sum_{i=1}^{N_i} U_i \,.\, A_i - \sum_{j=1}^{N_j} \psi_j . l_j \tag{3}$$

where 'χ' is the point-thermal transmittance or chi-value [W/K], 'L_{3D}' is the 3D coupling coefficient [W/K] (total energetic loss divided by the applied temperature differential), 'U_i' is the 1D U-value [W/m^{2}K], 'A_i' is the area the 1D U-value is effective over [m^2], 'ψ_j' is the psi-value (ψ-value) [W/mK], 'l_j' is the length over which the psi value exists [m] (ISO, 2017b). In this 3D experiment, there was no linear transmittance, therefore, this part of the equation can be ignored.

2.3 **Simulation**

The steady-state heat transfer finite element (FE) analysis in ABAQUS calculates the conduction through the investigated construction detail. Convective and radiative transfers are represented as SRs (prescribed as surface-fluid HTCs) in the models at surface boundaries exposed to environmental conditions (BSI, 2017c) and temperature. After creating the 3D model of the set-up, it is meshed by dividing the geometry into numerous elements each with four nodes. The

conduction equation and energy conservation laws are then applied to these nodes, forming a system of equations as a function of temperature. Through direct or iterative solutions, a temperature distribution field is determined, and interpolation is used to calculate the heat flows (BSI, 2017b).

3 RESULTS AND DISCUSSION

3.1 Experiment

Table 3 presents the measured values for surface-fluid HTC, the reciprocal of the SR.

Table 3: Measured values for surface-fluid HTC [W/m^{2}K], the reciprocal of the SR [m^{2}K/W].

	Phase1 [W/m^{2}K]	**Phase2 [W/m^{2}K]**	**Phase3 [W/m^{2}K]**	**Phase4 [W/m^{2}K]**
External	4.64 ± 0.21	4.64 ± 0.21	4.64 ± 0.21	4.64 ± 0.21
Internal	22.87 ± 11.42	22.87 ± 11.42	22.87 ± 11.42	22.87 ± 11.42

Contrary to the standardised assumptions of 25 and 7.7 W/m²K for surface-fluid HTC, externally and internally respectively, as outlined in BS EN ISO 6946 (ISO, 2017a), the measured surface-fluid HTC values averaged 22.87 ± 11.42 [W/m²K] (±50%) internally and 4.64 ± 0.21 [W/m²K] (±5%) externally. Compared to the standardised values, the increase in internal surface-fluid HTC was significantly impacted by eliminating internal stratification through air excitation with a fan. Additionally, the decrease in external surface-fluid HTC was attributed to the absence of weather conditions (solar, wind, rain) as the tests were conducted in a controlled chamber.

Table 4 presents each U-value and its uncertainty at a 95% (k=2) level of confidence.

Table 4: Average U value and their uncertainty at a 95% (k=2) level of confidence.

Phase	**U= $\bar{U} \pm \delta_U$**
Phase 1 (Bare brick)	$U_1 = 1.67 \pm 0.14$ $(\pm 8.5\%)$
Phase 2 (Bare brick)	$U_2 = 1.67 \pm 0.15$ $(\pm 9.1\%)$
Phase 3 (EWI)	$U_3 = 0.58 \pm 0.06$ $(\pm 11.0\%)$
Phase 4 (EWI)	$U_4 = 0.69 \pm 0.05$ $(\pm 7.4\%)$

Retrofitting EWI improved the U-value, achieving between 0.58 ± 0.06 and 0.69 ± 0.05 [W/m²K], compared to the pre-retrofit U-value of 1.67 ± 0.2 [W/m²K].

The measured averages of external and internal air temperatures and maximum and minimum internal surface temperatures can be seen in Table 5.

Table 5: Experimental measurement results averaged over a 12hr period.

Measurements	Ext Air Temp [°C]	Int Air Temp [°C]	Ext Surf Temp [°C]	Int Surf Temp [°C]
Phase1	5.88 ±1°C	23.39 ±1°C	20.04 ±1°C	22.47 ±1°C
Phase2	6.10 ±1°C	23.35 ±1°C	20.14 ±1°C	22.52 ±1°C
Phase3	5.61 ±1°C	23.35 ±1°C	21.35 ±1°C	22.97 ±1°C
Phase4	5.69 ±1°C	28.95 ±1°C	25.89 ±1°C	28.31 ±1°C

The measured averages of the embedded flux are seen in Table 6 below.

Table 6: The experimental measurement average and uncertainty of embedded flux over a 12-hour period.

Measurements	HF1 [W/m^2]	HF2 [W/m^2]	HF3[W/m^2]	HF4 [W/m^2]
Phase1	51.16 ± 2.76	40.98 ± 2.21	55.71 ± 3.00	50.32 ± 2.71
Phase2	29.99 ± 1.62	16.71 ± 0.9	24.44 ± 1.32	16.96 ± 0.91
Phase3	34.86 ± 1.88	38.58 ± 2.08	31.73 ± 1.71	38.07 ± 2.05
Phase4	201.77± 10.87	103.17 ± 5.56	140 ± 7.54	74.04 ± 3.99

3.2 **Simulation**

For all phases, the model geometry and material properties were adjusted to reproduce the measured U-value (as shown in Table 4). The tolerance of their adjustable range is dictated by the uncertainty analysis. We used the calculated U-value instead of measured temperatures and heat fluxes so that only one parameter is needed to be reproduced while adjusting the model geometry and material properties. The final calibrated model parameters are presented below in Table 7.

Table 7: Calibrated thermophysical properties: final parameters.

	Phase 1+2 Conditions		**Phase 3+4 Conditions**	
Material	Thickness [m]	Conductivity [W/mK]	Thickness [m]	Conductivity [W/mK]
Brick	0.225	0.7	0.225	0.7
Plaster	0.013	0.2	0.013	0.2
Skim	0.005	0.2	0.005	0.2
TBK	0.025	0.187	0.025	0.187
EWI	~	~	0.05	0.05
Internal Temperature [°C]		23°C	Internal [°C]	P3(23°C), P4(29°C)
Internal Surface-Fluid HTC		25[W/m^{2}K]	Internal	25[W/m^{2}K]
External Temperature [°C]		6°C	External [°C]	6°C

External Surface-Fluid HTC	4.85[W/m^{2}K]	External	4.85[W/m^{2}K]

Analytically, the U-value depends on properties contributing to the total thermal resistance of the wall: SRs, material thickness, and their conductivities. The measured SRs, as shown in Table 3, are 22.87 ± 11.42 W/m²K (±50%) and 4.64 ± 0.21 W/m²K (±5%) for the internal and external surfaces, respectively. These values were applied to the models.

The following images examine temperature isotherms of cross-sections through the centre of the TB, allowing visual comparison in bare wall phases and retrofitted ones (Figure 2). In the top images, the limits to the temperature scale were not adjusted, whereas in the bottom images, the temperature scale limits were adjusted, illustrating isotherm deflection. The maximum and minimum were set, focusing on the temperature gradient through the TB break junction. Because the measured internal temperature conditions for phases 3 & 4 were different (23°C and 29°C, respectively), the illustrated example considered identical conditions, i.e. 23°C and 6°C, for internal and external temperatures in each simulation – producing a fair visual comparison between phases.

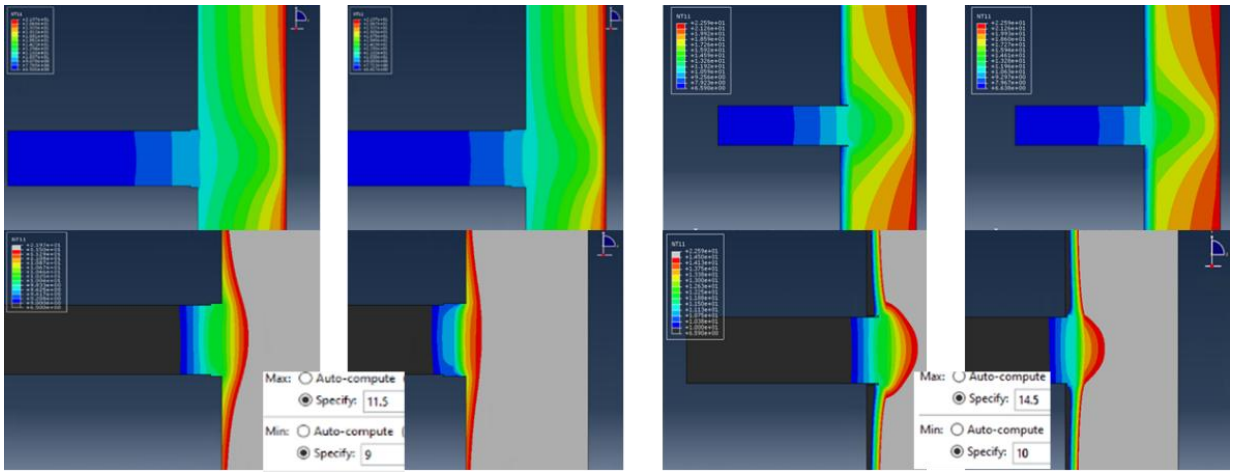

Figure 2: Left to Right: Phase 1 to 4, respectively. Temperature is scaled between 9°C and 11.5°C for phases 1 & 2 and between 10°C and 14.5°C for phases 3 & 4 in the bottom images.

Table 8 presents the calculated chi-value (following the standardised BRE methods) for each phase and the corresponding reduction when the STB solution is applied. A 6.73% reduction in TB-transmittance is observed between phases 1 and 2 (where no external wall insulation is present), raising the minimum internal temperature by a modest 0.1°C. In contrast, a 15.43% reduction in TB-transmittance is noted between phases 3 and 4 (when external wall insulation is retrofitted to exacerbate bridging), raising the minimum internal temperature by 4-5°C. This demonstrates an increase in overall TB-transmittance when EWI is retrofitted, confirming that the higher the resistance of the wall, the greater the benefit from STB solutions.

Table 8: Chi-value results of each phase and % reduction when STB used

	Phase1	**Phase2**	**Phase3**	**Phase4**

Chi-Value [W/K]	0.104	0.097	0.1814	0.2145
% Reduction	6.73%		15.43%	

4 CONCLUSION AND FUTURE WORKS

This study successfully developed a reliable in-situ evaluation method to capture the parameters necessary for thermal modelling of point thermal transmittance. By using Farrat's STBs at the EH at the University of Salford, we were able to thermally break the heat transfer from the point thermal bridge connection. The numerical modelling, conducted in ABAQUS and calibrated with experimental data, demonstrated that STBs significantly reduce the χ-value of point thermal bridges. Specifically, the χ-value of the bare wall was reduced by 6.73%, and the externally insulated wall saw a reduction of 15.43%. These findings underscore two critical insights: the importance of employing STBs to mitigate heat transfer through point TBs, achieving at least a 6.73% reduction, and the more pronounced impact of STBs in well-insulated structures. This research not only highlights the effectiveness of STBs but also establishes a dependable in-situ method for gathering the necessary parameters to evaluate thermal bridges accurately. In conclusion, the integration of experimental data into numerical models has proven to be a significant advancement in the accurate assessment of point TBs. This approach enhances the understanding of thermal characteristics in building envelopes and supports the design of more energy-efficient structures. The results of this study provide a robust framework for future research and practical applications in the field of thermal performance evaluation and provide the framework to test the thermal performance of connections in projects outside the controlled conditions.

SUMMARY
Rising temperatures due to climate change increasingly compromise thermal comfort and pose health risks in naturally ventilated buildings. Passive cooling strategies offer sustainable solutions to maintain indoor comfort while reducing energy use. While extensively studied for individual buildings, passive strategies at the neighborhood scale under future climate scenarios remain underexplored. This study assesses overheating risks in a mixed-use neighborhood in Kadıköy, Istanbul, with 2,455 buildings, 5999 zones, using a calibrated Urban Building Energy Model under the Chartered Institution of Building Services Engineers Technical Memorandum 52 and 59 criteria. Long-term overheating risks were calculated under the Shared Socioeconomic Pathway 5-8.5 extreme scenario, for residential and non-residential zones, separately until 2080. Retrofit scenarios incorporating cool envelope materials and glazing with low solar heat gain coefficient were investigated to mitigate overheating. Results showed that passive strategies can reduce overheating risks up to 36%, delaying the need for mechanical cooling to 12.19 years on average. The developed method can inform long-term retrofit processes and provide well-informed decision-making.

Keywords: indoor overheating risk, passive cooling, urban building energy modeling, climate change

1. INTRODUCTION

In urban areas, climate change increasingly harms public health and the built environment. Intensifying hot extremes disrupt sanitation, energy services, and overall human well-being (IPCC, 2023). Climate change, therefore, poses serious threats to the built environment, emphasizing the need for effective heat mitigation and adaptation strategies to protect vulnerable populations in urban areas (Ballester et al., 2023). The growing vulnerability of buildings under extreme heat conditions has prompted increased interest in energy retrofit (ER) strategies. Most ER strategies focus on energy use and decarbonization while often overlooking overheating in buildings without mechanical cooling. As temperatures rise, indoor overheating is becoming a critical performance metric due to its impact on occupant health and comfort. Consequently, addressing overheating in both existing and newly designed buildings is becoming an increasingly urgent priority for policymakers, researchers, and practitioners alike. In response, passive cooling strategies represent

a critical avenue for mitigating the effects of overheating in buildings and enhancing thermal resilience in the coming years.

Studies on building thermal resilience and cooling strategies largely fall into two main areas: (1) reviewing definitions of thermal resilience, comfort, energy performance, and mitigation strategies, and (2) assessing thermal resilience through simulations or real-time data. The first category focuses on defining key performance indicators related to thermal comfort, heat stress and energy performance (Hong et al., 2023; Holzer et al., 2024). Other studies in this category involve the evaluation of cooling strategies, particularly in extreme heat conditions or power outages (Elnagar et al., 2023). In the second category, several studies assess resilient cooling alternatives in retrofit scenarios using Building Performance Simulations (BPS), focusing on indoor overheating in individual buildings (Mehmood et al., 2023). Other studies focus on the prediction of future conditions (Abbas et al., 2024), and the examination of thermal resilience without retrofit scenarios through simulations and real-time data (Palma et al., 2024), typically by relying on existing metrics. At the district scale, studies often focus on residential zones (Morales et al., 2025). A study investigated the performance of combined heating and cooling systems in mixed-use buildings within a synthetic district (Gautier et al., 2022). Despite these, there remains a significant gap in research regarding the assessment of overheating risks and passive cooling retrofit strategies for the urban-scale, long-term continuous assessment of buildings.

This study aims to fill this gap by presenting a methodology for assessing the long-term overheating risk using adaptive comfort standards (CIBSE TM52 and TM59) and calculating the impact of passive cooling strategies in naturally ventilated homes and offices in mixed-use neighborhood in Istanbul, Turkiye. For buildings where passive strategies remain insufficient, this study also forecasts the future year that the indoor discomfort would require air conditioning. The methodology can help decision-makers in long-term planning of ER actions while indoor overheating.

2. METHODOLOGY

This study presents a methodology for the long-term assessment of the effect of resilient cooling strategies on indoor overheating considering future climate change impacts.

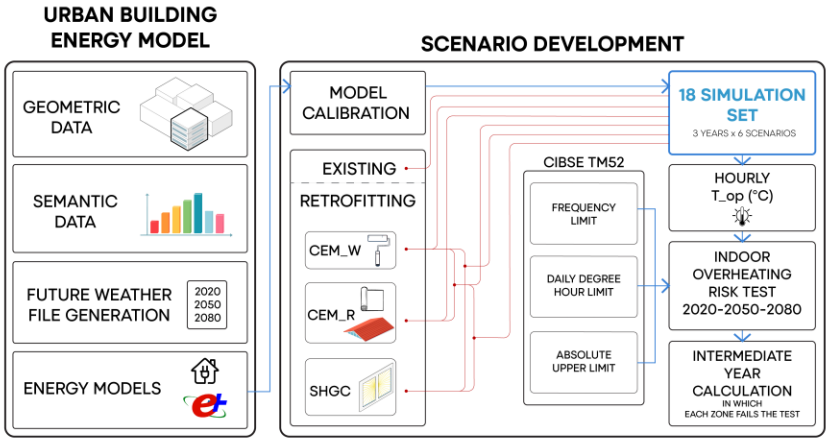

Figure 1. The overall workflow of the study.

To this end, a zone-level Urban Building Energy Modelling (UBEM) of a mixed-use neighborhood in Istanbul, Türkiye is developed, consisting of 2,455 buildings with a total number of 12016 zones. The method is developed based on three main steps (Fig. 1): (i) UBEM Development and Simulations, (ii) Retrofit Scenario Development, and (iii) Indoor Overheating Risk Assessment.

2.1. UBEM Development and Simulations

The development of the analysis dataset involves four steps: (i) Urban Building Energy Modelling (UBEM), (ii) Future Weather File Generation, (iii) Model Calibration, and (iv) Simulation-based Data Generation.

2.1.1. Urban building energy modeling

In the study, 2,455 mixed-use (residential + office) buildings, containing 12,016 zones in Istanbul, Kadikoy neighborhood (Fig. 2.), are modeled and simulated. This neighborhood represents diverse building thermal characteristics due to the various construction years (1960s to now). For the development of UBEM, two main types of data (i) geometric and (ii) semantic data are required. For 3D building geometries and their programs, a city GIS database is used. In each building, each floor is modeled as a single thermal zone. Grasshopper Ladybug V0.0.69 and Honeybee V0.0.66 plugins (Sadeghipour Roudsari et al., 2013) are used to create a basic EnergyPlus model for each building, ensuring uniform assignment of key parameters such as schedules, mechanical and natural ventilation setups. Out of the total number of 12,016 zones, 5,088 residential zones and 911 office zones are solely naturally ventilated without mechanical cooling. For heating, natural gas boilers with different efficiencies are used. All zones are naturally ventilated when the T_{indoor}>24.5°C and $T_{indoor}>T_{outdoor}$. The ANSI/ASHRAE/IES Standard 90.1 (2022) is used for the occupancy, equipment, and lighting schedules of the prototype midrise apartment building (midrise apartment apartment and midrise apartment office). Additionally, each building is considered as context shading to other buildings in simulations).

Following, using eppy, a Python library that can parse and edit EnergyPlus files (Santosh, 2014), all building-level and zone-level semantic data are assigned. Building-level semantic data includes characteristics of envelope materials (u_{Roof}, u_{Wall}, u_{Window}, u_{Ground}), infiltration rate, solar heat gain coefficient (SHGC), and boiler efficiency (η_{boiler}). For zones, lighting power density (LPD), equipment power density (EPD), people density (PPD), and heating set point ($T_{Heating}$) are assigned. U-values are assigned to buildings with an Energy Performance Certificate (EPC) (120 buildings), while for buildings without an EPC (2,291 buildings), U-values are generated using Kernel Density Estimation (KDE) based on the existing data. Except for U-values, all other data has 100% missingness; therefore, values obtained from the literature are used to generate a uniform distribution and assigned to buildings and zones accordingly (detailed modeling information can be found in our previous work (Canlı et al., 2024)).

Finally, simulations are performed to calculate zones' annual indoor operative temperature (T_{op}). In simulations, city's typical meteorological year EPW and future weather files (Section 2.1.2) is used.

Figure 2. A satellite image of the neighborhood (left) and a street view image of an example building (right) are considered in the paper.

2.1.2. Future weather file generation

A typical meteorological year (TMY) file of Istanbul obtained from the years 2007-2021 is used for simulations to represent current weather conditions. Future weather files for 2050 and 2080 are generated using the "Future Weather Generator" tool (Rodrigues et al., 2023), which converts current EPW data into 8760-hour future scenarios. The tool considers four SSPs (SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5); this study uses SSP5-8.5 (the worst-case scenario) to ensure buildings are prepared for extreme conditions. Both the existing and generated weather files are used in the simulations.

2.1.3. Model calibration

The UBEM is developed using data from EPCs. U-values of building components and LPD values are sourced from EPCs. Infiltration rate, $T_{Heating}$, and EPD are the three parameters used to calibrate energy models for 120 buildings, selected based on available EPCs and annual consumptions acquired from the natural gas distribution company. The calibration of 120 buildings resulted in a 2.42% MAPE for heating energy demand.

2.1.4. Simulation-based data generation

CIBSE TM52 and TM59 standards are selected to quantify overheating because (i) they distinguish zones based on their function, (ii) they use adaptive comfort limits, and (iii) they extensively can evaluate zones using multiple criteria such as frequency of overheating hours, daily degree hours and absolute upper limit. Analyses were conducted between May 1st and September 30th. Only zones that use natural ventilation for cooling are tested, which are 5,999 zones out of 12,016. Both residential and non-residential zones are assessed, but using different criteria defined by CIBSE standards. To calculate a zone's risk of overheating, the hourly T_{op} and the maximum operative temperature the zone can experience according to adaptive comfort limits (T_{max}) were compared. CIBSE TM52 defines three criteria that require at least two of them to be met for the office zones to be not at risk of overheating, and only the first criterion to be met by the residential zones. First is the Frequency Limit (FL), where the indoor operative temperature cannot exceed T_{max}+1 more than 3% of the occupied hours (Eq. (1)). Second is the Daily Degree Hours Limit (DDHL), where the daily degree-hours should not exceed 6°C, (Eq. (2)). The third is the Absolute Upper Limit

(AUL), where the T_{max} should never be exceeded by the T_{op} by more than 4°C (Eq. (3)).

$$\frac{\sum_{h\in H} 1[T_{op}(h)>T_{max}+1]}{|H|} \leq \frac{3}{100} \quad (1)$$

$$\forall d \in D, \left(\sum_{h\in d} \max\left(T_{op}(h) - T_{max}(h), 0\right)\right) \leq 6 \quad (2)$$

$$\forall h \in H, \; T_{op}(h) - T_{max}(h) \leq 4 \quad (3)$$

Where $T_{op}(h)$ is the operative temperature (°C) at hour at h, $T_{max}(h)$ is the maximum comfort temperature (°C) at hour at *h*, the set *D* is the days of interest (May–September), the set *H* be the occupied hours of interest (May–September). T_{max} is calculated according to BS N 15251 (Eq. (4)), for category 2, which is recommended for renovations. The running mean temperature (T_{rm}) is calculated using Eq. (5), using the outdoor temperature of the previous day (T_{od-1}).

$$T_{max} = 0.33 \times T_{rm} + 18.8 + 3 \quad (4)$$

$$T_{rm} = (1 - 0{,}8) \times \{T_{od-1} + 0.8 \times T_{od-2} + 0.64 \times T_{od-3} + \cdots\} \quad (5)$$

2.2. Scenario Development

Overheating risk calculation is conducted for three years (2020, 2050, and 2080) and six (existing and five retrofit) scenarios. The scenarios are developed based on two main passive cooling strategies; (i) installation of window glazings with SHGC=0.3 and (ii) application of cool envelope materials (CEM) to the building exterior surfaces (Table 1).

Table 1. Passive cooling retrofit scenario parameters related to building components.

	CEM_W	CEM_W_R	SHGC	CEM_W + SHGC	CEM_W_R + SHGC
Exterior Wall Solar Absorbtion	0.32	0.32	Existing Distribution	0.32	0.32
Exterior Wall Visible Absorption	0.39	0.39	Existing Distribution	0.39	0.39
Roof Solar Absorption	Existing Distribution	0.32	Existing Distribution	Existing Distribution	0.32
Roof Visible Absorption	Existing Distribution	0.39	Existing Distribution	Existing Distribution	0.39
Window Glazing Solar Heat Gain Coefficient	Existing Distribution	Existing Distribution	0.3	0.3	123

2.3. Indoor Overheating Risk Test

Hourly $\Delta T_{comfort}$ ($T_{op} - T_{max}$) values for both existing and retrofit scenarios are computed from EnergyPlus simulations for 2020, 2050, and 2080. Spline interpolation is applied between 2020–2050 and 2050–2080 to achieve a continuous approximation over limited data points. This method enables annual testing of each zone against CIBSE overheating criteria to the specific year when a zone exceeds the threshold and would require active cooling.

3. RESULTS AND DISCUSSION

The gap between operative (T_{op}) and maximum indoor (T_{max}) temperatures widens over time, with passive cooling strategies only partially mitigating this trend by delaying the increase in $\Delta T_{comfort}$ (Fig. 3). Notably, the combined strategies in Scenarios E and F reduce overheating risks effectively in 2020 and 2050 By 2080, passive strategies help mitigate overheating but cannot fully eliminate risks, emphasizing their role in *delaying* rather than *entirely preventing* the need for mechanical cooling. Without passive cooling, overheating risks affect 35.92% of residential and 79.68% of office zones in 2020, rising to 75.84% and 93.02% by 2050, and 89.2% and 95.94% by 2080. In contrast, with measures such as CEM and low-SHGC glazings, the overheating risk in residential zones is reduced to 4.6%, 51.2%, and 78.8% for 2020, 2050, and 2080 respectively (Fig. 3).

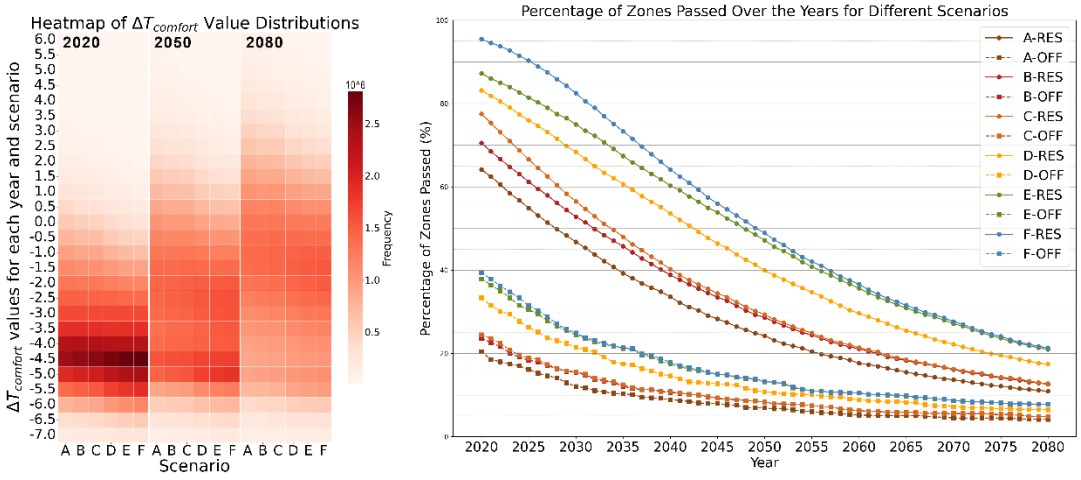

Figure 3. Heatmap of $\Delta T_{comfort}$ values of the zones in different scenarios and years (left), and percentage of zones that failed each criterion through the years (right) for each scenario: Exiting (A), CEM_W (B), CEM_W_R (C), SHGC (D), CEM_W + SHGC (E), CEM_W_R + SHGC (F).

A steep decline in the percentage of zones passing the CIBSE criteria is observed, indicating a significant increase in overheating risks over time without intervention. By 2080, less than 20% of zones meet the criteria. Residential zones generally exhibit higher compliance compared to office zones across all scenarios, highlighting differences in internal thermal loads. Another reason is that the offices are exposed to higher outdoor temperatures and higher solar heat gains during their operational hours (07:00-23:00). In contrast, residential zones are used throughout the day, and benefit from lower outdoor temperatures during nighttime hours, leading to lower overheating percentages. Due to these differences of occupancy hours and the dependent calculation routines, the overheating risk assessment do no serve to compare two zone groups of different functions.

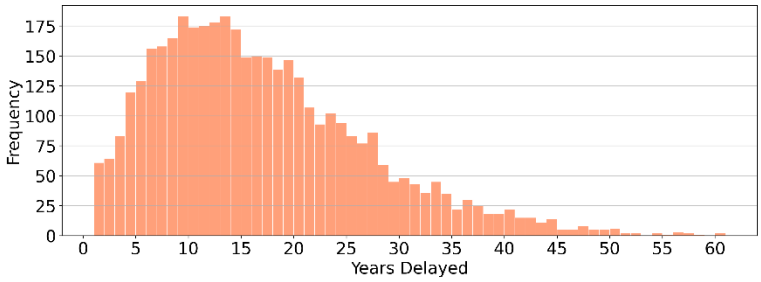

Figure 4. Distribution of Years of Overheating Delayed

Out of the 5999 zones, the predicted failure of 4842 falls within our analysis range. For those, on average, the combination of the application of CEM and low-SHGC glazing can delay the year in which the zone will need mechanical cooling for 12.19 years. This delay can go up to 60 years in residential zones and 56 years in office zones. The delay of overheating risk is 0 years for 783 zones. The distribution of 4059 non-zero years delayed can be seen in Fig 4.

4. CONCLUSION AND FUTURE WORK
